common at those centers toward which the foreign population trend. For example, the Northern Dispensary and the Jefferson College Hospital show the largest proportions, the former being close to the German population, and the latter near the Italian and Russian quarters. Moreover, it is not to be inferred that the percentages here given, although large, really represent the actual prevalence of the disease, for it is much more common than here noted. It is the custom in connection with dispensary services to record only such cases as personally present themselves, whereas often enough the patient is but one of a whole family affected.

Nor is this increase limited to one or two parts of our country, but it is widespread. Naturally, it is more frequently seen in our Eastern seaport cities. This general prevalence is shown in the next table (Table II), made up from the returns of the various members of the American Dermatological Association, as published in the *Transactions:*

of the American Dermatological Association, will show:

In seeking for causes for this increasing frequency several of the more potential factors, which are to a great extent responsible, should be referred to. Of first importance is the character of recent immigration. It is common knowledge that the present immigrant is, on the average, far below the standard in cleanliness, etc., that obtained some years ago, and this extremely undesirable class, largely made

When a disease of the character of scabies becomes so common among the poor, it may be certain that sooner or later it will, through many obvious channels, find its way among the better classes. And this is, indeed, already the fact. It was not until six or seven years ago that I saw a case in private practice, and then only one or two cases a year; whereas now an experience of ten to twenty cases yearly is not unusual. This I feel certain is also the experience of my colleagues in Philadelphia and in other parts of the country, as, indeed, the following table (Table III), compiled from the *Transactions*

[1] Includes both dispensary and private cases.

up of Russians, Poles, Huns, and Italians, have, especially for the past eight or ten years, been arriving here in great numbers. Judged by dispensary observation, it would seem that the itch is the normal state in the steerage of to-day, and many of those even who are free from the disease when embarking, are fairly certain to acquire it on their way over. These cases arriving in our midst are so many additional foci for its spread. Another factor in its increase, and not an unimportant one, is the

[1] After 1887 the private and dispensary cases were merged in the returns. Since that date private cases have, according to my own experience and that of others, increased almost as rapidly, proportionately, as have the dispensary cases.

"day nursery." An affected child is placed here for the day; it comes closely in contact with its comrades, and before its short sojourn is over several more cases have had their origin and are themselves carriers for the further spread of the disease. The children's "home," and "asylum" are likewise often responsible, for it is not unusual to find that the invasion of a whole family may be traced to the return home of a child temporarily placed in such institutions. These statements are not made at random, but are based upon repeated observation. The cheap lodging-houses are also fruitful centers of contagion; many of the Philadelphia (charity) Hospital cases have their origin in such places. Another element in its increase, and especially among the better classes, is to be found in our growing tendency to travel, and the rapid multiplication of travelling salesmen and drummers. With ordinary and proper precautions on the part of hotels, this factor should sink into insignificance, but it is extremely doubtful if the linen in the average hotel bed is always changed, or changed in its entirety, after a single night's occupation; and yet, if not, and had an affected person slept therein, the next occupant will almost assuredly contract the disease. I mention this method of spread for the reason that in a large proportion of private patients whom I have treated for scabies, the disease could be distinctly traced to such a source; nor were the cheaper hotels alone culpable. Finally, the failure on the part of physicians to recognize the disease, especially when ill-developed or in its beginning stages, must be looked upon as an important element in explaining its increasing prevalence. This is not said to reflect upon the profession, for it is the result of lack of opportunities. Graduates of the present day, if they make use of their advantages, are pretty well schooled in the recognition of this disease, as it is now a common one at the clinic; but some years ago—during my own student days, in fact—the presentation of a case of scabies was rare.

There are several points regarding the eruption which, if kept in mind, will serve to prevent error in diagnosis: distribution, itchiness, multiformity, the presence of burrows (cuniculi), and the linear character of many of the lesions. Moreover, in a majority of the cases inquiry will disclose the existence of the disease in a bedfellow, comrade, or in others of the family. The burrow, which is pathognomonic, is not always present. Special stress, in my opinion, should be laid upon the distribution and the linear character of the lesions as diagnostic symptoms of great value, and invariably present. Some or many of the lesions are always found to be longer than they are broad, appearing as elongated or oblong papules, vesicles, and pustules; scattered lesions of this kind, especially when seen about the fingers and hands, wrists, axillary folds, shaft of the penis, and anal region, even though few in numbers, should always excite suspicion. As a rule, private cases are most difficult to recognize, inasmuch as such persons are usually extremely solicitous about any skin-irritation, take daily baths, use soap and water freely, so that the disease is measurably held in check and the eruption remains scanty. It is not rare in some of the private cases to find but two or three lesions upon the fingers or other parts of the hand, possibly a few on the wrists, and one or several on the penis, with here and there an excoriated papule or a scratch-mark over the lower trunk. Even in private cases the anal region is a common site for several or more lesions.

The treatment of scabies is well known. It is as simple as it is efficacious, and every case thoroughly and quickly cured frees the community of a moving and active contagion-carrier. In the average case of the dispensary class I have usually prescribed a compound ointment, consisting of an ounce of sublimed sulphur, an ounce of Peruvian balsam, thirty to sixty grains of β-naphthol, and sufficient benzoated lard or petroleum ointment to make four ounces. The patient is directed to take a soap and hot water bath. Ordinarily any good toilet soap will answer, but in those of sluggish, thick skin, or of filthy habit, a good sulphur soap or sapo viridis is preferable. After the bath the ointment is to be energetically rubbed in over the whole surface from the chin down, special attention being given to the parts most affected. The back should not be neglected, the application to this part being preferably made by another person. Clean linen is put on, and clean bed-linen used; the soiled linen is to be boiled. At the end of ten or twelve hours another application of the ointment is made, and so on for six applications. During this time the same linen is worn. Some hours—about half a day—after the last application another bath is taken and a complete change of linen made. The linen which had been worn, as in fact all the underwear and bed-linen before being used again, should be thoroughly boiled. By boiling, all stray parasites and their ova are destroyed. During the treatment it is advisable to have a dusting-powder of sulphur sprinkled in the bed, in the bureau-drawer, and in other suspicious places. All outer clothing should be subjected to high temperature, if possible, or thoroughly beaten and hung out in the air and sun. Other members of the family should undergo inspection, and those affected treated in the same way, and those doubtful advised to make two or three thorough applications. It is only in this manner that the disease is cured and its recurrence prevented. In young children and infants the

β-naphthol is omitted and the quantity of sulphur reduced to one-half. In these younger cases, particularly infants, the disease often invades both face and scalp, also especially the lower part of the face, and this fact should not be forgotten in the treatment. In private practice I have commonly prescribed the same ointment, but with the β-naphthol omitted. In some cases, also, an ointment made up of equal parts of styrax and lard; two to four applications will usually suffice in these patients.

To control the cutaneous irritation which is not infrequently set up by the scabies or by the sulphur applications, and which sometimes persists for several days or longer after active treatment has been discontinued, it is well to advise the application, two or three times daily, of a saturated solution of boric acid, containing one to three drams of carbolic acid, two drams of glycerin, and four drams of alcohol, to the pint. Should the treatment have been inefficiently or carelessly carried out, as not infrequently happens in dispensary practice, evidences of an active return of the disease will soon appear, and a repetition of the plan described above, somewhat abbreviated, will be found necessary.

As to controlling the spread of the disease, in the broad sense of the term, and placing it again low down among the comparatively rare skin-diseases, I am convinced much can be done. The recognition and prompt cure of each case, as soon as it is presented, as already remarked, is a step in the right direction. Patients should be cautioned as to the contagious nature of the disease. Moreover, there is absolutely no reason why an immigrant with the itch should be allowed to land. The disease may be rapidly cured, when circumstances demand it, by employing much more energetic measures than those already mentioned, but which need not be outlined here. Such an immigrant may be rendered entirely harmless in an hour or so by such vigorous treatment, during which time his clothing and effects could be baked, steamed, or sulphur-fumigated. Energetic treatment of this kind, it is true, often leaves the skin in a state of active irritation, but this with several days' use of a mild, soothing ointment will subside. Infants and young children should be carefully inspected before being admitted to "day nurseries," "asylums," or "homes," and if found with any evidence of skin-disease should be rejected till a professional assurance of its harmless character is obtained. The same rule should be applied in the admission of children to the public schools. Hotels, small or large, should be legally required to make complete change of bed-linen before the bed is assigned to another occupant—not to mention other reasons why this should be done. Lodging-houses to which cases may be clearly traced should be reported to the Health Board for investigation, and the institution of proper measures of disinfection.

It is, I know, a common thing to speak of the itch with more or less humor, as a joke, but it is an exceedingly unpleasant experience for the immediate victim, his family, and for the community at large. A disease so readily cured, so readily controlled, and so readily preventable as this, has no reason for its existence in our midst—certainly not to such a great extent as it exists at the present day.

ORIGINAL LECTURE.

CHRONIC NEPHRITIS WITH HEART-COMPLICATIONS.

BY JOSEPH M. PATTON, M.D.,
OF CHICAGO, ILL.;
PROFESSOR OF INTERNAL MEDICINE IN THE CHICAGO POLYCLINIC.

GENTLEMEN: We have this afternoon two cases which are of much interest, because they present different phases of the same disease, phases that are of interest both from a diagnostic and from a therapeutic standpoint. This gentleman is fifty-five years of age. He has followed various occupations, none of which entailed very vigorous labor, while they all furnished him with plenty of exercise. He has always been in good health, so far as his memory serves him, until within the past two years, when he noticed that he was passing considerable urine—not that this troubled him any, for with the common idea that people have that when they are passing plenty of urine there can be nothing wrong with the kidneys, he gave this matter little attention; but as we call his attention to it he remembers that for a long time he had to get up two or three times during the night to empty his bladder. He says that about a year ago he at times noticed a little swelling of his ankles, but as he was on his feet a great deal during the day he paid little attention to it. Some six months ago he noticed that this swelling was a little more marked, and that he began to suffer from shortness of breath, which became so marked that at times he was unable to follow his business. About a month after this it began to trouble him seriously, and he noticed that his urine became more scanty; that it was cloudy in appearance, and that micturition caused him some little irritation. He was then also suffering from more dyspnea than he had formerly experienced; he had some slight cough. The swelling in the lower extremities began to increase until he called in the services of a physician. This condition became worse, instead of better, until the edema of the lower extremities reached above the knee. The skin was very tense and shiny, and in one or two places had broken, and the serum was oozing. He had now very great dyspnea, could not lie down, could not walk, and there was some cough and expectoration of a little frothy mucus. The appetite was bad; the stomach irritable; the bowels were comparatively regular. At this time he appeared at the clinic, and on examination we found the condition described. We found that his heart was very much enlarged; the apex was under the sixth rib, about half an inch outside of the nipple-line. The

first sound heard was diminished in force and very muffled in character. The second sound was relatively intensified, particularly over the aortic and pulmonic valves. The lower third of the lung was edematous from passive congestion; the liver was considerably enlarged from the same cause. The man was passing about eight ounces of urine in twenty-four hours, and the secretion contained a large percentage of albumin, some granular casts, and occasionally also hyaline casts. The specific gravity was 1024, and the urine was of a dark and reddish color. Here, then, was a case evidently of chronic nephritis, probably of the parenchymatous variety, upon which had been engrafted an acute inflammation of the kidney, which caused the sudden appearance of all the severe symptoms and the great diminution in the amount of urine secreted.

At that time the man was placed upon the following treatment: He was given three grains of calomel three times a day, until he had taken six doses. This was for its diuretic effect. A small amount of deodorized tincture of opium prevented any pronounced laxative effect upon the bowels, and allowed time for its effect on the kidneys. He was given a small dose of fresh infusion of digitalis containing ten grains of potassium nitrate. The dose was at first two teaspoonfuls every four hours; this was gradually increased to a tablespoonful, and in the course of two days he was taking a tablespoonful every four hours, night and day. In the course of three or four days the amount of urine had increased to four quarts in the twenty-four hours, and the man continued passing from four to four and a half quarts of urine daily for about five or six days, when the quantity gradually returned to from sixteen to twenty ounces. By this time the edema of the limbs had entirely disappeared, as had also the edema of the lungs and the congestion of the liver. The patient was now given small doses of sodium bromid with a preparation of pepsin and tincture of nux vomica for his stomach. He progressively continued to improve for about two weeks, when suddenly his pulse dropped to 32 beats per minute. At this time he reappeared in the clinic, and on examination of his heart we found that it was beating at about 80 per minute, while the radial pulse only showed from 35 to 40 beats per minute. This was due to the fact that every alternate cardiac systole was a very weak one, and while each beat of the heart could be distinctly heard with the stethoscope, all of the sounds being distinguished, the weak beat did not affect the radial arteries. The heart was arrhythmic and irregular both in force and rhythm. The first sound was distinctly muffled, and the second sound was very much more intensified than formerly. The digitalis was stopped, and caffein was given. This was administered in the form of the alkaloid of caffein combined with sodium benzoate. This makes a solution which contains about 48.5 per cent. of caffein. A soluble salt is also readily made of this medicament with sodium cinnamate or salicylate. The combination with sodium cinnamate contains about 58.9 per cent. of caffein, and that with sodium salicylate 61 per cent. of caffein. It is a matter of election which of these salts you will use. As a matter of experience, I am more in favor of sodium benzoate. Three drams each of sodium benzoate and the alkaloid of caffein were ordered in three ounces of distilled water. A teaspoonful of this mixture was given every four hours. At the time that this was prescribed the heart was very irregular, at times beating 35 to the minute at the wrist, and again 60 or 70, and then dropping back suddenly to 35 or 40. The first sound was so weak, and the second sound so much intensified, that it appeared doubtful if any good effect could be obtained from cardiac stimulants. Under the use of this combination, however, he steadily improved, and in the course of ten days his pulse became quite regular. The action of the kidneys was maintained by means of this prescription, without any other medication. As you see him to-day, he looks quite well; there is no edema of the feet; no congestion of the lungs; no congestion of the liver. He is able to walk at a moderate gait, and to climb steps without getting very much out of breath. The pulse now is 76 to the minute, strong, and regular. As you examine his heart you notice that the apex is just under the nipple. The first sound is of a very fair character, though not as strong as it should be in a perfectly healthy heart. The second sound is still somewhat intensified over the aortic and pulmonic valves. The man eats well, and digests well; his bowels are regular, and he is passing about the normal amount of urine, which contains no albumin; and to-day we are unable to detect any casts in the sample that he has furnished us; they are probably temporarily absent.

This is a somewhat better result than you would expect in most cases of the kind. When cardiac disease has resulted from chronic nephritis, and you have dilatation, as in this case, and reaching the extent present here, it is very difficult to obtain any marked or permanent improvement, and the result in this case is largely due to the man himself; he was willing to go to bed, remain on his back for six or eight weeks, keep perfectly quiet, avoid excitement of all kinds, and confine himself to a limited diet, consisting of milk, broth, liquid beef-peptonoids, and as he grew better occasionally a poached egg and a little toast with tea.

This other man whom we show you to-day is thirty-eight years old. He has been a business man all of his life, and actively employed. He says that he has never previously been ill, but for the last six months he has been troubled with dyspnea, at times a little cough, some sleeplessness, and a capricious appetite He claims never to have noticed anything wrong with the action of his kidneys; that he never was compelled to get up at night, with any regularity, to pass his urine, and disclaims any idea of kidney-disease. He has been under treatment for two or three months for the dyspnea, which his physicians told him was due to a nervous irregularity of the heart. About four months ago he came to the clinic exhibiting great edema of the lower extremities, some congestion at the base of the lungs, marked dyspnea on exertion, loss of appetite, insomnia, and great muscular weakness. Examination of his urine showed that its specific gravity was 1022; it was of a rather light color, and contained a small amount of albumin, with a few granular casts. Examination of his heart disclosed a very much enlarged left ventricle, the apex being three-quarters of an inch outside of the nipple line and under the sixth rib. There was no evidence of valvular disease. The ventricle had evidently undergone hypertrophy and subsequent dilatation. The condition at that time, the man maintained, developed quite rapidly.

There was no history that would indicate an acute attack of parenchymatous nephritis, so that unless over-exertion were responsible for the precipitation of his symptoms, we are unable to tell the cause.

He was placed upon the same treatment as the case we have just detailed, that is, calomel as a diuretic, and infusion of digitalis. Of the mercurial he took a little too much through mistake and suffered a slight stomatitis, which responded readily to the action of a potassium chlorate mouth-wash. He improved rapidly under this treatment, and in the course of a week had gotten rid of his dropsy; his dyspnea had disappeared; the heart's action was regular, and he was feeling very much improved. The necessity of quietness was enjoined upon him, which injunction he failed to observe very closely, and shortly after this, while upon the street one day, he suddenly lost consciousness. He was taken home, and I saw him about six hours afterward. At that time he was not entirely unconscious, but could be roused partially. There was hemiplegia of the right side, with ataxic aphasia. The heart's action was regular and somewhat slower than it had been. From what I could learn from those who saw him after the attack, he was probably never totally unconscious, and with difficulty could be partially aroused. This is an important point in the differential diagnosis of this condition, which is due cerebral embolism. It is of importance in such an attack as this to determine just what we have to deal with. We know that embolism is frequent in diseases of the heart associated with nephritis, and that it may occur at any age. This man is not too young to be liable to cerebral hemorrhage, so that the liability to it from the standpoint of age would have some bearing on his case. Right-sided hemiplegia, with ataxic aphasia, points toward embolism, the left middle cerebral artery being in more direct communication with the left ventricle. The territory supplied by this artery is the one liable to suffer from the effects of embolic plugging as a complication; consequently right-sided hemiplegia is more distinctive of embolism, and left-sided hemiplegia more distinctive of hemorrhage. In hemorrhage the coma appears with the same suddenness as it does in embolism, but it is more profound, and lasts for a greater length of time. In embolism the coma is more liable to be partial than complete, and wears off sooner than in hemorrhage. In hemorrhage the face is usually flushed during the attack, or has a congested appearance, whereas in embolism it is usually pale, as was the case with this man. The breathing in hemorrhage is stertorous and puffing in character; whereas in embolism it is somewhat slower than usual, but otherwise not distinctive. The pupils in hemorrhage may be dilated, contracted, or unequal; in embolism they are more likely to be unchanged. The pulse in hemorrhage is more likely to be irregular than in embolism, although on account of the cardiac conditions present in this instance the pulse could not be relied upon to furnish any diagnostic points. You are more likely to have aphasia associated with hemiplegia of the right side in embolism than in hemorrhage. The aphasia is usually of the ataxic variety. It may be amnesic in kind—that is, with the ability to phonate, but only to pronounce such words or sentences as are repeated to the patient by others. In the ataxic variety there is an intelligent conception of words, but inability to coördinate the muscles to perform phonation. The coma in this case began to improve in about twelve hours, which is rather sooner than it would in hemorrhage. This improvement was gradual, and in the course of three or four days the man was able to coördinate the muscles of his jaw and the muscles of phonation so that he could talk fairly well. About twenty-four hours after the attack his pulse dropped to thirty-five beats per minute. This was due, as in the previous case, to alternate weak and strong contractions of the heart.

An interesting and peculiar feature of the cardiac rhythm that developed in this case has been called the "gallop-rhythm," because it resembles the sounds produced by the hoofs of a galloping horse. It has been described by various writers, notably by Potain, and also at some length by Fraentzel. Various causes have been ascribed to the production of this symptom, some claiming it to be due to unequal contraction of the ventricles. Fraentzel assumes that it is due to unequal tension in the two vascular systems, so that the closure of the pulmonic valves is not synchronous with that of the aortic valves. He describes it as a triple rhythm, consisting of three sounds, the second of which is an accentuated sound, a long interval occurring between the second accentuated sound and the third or last sound, two of these sounds occurring in diastole. This he claims to be the essential feature of the so-called "gallop-rhythm." This peculiar action of the heart may be found in disease of the kidneys associated with cardiac disease; also in some acute diseases, such as typhoid fever, pneumonia, etc. I have observed it in a number of instances, but never before have I had as good an opportunity of studying the sympton during its production and continuation as in this case. It is very evident to me, from examinations made at the time, that in this particular instance the production of the peculiar rhythm was due to the following conditions: There were alternate strong and weak contractions of the heart. The interval between the weak contraction and the strong contraction was greater than that between the strong contraction and the weak one, so that two beats of the heart appeared rather closely together. The muscular element of the first sound was most entirely lost on account of the degeneration of the myocardium and the dilated condition of the heart-cavities. The second cardiac sound was very much intensified, and was much the louder of the two sounds. During the stronger contraction of the heart the first, muscular sound, could be distinctly heard. With the second contraction of the heart, or the weak contraction, the first sound of the heart could not be heard, and the second very faintly, so that in listening to the action of the heart we heard the ill-defined first sound of the strong contraction, followed by a very much accentuated second sound of the strong contraction; then follows an interval longer than that between the first and second sounds just described; this interval covers the period of the first sound of the weak contraction, which is entirely lost, this period being followed by the second sound of the weak contraction, which is ill-defined, thus giving us a rhythm which is composed of three sounds, the second of which is accentuated. In the character of the rhythm, this corresponds to the gallop-rhythm described by both Potain and Fraentzel; it does not correspond

with Fraentzel's claim that two of the sounds must be produced in diastole, unlesss you admit that the diastole following two different contractions may be included in this definition. It is plain here that two of these sounds were produced in diastole, but they belonged to two different contractions of the heart. This peculiar symptom lasted for about a week, and gradually receded with the general improvement. At this time the patient is under the influence of caffein, as is the other patient, and this has been continued with more or less regularity up to the present time. As you see him now, he is still suffering from the effects of the hemiplegia, having little use of his right limb and none at all of his right arm. The face has regained its natural expression; he is able to talk freely, and is in a fair general condition. The hemiplegia is more persistent in this case, probably on account of the poor general nutrition. The man's heart is still considerably enlarged; the apex is one-quarter of an inch outside of the nipple-line and in the sixth interspace. The action is regular; the first sound is fairly well defined, but there is still considerable intensification of the second sound.

I am glad to present these two cases side by side, as they represent the uncertainties of prognosis in these cases. The younger man, at the time the dropsy was so marked, presented every indication of being a much more favorable case than the older one, and yet we now have a condition which can only be recovered from partially, and which leaves an unsatisfactory result. Both patients are taking caffein two or three times a day, together with iron, strychnin, and arsenic as general tonics.

I have here a young lady whom I wish to show you more as a matter of curiosity than for any other reason. She is twenty-three years of age, and has always been in fair health. Her mother tells me that she has always noticed that from a child the girl was inclined to get blue about the face and hands upon the slightest exertion; that there is always some dusky redness of the extremities present, such as you see now. The hands and forearms are of a rather dusky-red color. The circulation is poor, and the hands are cold. The fingers, you will notice, are slightly clubbed; the nails are widened, arched, and bent somewhat inward. You notice as she exerts herself walking up and down the room, she acquires the same dusky hue of the face that is present in the extremities. She also suffers from dyspnea on moderate exertion. She does not complain particularly of cough; in other ways she seems to be healthy.

Upon examination of her lungs we find nothing which would account for the dyspnea. Upon examination of her heart you hear a very loud, blowing, systolic murmur, which can be heard all over the chest, front and back, and in the course of the brachial arteries. This murmur can be heard through all of her clothing, and appears to be of the greatest intensity about the upper border of the third rib upon the left side of the sternum. The apex is in the proper position, and is not displaced at all to the left. The heart shows no unusual force or effort in its action, and there appears to be no change in the condition of the heart-muscle or in the size of the cavities.

The question of diagnosis here is the only one of interest. We have to diagnosticate this condition from any other systolic murmur which might be present. If it were due to aortic stenosis, the murmur should be heard on the right of the sternum in the second intercostal space, should be conveyed into the vessels of the neck, and there should be some resulting change in the size of the left ventricle from an aortic stenosis of such long standing. If the condition were due to mitral regurgitation the murmur should be heard in the mitral area, transmitted to the left, should be much softer and there should be compensatory changes in the right ventricle. These conditions are absolutely wanting. The character of the murmur, its loudness, its duration, its position of greatest intensity, the lack of any particular direction of transmission, the lack of any secondary changes in the heart-muscle or cavities, combined with the cyanotic appearance of the peripheral circulation and the history of a continued condition of this kind, would compel us to make a diagnosis of communication between the right and left sides of the heart of a congenital character. The time of this murmur, which does not in the least precede the first sound, and its point of greatest intensity, its duration, and its loudness, would indicate to me that the particular condition of the heart would probably be a deficiency in the upper portion of the ventricular septum, rather than an open foramen ovale. This communication we know often exists through the foramen ovale in the septum of the auricles. It may also result from deficient closure of the upper portion of the ventricular septum, which is normally very thin. Some writers claim that insufficient closure of the foramen ovale (the foramen is closed by a valve in the fetus, and may remain open after birth) does not lead to any admixture of the blood of the two auricles, or, at least, does not produce any symptom which is discoverable during life; and that insufficient closure of the ventricular septum does not lead to any discoverable symptoms. It has also been claimed by some that the mixture of venous with arterial blood does not cause cyanosis. The report of a case in which the left subclavian artery arose directly from the pulmonic artery, and in which the left upper extremity was normal in color, has been used to refute the opinion of older writers that the admixture of blood caused the cyanosis. Whatever the actual cause of cyanosis may be, it is a clinical fact that those cases in which the cardial septum is deficient exhibit cyanosis as a symptom.

Therapeutically, there is nothing to be done for these cases as long as the heart undergoes no change and has sufficient dynamic integrity to perform its functions. In a diagnostic way they are always interesting, and this case is simply shown for that purpose.

Congenital Umbilical Hernia into the Cord.—WARREN (*Archives of Pediatrics*, vol. x., No. 8, p. 627) has reported the cases of two infants in each of which congenital umbilical hernia existed at birth, for the relief of which an operation was successfully undertaken. In the one instance the hernial sac, upon operation performed when the child was twenty-four hours old, was found to contain a portion of the liver fastened by adhesions; in the other, in which the operation was performed when the baby was three hours old, the sac contained intestine.

CLINICAL MEMORANDA.

PUERPERAL ECLAMPSIA IN A PRIMIPARA BEARING TWINS.

By F. M. THORNHILL, M.D.,
of Arcadia, La.

On the morning of January 29, 1893, I was sent for by Mr. L. to visit a young negress living on his farm, about two and a half miles from my office. The messenger informed me that the woman was in labor. I ordered my horse, and in a short time was on the way. Before reaching the place I met the husband of the woman coming to hurry me up, saying that his wife was having "fits." On arriving at the house I found the woman just recovering from a convulsion, and in a short time she was seized with another. As soon as practicable after the effects of the convulsion had passed off, I proceeded to make a digital examination. I found the womb and its contents high up in the pelvic cavity, and the os uteri dilated scarcely to the size of a silver quarter-dollar. I barely had completed the examination when the woman had another convulsion. I immediately gave her a quarter of a grain of morphin sulfate hypodermatically, and as soon as she could swallow, thirty grains of potassium bromid by the mouth, which had the effect of arresting the convulsions for an hour or more. With the cessation of the convulsions, uterine contractions also ceased and for about the same length of time.

During the calm I elicited the fact that the woman's confinement had been expected for several days, and that an old colored midwife (who was present) had been in waiting upon her for some time. The patient was a primipara, sixteen or seventeen years old, and had been complaining for several days with headache and vertigo, and on the morning of the day on which the seizure occurred, while in the act of rising from her bed, was seized with a convulsion and fell unconscious on the floor. After an intermission of an hour or so without any convulsions, and with the return of uterine contractions, she again commenced having convulsions—almost each recurring pain exciting a convulsion, notwithstanding the fact that I gave her frequently repeated large doses of potassium bromid, chloral hydrate, and morphin sulfate. At the same time I attempted to stimulate uterine contractions by the administration of ergot, and to hasten the progress of labor by artificial dilatation of the os, together with compression of the fundus of the womb through the abdominal parietes. The uterine contractions were very inefficient and dilatation of the os and descent of the head very slow. I had hoped by this course of procedure to be able to terminate labor naturally and favorably, without instrumental intervention; but the convulsions continued to recur with such increasing frequency, and the brain and nerve centers were being so rapidly overcome by them, that I saw labor would have to be terminated by instrumental interference, or else my patient likely would die undelivered. I accordingly despatched a messenger for professional assistance, pending the arrival of which I had recourse to chloroform-inhalations to control the convulsions. This had the effect of modifying the violence and shortening the duration of the paroxysms.

After a delay of some two or three hours Dr. A. and Dr. P. arrived. The woman had just had a convulsion when they entered the room. I suggested that we administer chloroform and deliver at once, if possible. An examination at this time revealed the fact that dilatation of the os was nearly complete. Dr. P. proceeded to administer chloroform, and when anesthesia had been produced, I attempted to apply the forceps. The presentation was that of the vertex in the first position. For some cause, which we at the time did not appreciate, I was unable to adjust the forceps, and after endeavoring to do so for some time without success, I turned the instrument over to Dr. A., who, after considerable effort, also failed. I again made an effort to apply the forceps to the child's head, and after considerable difficulty at last succeeded in doing so. We supposed then that we would have no further trouble in effecting a speedy delivery; but to our surprise and disappointment, when I had made traction on the forceps to the utmost of my strength, no progress was made, the head still remaining immovable. After tiring myself out in the effort to advance the head, Dr. A. relieved me, and after exhausting himself in a futile attempt to move the head, I again took charge of the forceps and applied traction with all the force I could safely exert, at the same time employing a rocking lateral motion upon the handles of the forceps. After considerable persistence I succeeded in delivering the head, and removed the forceps. After waiting some time for uterine contraction to begin, I hooked my fingers in the axillæ and proceeded to complete the delivery of the child, when I discovered that unusual effort was necessary. After a good deal of difficulty the child was finally delivered, but the umbilical cord was found to be not more than six or eight inches in length. This we at once concluded must have been one of the chief obstacles to descent of the head and natural delivery; but when we came to deliver the placenta it was discovered that there was another fetus in the uterus, and on examination the face was found presenting. We converted the presentation into one of the vertex, this being easily accomplished, as the genital canal had been dilated by the passage of the first child. We again applied the forceps and now delivered at once without difficulty. The cord was found coiled once or twice around the neck of the second child, and of about the usual length. Both children were contained in a common amniotic sac and placenta and were females, in accord with the doctrine that twins of the same sex are always developed from different centers of one and the same ovum and are contained in a common chorion, placenta, and reflexa.

When the delivery of the second child had been effected, we congratulated ourselves that we were done and were to escape any further complications in the case; but when we came to deliver the placenta we found it firmly adherent to the walls of the womb, so much so that the vigorous employment of Credé's method, together with forcible traction on the cord, were insufficient to remove it. I was therefore forced to introduce my entire hand into the cavity of the womb and insinuate my fingers between the placenta and the wall of the uterus and break up the attachments by sweeping the hand around the entire circuit of the uterine cavity in order to effect the dislodgment of the placenta. The womb contracted well after the removal of the mem-

branes. The woman afterward had two or three convulsions and did reasonably well for the next twenty-four or thirty-six hours; but at the end of this time septic metro-peritonitis set in and death took place about a week after the delivery. Both children were born alive and did well for several days, when one of them died from the effects of cold, from careless exposure. The other child lived until June 10th, when it died of catarrhal croup. The first child born weighed six or seven pounds, and the second one about five pounds.

A remarkable feature in this case is that both children should have been born alive, after having gone through such a terrible ordeal. Delivery was, however, accomplished without unusual injury to mother or children. After delivery had been completed and the true state of things was revealed, it occurred to me that the difficulty experienced in adjusting the forceps and in delivering the first child was due to the crowding of the face of the second child down against the neck and occiput of the first one, producing locking of twins *in utero* as it is termed in the text-books. This is a complication which it is said is rarely or never recognized before the birth of the first child. In this case in the midst of the excitement and confusion of the hour the possibility of a multiple pregnancy escaped my mind, and I made no investigation with a view of determining the existence of twins. Did I leave anything undone that should have been done or could have been done? Perhaps the advocates of blood-letting and veratrum veride will say that I should have had recourse to the use of these measures; but in anticipation of such criticism I desire to say that if those agents are ever valuable in the treatment of puerperal eclampsia I did not consider them applicable to the case here reported. There was an absence of arterial fulness and venous stasis, and the pulse was small and feeble. In conclusion I desire to say that I consider the prompt and skilful use of chloroform and the forceps more potent for good in the treatment of puerperal eclampsia than all other agents.

THERAPEUTIC NOTES.

By SOLOMON SOLIS-COHEN, M.D.,
of Philadelphia.
Professor of Clinical Medicine and Applied Therapeutics in the Philadelphia Polyclinic; one of the Physicians to the Philadelphia Hospital, etc.

V.

ETHYL IODID.

This drug, formerly known as *hydriodic ether*, is one of the most useful, but least used agents in the materia medica. Its vapor, mixed with air, is to be inspired. Its effects are those of iodin modified by ethyl. Extremely volatile, the methods by which it may be administered are the simplest. One needs but to hold to the mouth or nostril a vial containing the medicament, and inhale the vapor which the heat of the hand is sufficient to cause to rise. I usually prescribe half a fluid-ounce, which is about one ounce by weight, to be dispensed in an amber-colored bottle wrapped in dark paper, in order to protect the drug from the light. When the patient is moving about he can carry the little vial in his vest-pocket and take a few whiffs of the vapor from time to time. Under other circumstances it should be kept in a cool place, to avoid the decomposition that eventually occurs under the influence of even moderate heat. Some little care is necessary to see, in the first place, that the druggist dispenses a good preparation. Of several brands upon the market differing widely in price, both pharmacist and patient are likely to prefer one of the cheaper products, unless cautioned otherwise. The drug must be chemically pure, or it soon becomes worthless, and I know of but one brand, that made by a well-known German chemist, that can be relied upon. In the second place, the patient must not continue to use a preparation that has undergone decomposition from unavoidable exposure. So long as it is fit to use, the ether will remain light in color and retain its characteristic odor, which, to me, suggests horseradish. When the liquid has become deep-brown in color, or the odor has lost its pungency, the drug has ceased to be therapeutically active by inhalation.

The method described, while convenient and applicable in every nearly case, does not give accurate dosage. For the latter purpose, when deemed essential, five or six drops with a teaspoonful of water may be placed in a wide-mouthed jar, and the patient may inhale the air from the upper portion of the jar. The liquid ether, being heavier than water, sinks to the bottom, whence the vapor gradually rises, diffuses through the air in the bottle, and is inhaled. Ethyl iodid alone, or mixed with terebene, alcohol, creasote, chloroform, menthol, thymol, or any combination of these and similar agents, may be placed upon the sponge of a Yeo respirator and inhaled in that way, as described by me in The Medical News for October 11, 1884. As the drug is expensive and highly volatile, methods that restrict its diffusion through the atmosphere are, however, as a rule, to be preferred.

In any case in which the local effect of iodin upon the air-passages is desired, or in which it is necessary to get a constitutional iodin-effect, without resort to the stomach, the inhalation of ethyl iodid offers a convenient and effective means of accomplishing the purpose. It is thus of use in syphilis, and especially in cases of syphilitic inflammation or ulceration of the nose, mouth, and throat. It is of great benefit in tuberculosis of the larynx, and in pulmonary tuberculosis, at any stage of the disease, but especially when local stimulation and disinfection are desired. In subacute and chronic nasal catarrh, in some cases of hay-fever, in subacute laryngitis and subacute bronchitis, and in chronic laryngitis and chronic bronchitis, when a sedative, sorbefacient, and disinfecting agent is desired, inhalation of a mixture of equal parts of terebene and ethyl iodid gives most satisfactory results. Ethyl iodid is extremely useful in ozena and in fetid bronchorrhea. It has been employed with apparent benefit in asthma and in acute croupous pneumonia and acute broncho-pneumonia of various types. In one case of whooping-cough in an adult, it was apparently of service. It may be introduced into the Eustachian tube and middle ear by means of a Politzer bag and catheter.

To get the full benefit of the drug it must be used frequently and persistently. Thus, in cases of pulmonary tuberculosis I have had patients keep up the daily inhalation for two, three, or more years. While in cases of active disease, the inhalations are sometimes practised so

often as every half-hour, in convalescent cases, or in cases of tuberculosis not showing active progress of lesions, the intervals are proportionately lengthened. Two hours constitute the average interval. Three times daily are sufficient in some cases. Some patients can inhale the vapor of ethyl iodid for ten or fifteen minutes without experiencing unpleasant effects. Others feel slight vertigo after inhaling for a minute or two. Ordinarily, I tell the patient to inhale for five minutes, unless vertigo is produced.

JUGULATING GONORRHEA IN ITS INCIPIENCY BY MEDICATED TAMPONS.

BY R. N. PITTS, M.D.,
OF PITTSBORO, ALA.

MY experience has been very unsatisfactory in treating gonorrhea by means of injections and internal medication. In the great majority of cases the disease will, in spite of treatment, invade the prostatic portion of the urethra, the seminal vesicles, and the bladder. When gonorrhea attacks the deep urethral structures it is a mooted question if there are ever many cases cured. Gonorrhea is a disease that will not only cause the patient much concern, but will also often discourage the physician on account of his inability to cure.

It is my opinion that all flattering statements of curing gonorrhea by internal medication ought to be taken *cum grano salis*. The main point in treating gonorrhea by tamponing the urethra in order to be successful is to begin when the diagnosis is first made.

1. The first step to be taken is to have the patient urinate.

2. Wash out the urethra to a depth of four or five inches with warm boiled water.

3. Use a 4 per cent. solution of cocain if the urethra is very sensitive.

4. Slit the meatus, if it is not large enough to admit a steel sound as large as the urethra.

5. Introduce a metallic tube the full size of the urethra to a depth of four or five inches.

6. Introduce into the urethra through the tube a cotton tampon that has been saturated in a 1 : 20,000 solution of mercuric chlorid. Each tampon should be of full size, and have a silk cord tied to it, so as to hold it in position and to facilitate its removal.

7. Inject through the tube upon the tampon a few drops of the mercuric solution by means of a long aspirating needle and syringe. After the first tampon has been deposited in the urethra, draw out the tube just a little, and tampon and inject until the meatus is reached.

The strings on the tampons should be successively longer as the meatus is approached, so that they can be withdrawn in the inverse order of that in which they were introduced. If they become troublesome the tube may be withdrawn and reintroduced by their side.

The tampons ought to be kept in the urethra as long as they can be borne.

After the first tamponing there will be a thick, yellow discharge, which will have lost its virulence after a few tamponings. The tamponing ought to be done at least every seven days.

Between tamponings, the patient should be given a mild injection of plumbic acetate and morphin. Oil of sandalwood given by the mouth will aid materially.

It is my opinion that the *modus operandi* in treatment with the tampon is that it changes a specific into a non-specific urethritis which is easily cured by means of mild astringent injections. The average length of time consumed in the cure of eleven cases has been twenty-five days, with absence of sequelæ.

MEDICAL PROGRESS.

The Proteids of Nervous Tissue.—HALLIBURTON (*Journal of Physiology*, vol. xv, Nos. 1 and 2, p. 90) has found that the normal reaction of nervous tissues is alkaline. The alkalinity diminishes after death and may be replaced by an acid reaction. This is most marked where there are most cells, namely, in the gray matter. Quantitative determinations show that proteid matter is a very important constituent of nervous structures. The average amount of proteids in the solids of the gray matter is over 50 per cent. It is less in the white matter and in parts like the spinal cord, which contain large quantities of white matter. It is still less in nerves. The gray matter is also the poorest in solids ; nerves the richest. In any region, like the spinal cord, where there is a mixture of white and gray matter, it will be found that the percentage of water, the proportion of proteid in the solids and the proportion of gray matter vary directly the one with the others. Qualitative examination of this proteid matter shows that the proteids present are three in number. They differ in temperature of heat-coagulation, in the readiness with which they are precipitated by neutral salts and by acetic acid; one of them contains phosforus and is a nucleo-albumin, so differing from the other two, which are globulins. The most important characters of these proteids are the following: (*a*) This proteid is a globulin ; it may conveniently be termed neuro-globulin *a*. It is coagulated by heat at the low temperature of 47° C. (116.6° F.), and is analogous to similar globulins found in all cellular structures, such as cell-globulin *a* of lymph-cells, paramyosinogen or musculin of muscle, hepato-globulin *a* of the liver, and kidney-globulin. This proteid seems to be as constant a constitutent of protoplasmic structures as the nucleo-albumins are. It is precipitated by a comparatively small percentage of such neutral salts as magnesium sulfate. It is not precipitated by weak acetic acid. It contains no phosforus in its molecule. (*b*) This proteid is a nucleo-albumin. It can be readily prepared from nervous tissues by making a saline extract, but under these circumstances it is mixed with the other proteids. Attempts to obtain it by the sodium-chlorid method fail. It may, however, be prepared in large quantities by precipitating an aqueous extract of brain by weak acetic acid. The supply obtainable from white matter is small. It is coagulated by heat at a temperature of from 55° C. (131° F.) to 60° C. (140° F.). Like globulins it is precipitable by saturating its solutions with neutral salts ; but more salt is necessary than in the case of neuro-globulin *a*. It contains 0.5 per cent. of phosforus. After subjection to gastric digestion an insoluble residue of nuclein remains behind. Dissolved in dilute sodium carbonate and injected into the vascular

system of rabbits it causes extensive intra-vascular coagulation. (*c*) This proteid is a globulin. It may conveniently be called neuro-globulin β, and is closely analogous to the hepato-globulin β of liver-cells. It is coagulated by heat at from 70° C. (158° F.) to 75° C. (167° F.); it is precipitable by neutral salts, but requires complete saturation with magnesium sulfate to precipitate it entirely. It is not precipitable by weak acetic acid, like the nuclein just described, and contains no phosforus in its molecule. Peptone, proteose, myosin, albumin, and fibrin-ferment are not obtainable from nervous tissues.

Perforating Appendicitis with Unusual Symptoms.—CABANES (*Montpellier Médical*, 1893, No. 4, p. 618) has reported the case of a man, twenty-three years old, who came under observation in an attack of measles. He was of robust appearance and had a good family history. Some ten months previously he had had an attack of enteric fever. The attack of measles pursued an uncomplicated course. On the thirteenth day, as the man was about to be dismissed, he was suddenly seized, after supper, with vomiting and a feeling of general malaise. Investigation disclosed the fact that for two days there had been looseness of the bowels, which the patient had concealed in order to escape a restriction of his diet. The general aspect was one of depression, with dyspnea, anxiety, elevation of temperature, and acceleration of pulse. Examination occasioned great distress. The abdomen was relatively soft; there was some gurgling; there was complaint of general abdominal pain, with special localization in the hypogastric and lumbar regions. On percussion, dulness was elicited over the bladder, but the catheter brought away only a few drops of urine. A boric-acid injection was easily made, the fluid returning through the catheter. The symptoms gradually became more profound; the vomiting continued; the anuria persisted; the diarrhea was troublesome. The patient occupied the dorsal decubitus. From time to time, however, he would abruptly turn upon his left side, as if to relieve intense pain, but soon returned to his original position. The dyspnea became intense and the small pulse reached 136 in the minute. The deep temperature rose to 104°, while the extremities became cyanotic and cold. At this stage the patient became unconscious and death supervened. Upon post-mortem examination, the thoracic organs were found quite healthy. The intestines were distended with gas, but otherwise presented a normal appearance in their upper part. The lower portion of the bowel, however, was hyperemic and presented disseminated areas of redness. Loops of small intestine occupied the pelvis, where they were bathed in a sero-purulent effusion, in which the vermiform appendix, which was seven inches long, was found floating. The organ was attached to the inner aspect of the cecum at the level of the superior pelvic strait and a little in front of the right sacro-iliac articulation; by its free extremity it was attached to the right aspect of the rectum by a band of mesentery. The mesentery was thickened at the lower extremity of the appendix, which itself was swollen to the thickness of a thumb. Upon the anterior surface of this extremity was a perforation as large as the head of a pin. The opinion is expressed that the antecedent attack of enteric fever may have had a predisposing influence in the development of the conditions found, a state of muscular atony permitting the entrance into the appendix of irritating and toxic matters.

Puerperal Eclampsia Treated by Bleeding and Gavage with Milk.—MAYGRIER (*Journ. de Médecine de Paris*, 1893, No. 29, p. 350) has reported the case of a primipara, twenty years old, in which with the onset of labor at term intense headache set in, at first intermittent but subsequently continuous. The lower extremities were edematous; vision was impaired, and there was pain in the epigastrium and dyspnea. In the midst of these symptoms an eclamptic attack took place, shortly followed by others, vomiting occurring in the intervals. A large proportion of albumin was found in the few drops of urine that could be obtained from the bladder. The presentation was left occipito-anterior. The os uteri was dilated to the size of a silver quarter-dollar. The fetal heart-sounds could not be heard. An enema containing a dram of chloral was only partially retained, but was followed by no amelioration. In view of the gravity of the situation, with the anuria, the coma and other evidences of profound intoxication, thirteen ounces of blood were withdrawn from the right median cephalic vein. The coma was not modified. The labor, however, progressed rapidly. As soon as the cervix was sufficiently dilated, the membranes were ruptured and a dead child was expelled, the placenta following shortly afterward. There was no noteworthy post-partum hemorrhage. Two hours after the delivery the sixteenth convulsion occurred. The bladder still contained no urine. In the absence of the apparatus for subcutaneous transfusion of artificial serum or a physiologic saline solution, gavage with milk was instituted. As it was impossible to separate the patient's teeth, the tube was passed through the nares, five ounces of milk being introduced into the stomach every hour. In the course of two hours an ounce of highly albuminous urine was found in the bladder. Thereafter the quantity of urine progressively increased, while the proportion of albumin grew progressively less. The coma also gradually became less and less profound and the respiration less embarrassed. To further stimulate the secretion of urine a bath was given in water at a temperature of 100.4°, and followed soon after by a purgative enema. The woman now became conscious and able to swallow the milk. The swelling subsided; the albumin disappeared from the urine; the headache was no longer felt, and the woman was soon convalescent. Upon recovery it was found that she had no memory of the events of the eight or ten days preceding labor, while the memory of events during the previous two or three months was distinctly impaired.

Dilatation and Hypertrophy of the Colon Fatal at the Age of Eleven Years.—WALKER and GRIFFITH (*British Medical Journal*, No. 1700, p. 230) have reported the case of a boy, eleven years old, in which nothing unusual was noticed at birth, but within a few weeks the abdomen was observed to be unusually large. This enlargement gradually increased until it reached an enormous degree. There was little pain, but the bowels were usually constipated. The appetite was poor, breathing was embarrassed, muscular development was feeble, and the health varied with the degree of distention.

From time to time flatus would escape from the anus, with marked diminution of the swelling. Toward the close of life the boy suffered a good deal of pain, and wasted considerably. He died suddenly while an enema was being administered. At the post-mortem examination the body was found much emaciated, the lower part of the thorax being greatly expanded, and thrown upward. On opening the abdomen nothing was seen but an enormous coil of intestine, which proved to be the transverse and descending colon, measuring twenty-three inches in circumference. The excessive dilatation extended to the sigmoid flexure, gradually diminishing, and leaving the rectum normal. The colon gradually became narrower toward the cecum. No constriction could be found. The small intestine was normal throughout its entire extent. Ascending and descending colon both had distinct mesenteries. There were no adhesions or other signs of an antecedent peritonitis, although the peritoneum was extraordinarily thick. The distention of the abdomen had caused the lower part of the thorax to be spread out and thrown up. The back of the diaphragm being fixed, the anterior edge was tilted up, so that the inferior surface of the liver looked directly forward. The distance from the supra-sternal notch to the top of the diaphragm was about two and a half inches, the lungs and heart being compressed into an entirely inadequate space. The immediate cause of death was concluded to be the embarrassment of the enfeebled heart's action by the distention of the abdomen. Histologically the mucous and muscular coats of the affected bowel were found to be greatly thickened, with atrophy of the secreting structure. The sequence of events was supposed to be a chronic colitis, with undue formation of gas and secondary thickening of the walls of the bowel.

Congenital Hemophilia; Fatal Hemorrhage from the Conjunctiva—MÜLLER (*Archiv für Gynäkologie*, B. xliv, H. 2, p. 269) has reported the case of a female infant of a primipara, born at the end of the ninth month and measuring 17.25 inches in length and weighing four pounds. Following labor, one drop of a one per cent. solution of argentic nitrate was instilled into each eye. On the afternoon of the same day a scanty white discharge was observed about the eyes, unattended, however, with swelling or other change in the lids. With the possibility of a blennorrhea in view, a second drop of the silver solution was instilled into each eye at night. Even before this was done the ocular secretion was already noted to be blood-tinged. On the following morning the eyelids were found covered and closed by blood-clots, upon the removal of which a few drops of red blood welled up between the closed lids. Neither lids nor conjunctiva presented any injury or any change (swelling, redness, slough), but upon the conjunctiva there appeared one drop of blood after another, although the source of hemorrhage could not be discerned. The bleeding persisted in spite of repeated irrigation and the frequent application of ice-compresses. At night on the second day a compressive bandage was applied. Careful and skilful examination failed to disclose any lesion about the eye; neither could any lesions of the adjacent mucous membranes be detected. The bandage was continued and irrigation with chlorin-water was added, but the hemorrhage would not yield. On account of the delicacy of the structures and in the absence of bleeding points it was not deemed justifiable to apply a solution of ferric chlorid or the actual cautery. The child remained fairly bright until the third day, taking its nourishment from the mother's breast, despite the persistence of the bleeding. Finally, however, the anemia became so profound that death took place on the evening of the fourth day. The post-mortem examination disclosed the existence of no gross lesion, but only the appearances of general anemia. Müller adds that in another case of the same kind he would practise subcutaneous or intra-venous transfusion and close the lids by means of a continuous suture.

Extirpation of an Hypertrophied Spleen.—TREUB (*L'Union Médicale*, July 13, 1893, No. 6, p. 65) has reported the case of a woman, forty-eight years old, who had borne seven children and had aborted five times. Seven years previously, ten weeks after delivery, she was seized with abdominal pain, which had continued with varying intensity and was less upon activity and worse upon recumbency. The pain was continuous; when it was at its worst the abdomen would become distended and the urine would be passed in drops. The distention of the abdomen was said to occur regularly every spring and autumn. Menstruation was profuse but regular, and unattended with pain. The last menstrual period had been followed by feverishness, abdominal pain, and nausea and vomiting. On examination of the abdomen an oblong tumor of irregular surface and solid consistence was found in the median line. The mass was movable laterally but not vertically, and extended upward to the level of the umbilicus; it was distinctly circumscribed laterally and superiorly, but was lost in the pelvis below.

On bimanual examination the tumor was found to be situated in front of the uterus, which was slighly enlarged, and adherent by its anterior surface. The liver occupied its usual position. The right ovary could be doubtfully felt, the left not at all. A diagnosis of cyst of the left ovary was made and celiotomy undertaken. The tumor was found adherent to the abdominal wall anteriorly and covered by loops of adherent intestine. The pelvic peritoneum gave evidence of inflammation. The ovaries were edematous and covered by fibrinous deposits. In color and form the freed mass resembled the liver, but this organ proved upon direct palpation to be in place. It was also thought that the spleen could be felt; so that it was concluded that the tumor was a neoplasm of the kidney. The pedicle was tied and the mass removed. Examination of the body showed it to present histologic structure of an hypertrophied spleen, partially necrotic and in process of further destruction. Recovery was interrupted. Three weeks after the operation the woman was dismissed. At no time was there any evidence of leukemia.

Rumination in Man and its Relation to the Act of Vomiting.—From a study of four cases of rumination in man and a survey of the literature upon the subject, SINGER (*Archiv für klinische Medicin*, Band li, Hefte 4 u. 5, 472) maintains that a distinction cannot be made between rumination and regurgitation, both, as observed

in human beings, being the expression of a nervous constitution. The immediate cause of the act is a relative insufficiency of the cardia, which manifests itself intermittently and is related to the quality and quantity of the contents of the stomach. The mechanism consists in the aspiration of the gastric contents by the exhaustion of the air in the thorax at a time when the cardia is relaxed, this exhaustion being maintained by the inspiratory position of the chest, with simultaneous closure of the glottis. The process may be restrained by forced expiration. The cardiac antrum corresponds to a demonstrable dilatation of the esophagus in its cardiac portion and is a result of mechanical over-distention from the swallowing of large boluses of food. It furnishes the anatomic basis for the defective closure of the cardia. Rumination is physiologically to be distinguished from vomiting; the only condition that can be compared with rumination is the esophageal form of nervous vomiting. The state of the gastric functions is variable and is but an accidental feature of the symptom-complex of rumination; abnormalities of secretion are but the result of the neurosis upon which the rumination itself depends and only require symptomatic treatment. Rumination occurring in cases of esophageal diverticula and total dilatation of the esophagus is to be differentiated from genuine rumination by the conspicuous difficulty in swallowing and the retching that attends the regurgitation; in the case of a diverticulum the pepsin and the rennet-curdling ferments are absent. The treatment of rumination must be based upon the neuropathic disposition and upon individual conditions. It is important to abjure hasty eating and excessive drinking and to enjoin the voluntary suppression of the act. As an adjunct measure, tonic treatment, calculated to increase the tonicity of the cardia, is to be instituted.

Bronchial Casts in a Case of Mitral Regurgitation.—Lawrence (*Lancet*, No. 3648, p. 247) has reported the case of a boy, nine years old, who some nineteen months previously had an attack of "inflammation of the heart." Thereafter there had been weakness and an inability to keep up with school-work; but no dyspnea or cough. The child was small and poorly nourished, his skin harsh and dry. At the apex of the heart a loud systolic murmur was heard, but nothing abnormal was detected in the lungs. A short time later the child was reported to be spitting up "queer things like little trees," which upon examination proved to be bronchial casts. Just below the angle of the left scapula a small patch of consolidation was detected. The expectoration of the casts continued from time to time, one or two being ejected daily for several days and then none for a month or so. The casts were white and occasionally streaked with blood, which could be readily washed off. Sometimes they were not perfectly round on section, but flattened as if the individual cast had not completely occluded the bronchus. The expectoration of a cast was preceded for some hours by a tickling cough. Ascites and a left inguinal hernia developed. The area of consolidation previously present could not be found, but there was a new area of similar size in the second right intercostal space. There was no dyspnea or pyrexia. Treatment by rest in bed and the administration of strophanthus and nux vomica was followed by general improvement, but the area of consolidation increased in size until finally the whole upper lobe of the right lung became solid. Now the respiration became accelerated and the temperature elevated. Cough was troublesome and expectoration copious, the expectorated matters consisting of bronchitic froth and shreds of dirty-white material. Emaciation and weakness progressed, and amid the signs of pulmonary congestion and edema death took place. An autopsy could not be had.

Symptoms Caused by the Electric Light.—Freeland (*British Medical Journal*, No. 1700, p. 234) has reported the case of an electrician, who was suddenly seized with intense pain in both eyes and severe headache. The eyes were suffused and the conjunctivæ congested. There was marked photophobia and partial blepharospasm. The skin was hot and dry. The temperature was 102°. The free instillation of a five per cent. solution of cocain was soon followed by a subsidence of the pain and a desire to sleep. After little more than an hour, however, the man became wildly delirious. The administration of fifteen grains each of potassium bromid and chloral was followed in half an hour by quietness and sleep. An ice-bag was applied to the head. The man slept for several hours, meanwhile perspiring quite freely, and on awaking felt much refreshed and was quite rational, although somewhat shaky. The pain in the eyes and head had gone, but the eyes were still suffused and injected and intolerant of light. The temperature was normal and the skin moist. The man was kept in a dark room for the remainder of the day, and on the following morning was able to resume his usual occupation. It was learned that he had had charge of a powerful electric search-light and had neglected to wear protective goggles.

Changes in the Urine after Administration of Thyroid Extract.—Ord and White (*British Medical Journal*, No. 1700, p. 217) report the result of observations in a case of myxedema in which twenty drops of a glycerin extract of the thyroid body of the sheep (an equivalent of one-sixth of a gland) were administered daily, the conditions before and during the experiment being otherwise the same. It was found that the urine was increased in volume; that the nitrogen excreted in the urine exceeded the total quantity of nitrogen in the ingested food; that the elimination of phosphoric acid and of chlorin was practically unaffected; that the increased excretion of nitrogen was chiefly in the form of urea; that the body-weight rapidly diminished; and that the body-temperature was raised.

A Bullet in the Orbit for Twenty-three Years.—Roose (*Rev. gén. d'Ophthalmologie*, 1893, No. 7, p. 309) has reported the case of a man, fifty years old, who related that he had lost his right eye in the battle of Sedan in 1870, in consequence of an injury from a fragment of a shell. The patient complained of some pain, and the stump presented an appearance of redness. Examination disclosed a metallic body at the fundus of the orbit, and upon the patient being anesthetized a leaden bullet, almost an inch long and weighing more than an ounce, was removed. The visual acuity in the remaining eye was normal and the fundus presented no lesion.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 23, 1893.

IN SOCIETIES AND CONGRESSES LET US HAVE LESS "SCIENTIFIC WRITING" AND MORE PRACTICAL WORK IN PREVENTIVE MEDICINE.

IT is as important for human progress that the science already gained should be made practical, brought to effective use by the people, as it is that new science should be acquired. One may even question if it is not more important, just as in ethics the greatest need is not that we should know more accurately what is right, but that we should better practise that which we already know. With medicine it is as with every other science—it is easier, at least more common, to strain after unacquired truth than it is to bring down to work-a-day realization and use the truth we have long since gained. Hence we have to deplore the very palpable fact that the meetings of medical men are almost entirely given to the reports of theoretic and acquired medical truth, to the entire neglect of the application to humanity's daily needs of the knowledge that is certain and that should be made to yield good results if put to use. At our congresses there are endless papers on the theory, diagnosis, and treatment of individual cases of produced disease when these cases shall be presented to the physician; but there it all ends, except in so far as the individual physician is concerned, and the members return to their work to await the specific cases of disease that may turn up.

In this, two things are forgotten—the duty physicians owe as a profession to the community as a whole, and the duty they owe to their profession to increase its dignity and prestige. Preventive medicine and hygiene, the education of the community in the knowledge and the practice of the laws of health, are duties sadly neglected by us. There is a beginning in this respect, it is true, an awakening perception, but it is so far only feeble and inconstant—no virile grasping with the stubborn reality. At the last meeting of the Ophthalmologic Section of the American Medical Association a committee was appointed to draft and secure the passage of State laws to prevent the appalling unnecessary number of cases of blindness due to ophthalmia neonatorum. This committee has undertaken the work with energy, and the results of its action will ultimately be of incalculable good. Some State societies have instituted working committees with similar motives and methods as regards the prevention of other diseases, but we here plead for a tremendous extension of the plan, and a radical change of the usual theoretic meetings that end in talk, into consulting and determinative gatherings largely devoted to the needed work of planning and carrying out practical medical work in every community.

Every medical society, local or general, should organize committees with some definite practical work before each for which the members are peculiarly fitted, and whose action should be pronounced upon by the committee of the whole. There are hundreds of legislative reforms and needed advances that only await the authoritative action of corporate bodies of medical men to insure the respectful attention and indorsement of our legislators. The question of pure, germ-free milk, for example, will never be settled until the profession speaks clearly and acts authoritatively about it. The secret-nostrum traffic and the unpatent patent-medicine disgrace can never be stamped out except by our common determination and united action. The hordes of despicable quacks that sprout like ill weeds in our unploughed fields, will never be rooted out unless we act. The doubtful and poor immunity we now have against cholera by means of Governmental control of quarantine has been made possible almost alone by the action of one or two societies of medical men. Every city has its pecu-

liar unhygienic scandals, wretched sewerage, polluted water, cobble-stone pavements, death-bringing unnecessary noises, hospital abuses, proprietary medical colleges, etc., that should be stigmatized with the condemnation of medical societies, and remedied by their antagonism.

The summarization of the whole suggestion lies in the teachings of cool-headed statisticians and their figures. According to our death-rate there are annually occurring in a city like Philadelphia, *i. e.*, in every million inhabitants, something like 2000 or 3000 unnecessary deaths. These deaths are due to criminal negligence. Now, more than this, according to DR. FARR, for every death there are on an average three years of sickness. It is not primarily or chiefly our fault that these 2000 useless and expensive deaths take place and the 6000 years are uselessly and continuously wasted. But it is our duty and our privilege to stop it all. Instead of only trying to cure the person after he is sick, instead of trying to prevent the single death by pulmonary tuberculosis, it is also our high function to prevent all the sickness possible and all the pulmonary tuberculosis whatsoever, and so all the needless deaths. Let us destroy the bacilli instead of merely writing papers about them.

The undertaking of such work by medical societies is also needed for other reasons. There are few professional evils more evident than that of the aloofness of medical men as a body from their lay fellows. It is at present difficult or impossible for the ordinary citizen, however intelligent, to get any adequate or sympathetic comprehension of our aims and methods. Enlistment in these commendable practical hygienic measures will serve to bring physicians and their fellow-men into a desirable community of understanding and mutual respect.

It is also one of the best methods of out-rooting quackery of all kinds. The scandalous condition of legislative indifference to medical reform, the diabolism of legislative control by the quacks, all this and more awaits our united practical protest. We can stop it if we will. When the community sees a united band of men unselfishly working for its welfare, sympathy and support will at once come to that band, and the self-seeking will be left to peddle their homeopathic pillules, offer their infallible secret nostrums, or otherwise pander to the fads and foibles of the little remnant of magic-mongerers who will always be with us to remind us of the barbarism whence we have emerged.

DANGER FROM CANNED GOODS.

SUGGESTION of danger from canned goods is not new to sanitary literature. Considerable attention has been paid to the subject both in this country and in Europe, yet beyond showing by qualitative tests the occasional presence of some of the less dangerous metals, no very extended results have been obtained. The French sanitary authorities have discussed at some length the extent and effect of the employment of copper in greening vegetables, but, in spite of this, the exact effect of this practice is in doubt. HEHNER, a well-known English food analyst, made in 1880 a series of analyses of both meats and vegetables, with the result that in many cases tin was found dissolved in the food. He also studied the effect of tin salts on animals, but the doses used were rather large. It has been noted in all investigations that unless the quantity of lead in the plate or solder be large, tin is dissolved in larger amount—a fortunate circumstance, for this metal is far less dangerous than lead.

Accurate and extended information of interest not only to the sanitary chemist but to the physician is, however, furnished by a recently-issued bulletin of the United States Department of Agriculture, in which are given not only the results of tests for metallic impurities and artificial preservatives in many brands of canned vegetables, but also determinations of general food value. The information furnished is anything but pleasing. Deliberate adulteration, and inferiority in quality are frequent. Salicylic acid and sulfites are freely used, obviously to cheapen the process of manufacture by permitting less care in sterilization. Even the material from which the cans are made is often impure; some samples of the plate showed over 11 per cent. of lead.

Four metals—copper, zinc, lead, and tin—possessing greater or less degrees of toxic power, are found in canned goods. Copper is frequently directly added to give to the vegetables a good green color, especially in peas. In thirty-eight samples purporting to be foreign, copper was found in thirty-six. American peas were not so largely colored; thirty-two out of forty-three samples contained either no copper or very small quantities. Noteworthy quantities of zinc were found in some cases, this being used in a greening process the details of which are not published. Zinc chlorid used in the soldering is also a cause of contamination. Tin is, of course, to be expected, but is found in varying amount. There is so little clinical information as to the

effect of repeated small doses of tin, that a judgment can scarcely be passed on the analytical data in this prospect. With regard to lead no doubt exists. It is probably the most insidious and frequent cause of chronic metallic poisoning. It is introduced into canned goods not only by the solder but also by the use of inferior grades of tin-plate. The adulteration of this article has been alluded to above. It appears also that an appreciable amount of solder often exists in such a finely divided form that it cannot be separated from that in solution, but it may be a question whether such suspension will not be capable of causing chronic poisoning. Not the least interesting and important source of lead is from the rubber rings used in completing the sealing of glass jars. Lead compounds, sulfate, oxids, and carbonate are largely employed in the preparation of rubber goods, and consequently the glass can, which is otherwise so satisfactory a substitute for the tin, becomes in practice a source of even greater danger. Glass bottles with lead tops are used by some firms, and one brand of French manufacture showed in the same bottle about twelve milligrams of lead, fourteen milligrams of copper and an unusually large amount of salicylic acid. The report gives elaborate data as to the food value of the various brands. It is not necessary to discuss this question in detail, and it will suffice to say that the results all indicate clearly that canned goods are most expensive forms of food.

The antiseptics found were salicylic acid, acid sulfites, and salt, the latter partly as a condiment, though occasionally in large amount. It is scarcely worth while to discuss the sanitary relations of the first two. Whatever may be thought of their direct action it is evident that their very function as antiseptics depends on their power to interfere with the actions of microbes and enzyms, and hence with digestive actions. There seems to be no doubt that their employment should be forbidden. Further steps should be taken to prevent the use of adulterated tin-plate or rubber washers containing lead compounds. These conditions represent the most serious phases of an industry which has arisen within this generation, and has reached an extent that is astounding to those who have not followed its development. With the evidence presented by this report, covering as it does only part of the field—for canned meats, catsups, and other classes of preserved food remain to be examined—some idea is formed of the extent to which chronic poisoning and digestive derangements are brought about. It is depressing also to note the indifference which manufacturers show concerning the quality of their goods.

EDITORIAL COMMENTS.

Local Quarantine.—The decisions on the subject of quarantine, other than those touching the quarantine of vessels, have been found by research to be very few indeed. The increasing attention which is almost everywhere being given to the subject of health, however, makes anything determined with regard to it very important. For these reasons, the recently rendered opinion of the Supreme Court of South Dakota in the case of State *v.* Butts (19 L. R. A. 725) is of much interest. Butts was convicted in the County Court of breaking a quarantine order of the County superintendent of health, which order and quarantine regulation prohibited him from leaving his own residence until further orders or permission of said superintendent of health, he having gone from his house upon the public streets, thereby exposing the public, as it was alleged, to the danger of a contagious and infectious disease—diphtheria But the judgment of the lower Court was reversed, because the Supreme Court said that the openly going from his residence upon the public streets did not make the accused a criminal offender against the quarantine order, unless he knew of its existence, while it was not alleged in the information that the order was served upon him or that it was in any way brought to his knowledge, directly or indirectly. All the matters charged in the information might indeed be proved and yet entirely fail to show the guilt of the accused, because his guilt would depend upon his knowledge that the act was prohibited, and was therefore wrong. Such an order is unlike a law, knowledge of which is charged against everyone. The order might have been duly and properly made, and after it was so made the accused might have done the very thing which the order prohibited and still be innocent of offence, unless he knew of such prohibition. Going from one's residence upon the public street is ordinarily an innocent act. To make it criminal, it must be done within knowledge, either actual or imputed, that it has been authoritatively forbidden.

The Index Medicus.—The completion of the first twelve volumes of the *Index Medicus* afforded the publisher and editors an opportunity to give a revised list of the medical journals and transactions regularly indexed for this publication. We have gone to some trouble to count these in order to give the imagination a help in realizing the vast literary labor of a serial character carried on by the profession. Leaving out those of a semi-scientific, purely commercial, or popular order (these will make up for some in the list not accurately or wholly "medical"), we are astonished to find the total number is 1119!

The medical profession should at least acknowledge the debt of gratitude due the editors of the *Index Medicus*, Drs. Billings and Fletcher, but more especially due the publisher, Mr. Geo. S. Davis, who nobly persists

in paying the heavy expenses of the publication with little hope that the few subscriptions will ever equal the outlay. Such an action deserves unqualified thanks, though coupled with shame in confessing that, while we can support hundreds of so-called medical journals, we have to be the recipients of a charity (however willingly given) for the execution of a work so scientific and so useful to every literary medical man.

A Disgrace to the Exposition.—At the headquarters of the Homeopaths in the Exposition Grounds at Chicago, a notorious advertising firm has located itself and makes the Exposition a means of advertising its business. Both from these headquarters and far and wide it sends notices like these: *Rupture Cured or No Pay and No Pay until Cured. No Detention from Business. No Operation. Examination Free. The E. O. Miller Company, Homeopathic Headquarters, just west of the Woman's Building, World's Fair Grounds, Chicago.*

The Medical Century (a homeopathic publication), with commendable honesty, is ashamed of this, but confesses that the firm subscribed to the building on condition that it should have the place given it, and that one of the directors is the "attending surgeon" of the Miller Company, as also a member in good standing of the American Institute of Homeopathy.

The Universal "Shot-gun" Elixir!—That excellent serial the *Provincial Medical Journal*, in commenting on the multiplication of fluid extracts and other preparations of animal glands and tissues, suggests that the modern therapeutists imitate Shakespeare's prescription, as given by the Witches in "Macbeth:"

> "Round about the cauldron go;
> In the poisoned entrails throw," etc.

and in place of administering single remedies, use compound ones, placing in one cauldron, with due antiseptic precautions, the extracts of testicles, ovaries, brain-tissue, pancreas—all the *-ines* that modern medical atavism has imagined, so that we shall always be able to hit the mark, some one of the miraculous remedies going straight to the affected organ and rejuvenating it for a new life-work!

Opium in the New Pharmacopeia.—The strength of opium preparations as prescribed in the new pharmacopeia is slightly different from the requirements of the pharmacopeia of 1880. Powdered opium is to contain from 13 to 15 per cent. of crystallizable morphin—from 12 to 16 per cent. having been the former standard. The average remains the same, but the limits of variation have been reduced. *Acetum opii*, *tinctura opii*, and *tinctura opii deodorata* are each to contain one gram of opium of from 13 to 15 per cent. morphine (cryst.) in ten cubic centimeters, a slight reduction in the strength of the vinegar, a slight increase in that of the tinctures. *Tinctura opii camphorata* is to be one gram in 250 cubic centimeters, instead of one gram in about 257 cubic centimeters. These changes are all improvements.

Dr. Reeves and "The Amick Cure."—Dr. James E. Reeves, of Chattanooga, Tenn., has been arrested on a warrant sworn out by Dr. Amick's representative, on the charge of sending defamatory matter through the mails, and is bound over to Court under bond of $1000. Dr. Reeves says he is not in the least disturbed and that he shall go on with his exposures "though there may be as many devils in the way as there are tiles on the houses of Chattanooga." "I welcome the opportunity to expose the whole thing and make a Waterloo of it. I have twenty-one letters from people whose names appear in the Amick pamphlet showing the cure to be worthless."

Alligatorine is the latest! The homeopathists have beaten us. They have made the toad and the fox yield "most valuable therapeutic products," and now the prepared fat of the alligator, "saponified by alcoholic potash, the soap decomposed by hydrochloric acid, and the fatty acid mixed with cotton-seed oil," is highly recommended. Has any daring investigator prepared any extracts from the brain of our long-eared, four-footed friend, the ass? The balloonists and those afflicted with mountain sickness should get some extract of eagle's-wings, and surely mole's blood or flounder serum would at once cure caisson-disease.

The Struggle for Pure Water in Sacramento.—The *Occidental Medical Times* has done the profession an honor and the public a great service in publishing a special number, or pamphlet, devoted entirely to the question of the pure-water supply of Sacramento, and looked at from every standpoint—economic, sanitary, etc. Those interested in such questions should see and imitate the labors of Dr. Parkinson and his co-workers, lay and professional—to whom, congratulations!

Microbes in the Mails.—PROF. UFFELMAN, of Rostock, Germany, sent a letter infected with cholera-bacilli through the mails, and the bacilli were found alive twenty-three and one-half hours later. On postal cards the microbes lived twenty hours in the mail-bags. On coins they died more speedily. Of what use was the dangerous experiment? The moral of these experiments is said to be obvious. The immoral is glaring!

Shorten the Nomenclature!—

> "Who says convolution,
> When he might say gyre,
> Would cry conflagration!
> When he might shout fire!"

SPECIAL ARTICLE.

MEDICAL EDUCATION.

An Address before the Harvard Medical Alumni Association, June 27, 1893.

BY J. M. DA COSTA, M.D., LL.D.,
OF PHILADELPHIA.

I HAVE often asked myself why it is that medical education is so discussed by the profession, why this never-ceasing upheaval. We do not see the education in law, we do not see the education in theology, a matter of constant dispute and agitation. And I have concluded that the keen interest, the deep feeling, which it

engenders, is really due to the state of medicine itself. The agitation is but a sign of the unrest in medicine we see everywhere. It is but a recognition of the spirit of research and investigation that is so conspicuous now, of the enthusiasm that is constantly adding new facts, almost new sciences. Medical education must be discussed, must be recast, since the groundwork on which medicine stands is being from day to day enlarged and strengthened. Let us, therefore, after all, be glad that the subject attracts so much attention. It attracts attention because medicine itself is a most progressive science.

We cannot congratulate ourselves on the state of medical education as it existed in this country some years since. There were, as there are now, many earnest and eloquent teachers; but the wretched system of going over the same ground year by year, the total inadequacy of the time allowed for preparation, the utter lack of laboratory and hospital facilities, made the condition of medical education a reproach instead of a subject of honest pride. Now it is becoming vastly different. There is, indeed, no self-respecting medical school which can stand the pressure of public opinion and go on in the forefatherly ways. The sacrifices, the struggles, of Harvard and of those great schools that stood by her side in honest rivalry, schools that appreciated the inherited wants of the past and the needs of the present, have not been in vain. They have done what the profession of medicine wanted them to do, and have done it splendidly.

The chief difficulty in making a high standard universal lies in the number of the medical colleges. It is, indeed, a sorry admission that the medical schools in this country are the greatest enemy to medical progress, not in themselves, but in their number. Some years ago there were nearly three hundred. Now there are not far from one hundred and fifty; and they are dying at about the rate of three a year, without, it must be said, many mourners. A further reduction would be a national benefit. The reason they constitute in their number a bar to medical education is not only that in their struggle for existence the feebler ones tend to keep the general standard down, but that it is utterly impossible that all can keep pace with the requirements of modern medicine. How can all have well-equipped laboratories? Where can the clinical work be done on which the medicine of the day depends? The remedy lies in their amalgamation. Let the absurdity cease of small towns having three, four, six, of these struggling institutions, no one of which can have a vigorous life. The remedy also lies in the profession—in the stand taken by potent representative bodies and their authoritative action, in public opinion discountenancing the establishment of medical schools except where the development of the country proves them to be imperatively needed in fresh growing centers. Thus in time the preposterous disproportion of medical schools as compared with schools of law, of divinity, of engineering, will cease; and it will come to be recognized that there is nothing about medicine that calls for such a profusion of teachers.

There is now all over the country a growing disposition for the universities to take charge of medical teaching, and to develop their medical departments with all the zeal they give to the others. We see it in Michigan, we see it in California and Colorado, we see it in Louisiana and in Texas, as strikingly as in our Eastern States. There is nothing but good in this. The power, the means, the spirit, of the university, go out to its branch. The university, in turn, gains by the reputation of its medical faculty, and by the recognition that medicine is an essential part of the new learning which leads on to the highest attainable civilization. Thus both are benefited. The future of medical education certainly lies in the universities, and in such great schools as can vie with them in clinical and other facilities.

But, as this state of things becomes more and more general, and the weak colleges disappear, the university has increased obligations. It must encourage, it must satisfy, the legitimate ambition of those who wish to become teachers, and who prove their aptitude. Throw open the doors as widely as possible, grant the use of the lecture-rooms, attach men of rising prominence to the university, accustom them to look upon her as their true mother. You need not fear. You will not have too many. Students are keen critics. It will be a survival of the fittest at the end.

You have in this great school adopted a four years' course. I observed a rivalry here between you, Mr. President, and you, Mr. Chairman of the Committee on the Medical School, who should be the one to announce its success to this Association. I am sure that there is not a member present who would not like to be in either of your places, and make this announcement; for it is one of great gratification to every member of Harvard, to every member of the whole profession in the United States. I am equally sure that, should the time come when Harvard calls for a fifth year, its loyal alumni would at once respond. Do not, however, understand me as thinking this necessary or even desirable. I believe that for the present you have done enough, and that the curriculum is sufficiently extended. I hope to see the advance in medicine, or rather, I should say, in medical education, going on at the other end. I want to see trained minds enter on the study of medicine. It is so much easier for a teacher to speak to, and to instruct those who have had good mental training. It is frightful to talk in an uphill manner to men—fortunately, now a diminishing proportion in medical classes—who are unaccustomed to thinking, and who show in their faces that they have to labor to understand. Therefore, I say again, that it is to the beginnings that we must look. Let us have preliminary standards of sufficient kind, and the curriculum will, in process of time, and with growing subjects, and with the wealth of the country aiding, take care of itself.

It is gratifying to know that the medical colleges are, with almost unanimity, moving in the direction of exacting certain educational requirements for matriculation. In the Report of 1891 of the Illinois State Board of Health it is stated that 129 colleges out of 148 in the United States and Canada have adopted some standard of general qualifications. It will soon be the universal rule. Even if the requirements are with many of the most shadowy kind, still they are requirements. They aim at securing mental training as a preliminary, and the whole means progress. The most desirable state of things would certainly be if, as a prerequisite to the study of medicine, a degree in arts and science be demanded.

But the country is not ready for this. It would exclude many who are fully competent to study and to profit by their studies. All we can now ask for is proof of sufficient mental training, and it would be best if this proof were forthcoming from bodies unconnected with medical teaching.

But, if we are to get our students of medicine from the universities and colleges of the country, we must be sure that these give us help. Here I fear I am treading on ground which has been gone over thoroughly; but I wish to record at least my individual opinion that, if you want medicine in its higher branches to flourish, if you want it to flourish through university influence and university support, especially if the universities are to become the general medical educators, the university must meet you more than half-way. You must have not simply a shorter course of preliminary study at these universities—and I am an advocate of the three years' course for the degree in arts and in science—but you must also have them in every way giving facilities to those who are desirous of choosing medicine as a profession.

The assertion that the medical classes show a smaller proportion of college graduates than was formerly the case I know to be true. I have followed the matter for some years; and the reduction, I find, is general. The Dean of the Harvard Medical School states that in 1884 the per cent. of college graduates in the Medical Department at Harvard was 53.9, and that in 1892 it was 28.2. At Columbia it rose from peculiar causes to 34.7 in 1891, and was 32.5 in 1892. At the University of Pennsylvania, the Medical Department of which is solving the same problems as Harvard in the same spirit, the college graduates were, at the session of 1890–91, 152 out of 582, or 26 per cent.; in 1891–92, 167 out of 693, or 24 per cent.; in 1892–93, 168 out of 835, or 20 per cent. In some of the medical departments of universities in which the proportion has not been very high there is much less difference to be noted. For instance, in the well-known University of Michigan, in 1882–83, in a class of 378, 40 were college graduates, or 10.6 per cent.; in 1890–91, in a class of 369, 39, or 10.5 per cent.; in 1892–93, in a class of 370, 35, or 9.4 per cent. There are sixteen medical colleges, as I learn from a recent instructive paper by Dr. Bayard Holmes, in the *Journal of the American Medical Association*, with no student enrolled who had obtained a literary or a scientific degree.

Yet I am quite certain that, while the number who complete their academic studies is less, the general average of those of mental training is much higher, and the number much greater who have been for a year or two at some of the higher educational establishments, but have left without graduating. I made it a point for years, while actively connected with a medical school, to inquire into this matter, and kept records that were convincing. This is, I think, only an additional argument for the universities and colleges to consider. The age at which they graduate young men is certainly too high for the professions, especially that of medicine, which requires a long period of special study. It is, undoubtedly, the chief cause why the graduates of colleges are diminishing in the medical schools. Why should the age be so high? Why, here, in a young, rapidly developing country, where men want to, and mostly have to, get to work early, should we require this long preparation? I have taken some trouble to go over the reports of the universities of France and of Germany, and I am astonished to see the difference. The men who enter the professions, with their academic course completed, are, as a rule, nineteen years of age. In a work *On the German Universities for the Last Fifty Years*, by Professor Conrad, of Halle, he states that during a long term of years there was but 23 per cent., or, to speak accurately, 23.1 per cent. of men who were over twenty. We must attain the same here if we want to have college-bred men enter the professions. The colleges must recognize and take into account that professional work is itself a continuance of mental training and culture.

But this subject is too wide a one to follow further here. Let me return to the aims and results of medical education in this country. Vast good has been accomplished by the methods now gaining. It educates those who are trained by it before they see their patients; formerly they educated themselves largely off their patients. I need scarcely say that I am heartily in sympathy with the advance that is going on—the advance as to time required for the course, the advance as regards the subjects taught. But there are in all great movements periods of ebb and flow, of advance and retrogression. We are in risk of retrogression in trying to put too many subjects into the curriculum. The medical student cannot master them all. You cannot turn him out a finished article. The thing is impossible. Let him keep some of his angles. They will be worn off quickly enough when he gets into practice. Teach some subjects thoroughly and let the rest alone. Treat him less as a school-boy and more as a member of a university; develop in him the university idea. Allow him after the first year to choose for himself much more than he is now permitted to, with full knowledge of the subjects required at the final examination. And there is another matter allied to this on which I feel strongly—the constantly recurring examinations. I am utterly opposed to the everlasting examination of the poor medical student. Why cannot you take it for granted that he is developing? Why must you always pull him up by the roots to satisfy yourself that he is growing? We all know that the knowledge of examinations and real knowledge, knowledge that from training and use has become a part of the man, are not always the same thing; and, after all, you do not want to turn out medical prize oxen stuffed and fattened for examination, but medical men with thought, with power, with intelligence, and with love of work and of original investigation. Let us act on the belief that the medical graduate is a compound to be made by synthesis, not by analysis.

A good deal has been said here, and well said, about the desirability of endowing universities. I am sure I sympathize deeply. I think that if Dante is still at work on his *Inferno*, he ought to add a chapter on the tortures that shall await rich men who do not give large sums to universities and colleges. But, after all, it is not simply by endowments that institutions flourish. It is also by appreciating the great teachers they have, doing them every honor, treasuring them. A great teacher in medicine, as a

great teacher in anything else, is rare. Hold him dear when you have got him. Show him every honor. Advance him. He is a potent influence in life: his memory is a power. Who goes to Paris without thinking of Laennec, Andral, Trousseau, and Nélaton? Who visits Vienna and does not have before him Rokitansky, Skoda, and Oppolzer? Who can go to Berlin and not think of Langenbeck and Frerichs; or to London and be unmindful of Hunter and Cooper and Bright? Who comes to Harvard and does not remember the Jacksons and Bowditch and Bigelow and Clark and Ellis and Storer and Shattuck and many others of fame? Their memories go to make up the School, and continue from generation to generation. In these memories they have left much behind them. Some have left also, from their very households, worthy successors; but all have left that great influence which, like the unseen subtle ether, goes to form the rays of light that illuminate a great university. I have made it a rule in these remarks not to speak of the living; but I must make one exception. In the list of those in whose memories Harvard is rich—I find myself speaking almost as if he had passed to another world and bequeathed his immortal name—there is also Holmes. Who has struck a straighter, a keener blow for medical rights, for honesty in the profession, and against shams, than Holmes? He reminds me of one of those Eastern knights whose blade was so skilful that it severed the head of an adversary or cut him down to the saddle, yet he would keep together until he was touched, when he fell asunder.

But I must not be tempted by the interest of the occasion and the kindly warmth of your reception to say more. As I look around me and see the earnest faces of those who are fighting together life's battle in the same cause; as I see side by side the veteran whose name is honored everywhere and the young man who is still to win his laurels, united in one desire, eager all for helpful aid and to promote useful endeavor—it is not teacher and pupil I think of, but brother joined to brother, intent on upholding the beneficent influence, the traditions, the fame, of Harvard, and joyfully ranged around the glorious old banner that, on its crimson folds, shows victories in all science, literature, learning, progress.

SOCIETY PROCEEDINGS.

FIRST PAN-AMERICAN MEDICAL CONGRESS,

Held at Washington, D. C., September 5, 6, 7, 8, 1893.

(Continued from page 335.)

SECTION ON GENERAL MEDICINE.

FIRST DAY—SEPTEMBER 5TH.

THE PRESIDENT of the Section, PROF. VICTOR C. VAUGHAN, delivered an address on "The Principles of Immunity and Cure in the Infectious Diseases," which will be published in full in a future number of THE MEDICAL NEWS.

The paper of DR. FRANCISCO A. RISQUEZ was entitled "Forms of Malaria and their Characteristic Features." The malarial diseases in Venezuela may be classified as follows: I. Intermittent forms, generally quotidian, occasionally tertian. II. Continued forms, including the varieties: (*a*) bilious, (*b*) icterohematuric. III. Pernicious forms, including the varieties: (*a*) pernicious proper, (*b*) complicated. IV. Larval forms, including the varieties: (*a*) periodic, (*b*) continued.

The forms of the first group are easily recognized by the features of the paroxysm and by the periodic element. When the access is prolonged, the diagnosis may be difficult. The forms of the second group are distinguished by the gastro-hepatic symptoms and the indications of the urine. They may be confounded with others, especially with those of yellow fever, and the distinction becomes often a matter of life and death. The forms of the third group are recognized by the preëxistence of malarial paroxysms. It may become almost impossible, however, to distinguish between cholera, pneumonia, or tetanus, and cases of choleriform, dysenteric, tetanic, or other pernicious fevers. The forms of the fourth group present still greater difficulties, especially in the continued varieties. They may assume all the appearances of typhoid fever, of cholera, of dysentery, of paralysis, of hemorrhage. The malarial cachexia may simulate tuberculosis, hepatic abscess, etc.

An early diagnosis is indispensable in these cases, because they require the fearless administration of quinine; and this drug may be contra-indicated in the non-paludal diseases. There is but one unquestionable method of diagnosis: *the microscopic examination of the blood.* All malarial manifestations are accompanied with melanemia; melanemia presents itself exclusively in malaria, and the sign is, therefore, pathognomonic. A drop of malarial blood, under the microscope, shows the masses of black pigment in the plasma. The manipulation requires no special technique; it is simpler than the examination of the urine. It does not require, as the parasite of Laveran does, an investigation by an expert with high powers of the microscope. Our method requires only a few slides and covers, and a drop of blood obtained from the finger, previously washed. The preparation is taken to the laboratory and there examined. The strong mineral acids may be used as reagents.

A search for pigment should be made in all suspected cases. The number and size of the pigment masses is proportional to the degree of malarial poisoning. If they are found at all, quinin should be given. The author has found pigment in all forms of malaria. He has found it also in other diseases, but only as evidence of malarial complication. Melanemia is always an indication for the administration of quinin. The life of the patient depends often in these cases upon a prompt diagnosis.

DR. MENDEZEBAL, of Mexico, read a paper on "Paludal Fever in Orizaba."

SECOND DAY—SEPTEMBER 6TH.

DR. WILLIAM C. DABNEY, of the University of Virginia, read a paper on "Typhoid Fever," based on a study of fourteen cases of continued fever occurring at the University of Virginia between January 15th and April 1, 1893. The epidemic, or outbreak, presented the following features of interest: 1. There had been no typhoid fever in or around the University, so far as the author could learn, for several months. 2. Between the middle of January and the first of April, 1893, there occurred

fourteen cases of continued fever among persons living or employed on the University grounds. 3. The persons who had this continued fever had rooms at widely separated parts of the University grounds, but all took their meals at the same hotel. 4. The water-supply of this hotel was the same as that of the other hotels and of other parts of the University, and the sanitary condition of the building was good. 5. A part of the milk-supply was obtained from cows whose teats had been washed in water contaminated by sewage, and *probably* infected with typhoid-fever germs. It was in evidence also that at least five of the fourteen persons used milk at every meal. 6. Of the fourteen cases of continued fever five presented the typical features of typhoid, seven were typical in character, and of the other two the author could not speak with certainty, as they were not under his care, and he could get no satisfactory history of the cases.

DR. CLAIBORNE, of Petersburg, Va., in discussing the paper, said the differential diagnosis between typhoid fever and malarial fever is often quite difficult. It is not the habit of physicians in his part of the United States to make many post-mortems, and without post-mortem examinations he cannot see how these cases are to be classified. It is very difficult, indeed, for him to classify the cases which have a fever, commencing as a chill and running at once to a very high temperature, *without* other symptoms. Some time ago it was customary to call these cases of typho-malaria the result of two poisons —of vegetable and animal forms. However, the physician who made this classification has since practically recanted it. The writer had frequently seen cases of fever beginning, apparently, as a malaria and ending in typhoid. He is in the habit of testing these cases with gr. xx of quinin three times a day. If this does not produce exacerbation, he is pretty certain that it is something else than malarial fever. With the exception of that test, he is at sea, and he would be very much obliged to any member of the profession who will give any information on the subject.

DR. LARRABEE, of Kentucky: Dr. Dabney has mentioned a very common mode of the production of the disease; but the water, in his cases, was put on the outside instead of on the inside of the cow. In this respect it was different from the ones with which I have come in contact. In the city of Louisville forty cases were traced to a single milk-supply; there the water was used for washing the utensils. Thirty-seven cases were traced to this, leaving only three doubtful cases. In the malarial districts, in the West and Southwest, it is indeed difficult to differentiate typhoid fever without the use of quinin. If it be malaria, and quinin be given, it is well to have recourse to an old remedy; for, although we have moved into a new house, some of the old furniture fits very well. I refer to calomel. (Applause.)

DR. FORD, of Philadelphia: It would be interesting to know whether typhoid and malaria are ever mixed. It seems to me there must be some cases of mixed infection.

DR. LEIGHTON, of Brooklyn: During the war, in Maryland, there were many cases of intermittent and remittent fever which were difficult to differentiate. There was an opportunity to make quite a number of post-mortem examinations, for many cases terminated fatally, and there were found the diseased glands and congested liver.

DR. SIBBETT, of Carlisle, Pa: I was sent as medical inspector to a school where forty-two pupils were taken down with typhoid fever. Two of them died in a few days. The most malignant form, apparently, set in first. At that time we had an endemic of almost every form of typhoid or continued fever. It was my duty to find the cause and report. There were two difficulties: bad water and bad privies. In these forty-two cases I tried to determine when the fever began and when it ended. I came away from this investigation with the impression that it is impossible for us to tell.

DR. WEST, of Texas: A great mistake has been made by not recognizing the fact that the typhoid condition never exists without the typhoid fever. Not only do you have the occurrence of these abortive cases of typhoid fever, but often the patients remain on their feet almost until death. We have many cases of so-called mild typhoid fever, and the cases related are examples of this. When you know quinin is absorbed in the blood, it will have its effect on malaria. In the hospital where I serve we have malaria and typhoid-fever patients side by side, often from the same ship and various parts of the United States. We often have both infections occurring at the same time on board a vessel, but I have been unable to say positively that a certain case is typho-malaria.

DR. PURSELL, of Illinois, urged caution in the treatment of these cases owing to the danger of perforation.

DR. VICTOR C. VAUGHAN, of Michigan: There may be such a thing as typho-malarial fever, but no man has ever, as yet, demonstrated its existence. To-day there are three theories concerning the causation of typhoid fever: The German theory, that typhoid is caused by a certain germ; that it is a specific disease, the same as smallpox. One of the definite characteristics of the germ is, that it will grow upon potato, forming an invisible growth. The Koch-Eberth germ is the only germ capable of causing typhoid fever. The other theory we may designate as the French theory, which is that the cause is a modified form of the bacillus coli communis, which sometimes acquires extraordinary virulence. If the French theory is correct, the pollution of water with any fecal matter may cause typhoid fever. If the German theory is correct, it would be perfectly safe to drink all the fecal matter you wish, provided it comes from healthy persons. Now, there is another theory, and that is, that typhoid fever may be caused by any one of a number of germs, which are closely related to one another, but which are not connected either morphologically or physiologically, and consequently we cannot expect the symptoms to be the same in all cases. For the last twelve or fifteen years I have, on account of certain official positions, investigated every outbreak of typhoid in the State of Michigan, and for the last six or seven years I have accompanied these with a bacteriological examination, both of the drinking-water supply and, for the last two or three years, of the spleens of the persons dead from typhoid fever. While I have seen thousands of cases of typhoid fever, I have yet to see a case of *typical* typhoid fever, as described in the text-books, where the temperature is graded day after day. Of course, in many of these cases the tempera-

ture is interrupted by the treatment. Further, I have never, as yet, found in the drinking-water, or in the spleen of a person dead from typhoid fever, a germ identical with the supposed specific germ. Occasionally I have found germs which form an invisible growth on potato, but they have been different from the Eberth germ. In a recent outbreak at Ironbrook I inoculated beef-tea, and after twenty-four hours injected it into animals. The germ was then found in the spleen, kidney, and liver. I directed sent to me the spleens of all persons dead from typhoid fever, and in these, which were quite a number, I found the same germs as in the water. I think this pretty positive proof that the germ caused the disease. I think we have a group of causes, just as in the vegetable world we have a number of plants which produce poison, varying in virulence according to the conditions in which the plant grows. Tobacco grown upon different kinds of soil will show changes. Why not germs, which pass through a number of generations in a short time? A woman living in the country does not go from home, but dies of typhoid fever. A post-mortem is held, and it is found to be true typhoid fever. Some contend that such cases are caused by infection carried by a tramp with walking typhoid fever, who, visiting the various water places, infects the neighborhood. There are 50,000 deaths in this country of typhoid fever and 500,000 sick with it. This shows that the germs must be widely distributed. I am sure that healthy individuals aid in distributing the disease.

DR. DAVID LOBO, of Venezuela, read a paper entitled "A Contribution to the Clinical Study of Prolonged Remittent Fever." It was his purpose to describe a certain form of malarial infection which, he believed, has received very little attention from standard writers on tropical diseases. The description was based on clinics exclusively, referring to the various individual conditions, and was intended to impart his personal views in regard to the malady as it occurs in Caracas.

Etiology. The aspect and extraordinary course of the pyrexia are probably due to corresponding variations in the power and quality of Laveran's corpuscles, to overpoisoning of the blood, or to some distinct element operating simultaneously with the paludal germ.

Variations in temperature do not respond to any fixed law of recurrence. The temperature generally ranges from 38.5° to 40.5° C., and drops or rises unexpectedly. Remissions take place at any moment of the day. Intermissions may recur, but they should never be trusted. *Chills* and *sweating* may be observed, but never as definite stages of the fever.

Special symptoms. *Circulation* and *respiration* do not exhibit any deviations, except those induced by the reaction of the organism under the influence of abnormal heat. Divergencies between pulse or respiration, and temperature, should be looked to and carefully treated.

The fever frequently runs its entire course free from complications. There are serious incidents generally; their gravity depends on the importance of the organ attacked.

It is obvious that the whole clinical history of the disease may be condensed into two prominent facts, viz., an irregular temperature and a long, weary course.

Diagnosis. The main points by which long remittent fever can be discriminated from other *malarial forms*, are its uncommon course, its irregular temperature, the absence of marked stages, of hepatic or splenic troubles, and its resistance to quinin.

Between it and *typhoid* there is no possible confusion; typhoid is cyclic in its career, is accompanied by intestinal lesions, presents peculiar eruptions, and is extremely rare at Caracas.

The so-called *typho-malarial* fever exhibits typhoid symptoms, which are never present in ordinary remittent.

Vomiting of black matter and albuminuria are perfectly distinctive of *yellow fever.* The course of this never exceeds ten days.

Pernicious fevers are sufficiently distinguished by their short duration and characteristic aspect.

When complicating or intercurring processes do not occur, a fatal issue is seldom to be feared. High temperature, extreme weakness, frequent vomiting, copious sweating, and diarrhea, generally impart a serious character to the disease.

Prognosis is entirely different when we have to deal with organic complications.

Complications. The fever may give rise to a special inflammation of the lung, to which the term *pseudo-pneumonia* can be properly assigned.

Among nervous complications, none is so terrible as *cerebral congestion.* It may assume a *convulsive* or a *comatose* form, but the latter is more common. The convulsive form is probably due to meningeal congestion. The issue is fatal in nine cases out of ten.

Acute entero-colitis, *dysentery*, and *choleriform diarrhea* are fearful complications, as they often lead to a fatal result. *Hemorrhage* and *acute peritonitis* are apt to occur as secondary phenomena, subsequently to ulceration of the digestive duct. The *kidneys* generally undergo no injury at all. Urine is *never albuminous.*

Treatment. Long remittent fever is very slowly influenced by quinin. There are cases in which the drug is absolutely useless, whether it be given in large or small doses. If administered to excess, it is apt to cause irritation of the stomach, vomiting, diarrhea, heart depression, and collapse. The view that quinin will prevent complications is merely hypothetic.

Aconite, *arsenic*, and *carbolic acid* may be resorted to in protracted cases. I place very little confidence in their action.

Warburg's fever tincture is a valuable remedy. *Salicylate of sodium*, *antipyrin*, *antifebrin*, and similar agents will surely act on temperature, but their effect should be carefully watched.

Tonics should be freely ordered.

Chlorate, *iodid* and *potassium bromid* are indicated in very chronic cases.

Cool baths or *lotions* are an innocent and efficient means of lowering the temperature. They must not be spared.

A *proper diet* should be prescribed from the first, including good wine and diluted brandy. Complications call for a special treatment, entirely dependent upon the nature of each case.

In the discussion of Dr. Lobo's paper, DR. OSLER, of Baltimore, said: Without a very careful study of the blood in such a disease as Dr. Lobo describes, it would be very difficult to distinguish it from typhoid fever. In this latitude we do not have the protracted cases of remittent fever in the form he described, which will not

yield to quinin. A fever in this latitude which does not yield to quinin, properly given, within three or four days, is not malaria. Dr. Risquez lays great stress on the black pigment in malaria. In many of the cases of very acute malaria in this latitude, there is very little pigment indeed. *In some of the most malignant forms* there is very little pigmentation to be seen in the red blood-corpuscles, in the early stages of the disease. I would emphasize the importance of careful study of the blood in all cases of continued fever.

Dr. Lobo: I think that the clinical appearance of the disease is usually characteristic. Its course is so extremely different from typhoid fever and ordinary remittent fever that the symptoms described, in my opinion, are sufficient to designate it. In reference to influenza, I think there is no confusion possible between the two diseases. As to typhoid, you must bear in mind that typhoid is extremely rare in Caracas, and almost absent from the city. I have seen only two cases of regular typhoid fever in Caracas. Can you say that a person affected with a fever, having no congestion of lungs, of liver, of bowel, of spleen, no delirium, no convulsions, etc., is affected with typhoid fever? In pernicious malarial fever the symptoms develop rapidly, the patient dying in twenty-four to thirty-six hours, and there is scarcely any time for the employment of quinin. In intermittent fever you have never such startling symptoms. Your patient may sit up with it one, two, or three months, and you may be almost sure your case will recover. Quinin does no good in such cases.

Solomon Solis-Cohen, M.D., of Philadelphia, then read a paper on "Vasomotor Ataxia."

1. By the term "vasomotor ataxia" it is proposed to designate the condition of instability of the mechanism of circulation present in certain persons, and characterized by abnormal readiness of disturbance with tardiness of restoration, of the equilibrium of the cardio-vascular apparatus. The manifestations are most strikingly displayed in the terminal vessels and occur chiefly under the action of external influences, especially cold; of toxic agents; and of emotion. The stimulus may be applied centrally or peripherally, but in each case the resulting phenomena indicate a defect of central inhibition.

2. Vasomotor ataxia is in many cases congenital; in some inherited; the condition is not rarely present in several members of a family.

3. In some cases the phenomena are of paretic, in others of spasmodic character. Usually the two kinds of phenomena are displayed in varying degree in the same patient. Whether spasmodic or paretic, the symptoms are suggestive of incoördination.

4. In exophthalmic goiter, especially such cases as are produced by emotion or are markedly intermittent, is found the extreme type of the paretic variety of vasomotor ataxia.

5. The form of Raynaud's disease known as "local syncope" furnishes an extreme type of the spasmodic variety, while "local asphyxia" exhibits both spasmodic and paretic phenomena.

6. Between these extremes are numberless gradations down to the slightest departure from normality, while even the extreme symptom-groups represent merely exaggerations of phenomena that under certain conditions occur in normal individuals.

7. Dermographism is an essential feature of vasomotor ataxia, and in most cases factitious urticaria can be readily produced by cold or by pressure, or by both; mottlings of the skin, certain peculiar markings of the nails, telangiectases, and stigmata, are common.

8. There is usually a hemorrhagic tendency, as shown by ecchymoses, petechiæ, epistaxis, hemoptysis, hematemesis, hematuria, and retinal hemorrhage.

9. Even in the absence of hematuria, red blood-cells are often found in the urine; uric acid, urates, and oxalates are likewise common; the presence of albumin, tube-casts, and cylindroids, is less common, and is usually intermittent. Glycosuria has been observed.

10. In many striking cases there has appeared to be morbid alteration of the thyroid gland.

11. The action of the heart is usually rapid, irregular, and easily disturbed; palpitation is common, and in some cases intermittent tachycardia has been noticed. Hemic and functional murmurs are not uncommon.

12. Among other symptoms and morbid associations observed are drug-idiosyncrasies, urticaria, local edema, angina pectoris and pseudo-angina, hyperidrosis, asthma, hay-fever, vertigo, migraine and other forms of headache, transient hemiopia and other visual disturbance, persistent mydriasis, astigmatism, myopia, hyperopia, menstrual irregularities, intermittent polyuria, rheumatism, chorea, epilepsy, neurasthenia, gastralgia, enteralgia, and membranous enteritis—most of which are doubtless related as effects of a common cause or as secondary results.

13. The development of pulmonary tuberculosis in some cases is probably a sequence of vascular and trophic disturbance in the lung.

Dr. West, of Galveston, Texas (in discussion): I recall a number of cases, and I find these have generally occurred in females, and those I recall now occurred in sterile women and were associated with menstrual disorders. It seems to me the name of vasomotor ataxia is a very good term. It gives a local habitation and a name to a disease we frequently meet with, and whose cause is exceedingly obscure.

Dr. Cohen: The pathology of the disease is obscure, of course. The pathology of the whole sympathetic system is obscure. I believe the disease is a congenital one. It is largely a defect of development, and if searched for would be found in many more instances than have been recognized. By recognizing the liability of our patients to such conditions, and by taking proper treatment, we can, I believe, in very many cases save our patients from many of these graver conditions.

Dr. J. M. Anders, of Philadelphia, read a paper on "The Complicating Conditions, Associated Diseases, and Mortality-rate in Erysipelas." During the year just past the writer had been engaged in conducting a collective investigation into the disease of erysipelas. The average duration of the affection was computed in 1880 cases, and found to be (including relapses) 25.13 days. Erysipelas in a typical form is a self-limited disease; that the length of the attack is greatly influenced by the age of the person *per se*, its average duration in persons over fifty years being considerably longer than in younger subjects; sex has no influence in this direction. Certain conditions and diseases increase the liability to the complaint.

I propose to present the results obtained from a study of a series of 1674 cases, which were analyzed with particular reference to complications. In the opinion of all authors the death-rate is exceedingly variable, ranging, according to some writers, from 1 to 50 per cent. The comparative gravity of the leading complicating conditions and diseases is shown by the following table:

Complications.	No. of instances.	Deaths.	Recoveries.	Per ct. of deaths.
Abscesses	105	8	97	7.6
Acute rheumatism	20	2	18	10
Pneumonia	7	4	3	57.1
" catarrhal	2	...	2	0
Delirium	7	4	3	57.1
" tremens	10	8	2	80
Pleuritis	7	1	6	14.3
Acute nephritis	6	3	3	50
Phlebitis	7	0	7	0
Synovitis	5	0	5	0
Diarrhea	5	0	5	0
Edema of larynx	2	2	...	100
Pyemia	1	1	...	100

It will be seen that, while abscesses are common, they do not to any extent augment the mortality-rate. Pneumonia, delirium, delirium tremens, and acute nephritis are among the graver complications. Acute rheumatism, on the other hand, stands second in frequency, but is comparatively harmless. To account for the increase in the percentage of fatal cases due to acute articular rheumatism we possess no positive knowledge. The opinion is, and long has been, prevalent that erysipelas benefits and even cures articular rheumatism and other affections (including carcinoma and sarcoma).

These deductions may serve not only to reiterate some of the leading demonstrated facts, but also to facilitate a discussion of the same:

a. In typical cases erysipelas is a self-limited disease, the average duration in persons under forty years of age being fourteen days.

b. The course of the disease was greatly lengthened when complications were present or chronic affections preëxisted, as well as when occurring in persons over fifty years of age.

c. Certain chronic affections, notably pulmonary tuberculosis, chronic nephritis, chronic rheumatism, and organic diseases of the heart increase the susceptibility to the complaint, having been present in 7.8 per cent. of the total number of cases.

d. The most common complications were abscesses and acute rheumatism; the rarest meningitis, ulcerative endocarditis, and pericarditis, the latter not having furnished a single instance.

e. The general average mortality was 6.57 per cent., while in the cases from private practice it was 4.16 per cent; in persons under forty years it was only 3.5 per cent.; in those over seventy years, 46 per cent., and in the traumatic cases 14.5 per cent.

f. The mortality list was augmented as much as 25 per cent. by the presence of coexisting chronic affections.

g. The numerous complications also increased the percentage of deaths, and certain of them in an especial degree, notably lobar pneumonia, acute nephritis, delirium tremens, and active delirium.

h. Age has a decisive influence upon the mortality after the fiftieth year, this effect becoming more pronounced after the sixtieth year.

DR. VAUGHAN alluded to a case in which a child suffering with a sarcomatous growth was inoculated with erysipelas. The child's death was apparently hastened by the erysipelas.

DR. CRONYAN, of Buffalo: Some time ago we had a patient in the Buffalo Hospital with progressive locomotor ataxia. He was attacked with erysipelas of the face, extending over the whole of it and over the head, involving the meninges of the brain. We administered the tincture of iron, after which we purged him with calomel. After recovery from the erysipelas, the patient required no "sticks," but was able to walk about as well as anybody, and continued to do so the rest of his life—a number of years. I agree with the author, the age of the patient has much to do with the fatality of the disease.

DR. DESAUSSURE: The author mentions the frequency of heart-disease in these cases, and I would like to ask if he attributes erysipelas to that disease. Also, were the abscesses in his cases located in the deep cellular tissue or in the neighboring lymphatic glands?

DR. ANDERS closed the discussion: The fact that so few die of this disease who are attacked with acute articular rheumatism, is very good evidence of its action. In fact, erysipelas is supposed by some to cure acute articular rheumatism. Endocarditis is apt to occur in cases of articular rheumatism; perhaps the percentage of cases in which they do occur is not less than thirty. As to whether organic heart-disease causes erysipelas, I would say, By no means. Chronic affection of the heart merely predisposes to the disease.

NEWS ITEMS.

Colorado Medical Library Association, of Denver, Col.—The medical fraternity of Denver and Colorado are endeavoring to build up a medical library in Denver. Owing to remoteness from the centers of population the work undertaken is difficult in many ways. Societies can aid materially in this enterprise by sending their *Proceedings*. Anything in the way of medical literature sent will be acknowledged, placed on the shelves of the library, and brought to the attention of readers. Address, care Public Library, Denver, Col.

Cholera has appeared in Hamburg again, twelve cases and nine deaths having occurred from September 13th to September 18th. In Italy and France the disease is still spreading. In Palermo there were fifteen fresh cases and nine deaths on the 18th. The disease is also on the increase in Russia, Galicia, in Bukowina in Austria, and there is much alarm in Germany. Braila in Roumania is infected. During August nineteen deaths occurred in Antwerp.

Yellow Fever.—At Brunswick, Ga., yellow fever has broken out, according to telegrams from Dr. Guitéras to Surgeon-General Wyman. The latter is acting with most commendable intelligence and energy to stamp out the disease and to prevent its spread, by quarantine, disinfection, and restriction of travel, mail-communication, and a thorough organization of all means of control.

SOME POINTS IN THE DIAGNOSIS AND TREATMENT OF INTRA-CEREBRAL HEMORRHAGE AND IN THE TREATMENT OF CHOREA.[1]

BY J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES AND MEDICAL JURISPRUDENCE IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST AND ALIENIST TO THE ARAPAHOE COUNTY AND THE ST. LUKE'S HOSPITALS.

INTRA-CEREBRAL HEMORRHAGE.—Usually the first and most obtrusive symptom of intra-cerebral hemorrhage is apoplexy, or partial or complete loss of consciousness, more or less sudden in onset, and more or less prolonged in duration. In the majority of cases we have added the local or hemiplegic symptoms. In the severer forms of cerebral hemorrhage there is complete relaxation of all the voluntary muscles of the body, including the sphincters of the anus and bladder. In the milder cases there may be only slight obscuration of consciousness; in the severer ones, unconsciousness is profound.

In a typical case of cerebral hemorrhage, ushered in by marked apoplectic symptoms, the patient lies as in a profound sleep, with a tendency to stertorous and labored breathing. The skin is usually bathed in perspiration. The pulse is often full and bounding; sometimes it is small, rapid, and incompressible. The temperature, at first, in all but the milder cases, is lowered from 0.5° to 1° or 2°, but in a few hours it rises from 0.5° to 1° or more above normal. Immediately after the shock the temperature on the paralyzed side is lower than on the unaffected side, but in a very few hours it is higher on the affected than on the non-affected side. A careful study of the temperature is of considerable importance, both in the diagnosis and prognosis. The face is often flushed, but sometimes it is pale. The urine is at first abundant and of rather low specific gravity, but soon it becomes less abundant and has a high specific gravity. Sometimes it contains albumin, but no tube-casts, unless there is some renal complication. Convulsions are more common in lesions of the cortex; vomiting is most frequently met with in lesions of the cerebellum.

In nearly all cases, except the severer ones, in which there may be complete relaxation of all the voluntary muscles of the body, there are local, or one-sided, symptoms. The most pronounced of these is the hemiplegia, involving the leg, arm, and face on the same side. In rare instances there is crossed paralysis, with affection of the leg and arm on one side, and of the face on the opposite side. When the hemiplegia is incomplete, the arm is most affected, the leg next, and the face least of all. The distal portions of the extremities are more affected than the proximal. Immediately after the shock the deep reflexes are abolished on both sides. They return first on the unaffected side, but they soon return on the paralyzed side and become more pronounced than in the unaffected limbs. The superficial reflexes not infrequently remain absent on the paralyzed side for several weeks. One pupil may be dilated and fail to respond to light, or both may be dilated or contracted. The eyeballs are usually fixed, and more commonly they deviate to the paralyzed side, although there may be conjugate deviation of the eyes with turning of head toward the unaffected side. The facial paralysis is limited to the lower part of the face, and the affected cheek puffs out during expiration. If the patient is able to protrude the tongue, it deviates toward the paralyzed side. Even when the unconsciousness is profound, the muscles on the affected side are not so completely toneless as those on the unaffected side. The local symptoms vary according to the seat of the hemorrhage.

In a given case of supposed cerebral hemorrhage, during the apoplectic state, the diagnosis has to be made from a similar condition caused by syncope, or by chloral, opium, or alcohol poisoning, or by uremia, epilepsy, hysteria, embolism, thrombosis, the apoplectiform attacks occurring from cerebral congestion or from the cerebral state found in paretic dementia, and from "simple apoplexy" in the aged.

Syncope from cardiac failure is easily distinguished from cerebral hemorrhage. In the former the heart's action is exceedingly weak; the pulse is small, very feeble, and almost imperceptible; the face is blanched; the lips are very pale; respiration is shallow, or it may be sighing and irregular; reflex action is rarely abolished; the sphincters are not relaxed; the pupils are equal and widely dilated, and there are no hemiplegic symptoms.

Chloral-poisoning. In profound unconsciousness from chloral the subject is in a peaceful and undis-

[1] Read at the meeting of the Colorado State Medical Society, held at Denver, June 20, 21, 22, 1893.

turbed slumber; not a voluntary muscle moves, and all is calm. Breathing is rather slow and shallow, the pulse is soft, weak, and infrequent, and the temperature is usually slightly subnormal. There is complete absence of all local symptoms.

Opium-poisoning. The onset of the symptoms, if this is known, the equal and contracted pupils, the slow respiration, the normal temperature, and the absence of all hemiplegic symptoms, would point to opium-poisoning. If the symptoms began suddenly with a general or a partial convulsion, chloral, opium, and alcohol poisoning could be excluded.

Alcoholic unconsciousness. An alcoholic odor of the breath, a coma from which the patient may be temporarily aroused by loudly calling his name, equal pupils, nearly normal temperature, and the absence of unequal temperature on the two sides of the body, point to alcoholic poisoning. Violent struggling, when it occurs, strongly indicates alcoholism. There are no localizing brain-symptoms.

Uremic coma. Albumin and tube-casts in the urine suggest uremia, but albumin is frequently found in considerable quantity in the urine in cases of cerebral hemorrhage, especially if attended with convulsions, but tube-casts are usually, if not always absent, except when kidney-disease has preceded the hemorrhage. It must be borne in mind that renal disease, especially the senile form (granular disease of the kidney), occurs in about one-third of the cases of cerebral hemorrhage. The peculiar physiognomy of renal disease, with local dropsy, equal pupils, less profound coma, and usually nearly normal temperature (according to Gowers it is always subnormal, except in cases in which local inflammation exists), the presence of the odor of urine in the breath, and the absence of hemiplegic symptoms occurring in a young subject, are usually sufficient to diagnosticate uremic coma. Gowers states: "Rigidity of limbs or local muscular twitching during the coma is, if constant in seat, in favor of cerebral mischief; if variable in position it is in favor of uremia."

Coma of epilepsy. If the history of the patient is known and the onset of the attack has been witnessed, no difficulty will occur in the differential diagnosis. If the patient is first seen in post-epileptic coma, without any knowledge of his previous history, the absence of hemiplegic symptoms and the short duration of the coma would serve to distinguish the case from one of cerebral hemorrhage, except in the status epilepticus (a state rarely, if ever, reached without the history of the patient being known), when in the absence of a history of the case it would be almost impossible to exclude cerebral hemorrhage in which no hemiplegic symptoms are present. Fortunately for the diagnostician, in nearly all cases of cerebral hemorrhage attended by convulsions following each other in rapid succession, unilateral symptoms exist, but multiple thrombi and emboli may give rise to a condition resembling the status epilepticus without a single unilateral symptom.

Hysterical coma. I have yet to meet with my first case of hysterical coma in which difficulty has been found in excluding cerebral hemorrhage. In the cases that I have seen, the absence of all positive symptoms of organic disease and the presence of hysterical stigmata have rendered the diagnosis easy. The face is rarely, if ever, paralyzed in hysteria. The danger of mistaking cerebral hemorrhage for hysteria is much greater, and in some cases can only be avoided by a careful search for symptoms of organic origin.

Apoplectiform attacks of cerebral congestion. In this condition the symptoms are general, with less profound unconsciousness than is found in cerebral hemorrhage. There are no local or hemiplegic symptoms. There is usually a history of previous similar attacks which have passed off without leaving any weakness of muscles. Gowers is inclined to the opinion that in first attacks of this character a positive diagnosis cannot be made.

Apoplectiform attacks in paralysis of the insane. The previous history of the patient is usually sufficient to put the physician on his guard. The seizure is ushered in suddenly with convulsions, local in seat, clonic and tonic in character; the head is drawn to one side; the muscles of the eyes and face may keep up a constant twitching for hours; unconsciousness is profound; the face is dark; respiration is shallow and rapid; the pulse is quick and weak; the temperature is elevated; a profuse perspiration covers the body, and the whole aspect of the patient points to speedy dissolution.

The seizure lasts for a few hours or a day, and is followed by a sleep from which the patient slowly wakes and gradually recovers consciousness. A day or two later, however, the patient is apparently as well as he was before the attack, except that mental deterioration becomes more rapid, with a tendency to the formation of bed-sores and the development of other trophic disturbance. If one were called to see a patient in a first attack of this character without a history to guide him, a diagnosis from cerebral hemorrhage would be impossible. The same character of attacks occurs as a manifestation of cerebral pachymeningitis, and it is probable that these seizures in paralysis of the insane are due to hematoma of the dura, and the immediate cause is hemorrhage.

Simple apoplexy. In persons advanced in life a condition sometimes occurs with a train of symptoms that perfectly resembles that of cerebral hemor-

rhage, but at the autopsy no trace of hemorrhage or other gross cerebral lesion can be found. Such attacks are truly "mysterious" in their nature, and it frequently happens that they cannot be distinguished from cerebral hemorrhage.

Embolism. The younger the patient, with the presence of endocardial disease or syphilis, the greater the chances are in favor of embolism against hemorrhage, except in cases in which the apoplectic symptoms have been very severe, coma profound and long in duration. The parturient state favors embolism. The less the primary disturbance of temperature, provided the paralysis is extensive, the less the chances are in favor of hemorrhage.

Thrombosis. The differentiation of thrombotic softening from cerebral hemorrhage is probably one of the most difficult diagnoses that the physician is called upon to make. Gowers states that "Some writers contend that we can be sure of our diagnosis in only one-third of the cases." He does not agree with this broad statement, and believes that by a careful analysis and comparison of the symptoms an accurate diagnosis can much more frequently be reached than might be inferred from the writings of some physicians.

An accurate diagnosis is of considerable importance, because the treatment of the two conditions is entirely different. I will give the most important diagnostic points of each:

THROMBOTIC SOFTENING.	CEREBRAL HEMORRHAGE.
1. Prodromata frequent.	1. Prodomata infrequent.
2. Great degeneration of the arteries of the limbs.	2. Turgid face and strongly beating arteries of the neck.
3. Pulse soft and often very compressible.	3. High arterial tension, regardless of the size of the pulse.
4. Heart feeble, dilated, and irregular.	4. Heart hypertrophied and beating strongly.
5. Coma less marked in depth and duration.	5. Coma more intense and longer in duration.
6. Following grief and other depressing influences.	6. More likely to be induced by mental excitement.
7. Local convulsions more frequent.	7. General convulsions more frequent.
8. Slight initial temperature-disturbance.	8. Often great initial temperature-disturbance.
9. Slight variation of the temperature within a few hours.	9. Often a considerable rise of temperature from twelve to twenty-four hours after the attack.
10. Secondary inflammatory symptoms frequent and well-marked.	10. Secondary inflammatory symptoms less in frequency and in degree.

The foregoing is only an attempt to arrange the chief diagnostic points of thrombotic softening and cerebral hemorrhage side by side, but it must be evident to everyone that any one of the symptoms may be so modified by conditions and circumstances as to render it entirely valueless, *e. g.*, sudden fall of temperature, succeeded a few hours later by a rise of several degrees, indicates cerebral hemorrhage, but in occlusion of the basilar artery the temperature may rise four, six, or even eight or more degrees, a few hours subsequently to the occurrence of the apoplectic symptoms.

TREATMENT OF CEREBRAL HEMORRHAGE.

I must reiterate what I have said on former occasions in connection with the treatment of a patient while in the apoplectic state from cerebral hemorrhage, that most of such patients would do better without medicine than they do when medicine is simply administered with the hope of doing some good, but the administration of which is not governed by any logical or rational principle.

If we bear in mind that in hemorrhage into the cerebral substance, not traumatic in character, the immediate cause of the hemorrhage is the bursting of a miliary aneurism, we shall appreciate how futile must be our efforts to arrest such a hemorrhage by the administration of medicine. Immediately after the occurrence of the event the indications are to allow the effused blood to coagulate, to promote the flow of the venous blood from the head, to quiet the heart's action, to allay the restlessness of the patient, when such exists, and to prevent an undue amount of blood being carried to the head. We can render the best service in aiding the coagulation of the effused blood by keeping the patient absolutely quiet. The flow of the venous blood from the head is promoted by slightly elevating the head and shoulders, and not allowing the head to be bent forward and thus compressing the veins of the neck. The heart's action is best quieted by the careful administration of small and frequently repeated doses of aconite, when there are no contra-indications to the use of this drug. Restlessness, when considerable, is most effectually relieved by a hypodermatic administration of one-fourth of a grain of morphin; when it is slight, sodium bromid is effectual. Various means are at our command to lessen the flow of blood to the head; sometimes one or two, sometimes all should be employed. Brisk purgation should almost always be resorted to. If the stomach is not irritable, one drop of croton oil in ten drops of sweet oil should be placed on the tongue every hour until the bowels are opened freely. When the stomach is irritable ten grains of calomel should replace the croton oil. Whether calomel or croton oil is employed, an enema, consisting of one ounce of salts, a half-ounce glycerin, and four ounces of water, should be thrown up the large bowel as soon as possible after the occurrence of the hemorrhage. Mustard plasters applied to the back of the neck, the front of the chest, and on the calves of the legs, aid in lessening the quantity of blood carried to the head. Blood-letting is sometimes indicated, but cases necessitating the with-

drawal of blood by opening a vein are probably rare. In regard to the administration of ergot in the cases of cerebral hemorrhage under discussion, I do not believe that it does a particle of good, and there is a possibility of its doing harm. The practice of applying cold to the head, especially ice, in cases of non-traumatic, intra-cerebral hemorrhage, is, I believe, reprehensible. It seems rational to suppose that it may increase the engorgement of the intra-cerebral vessels. When the face is turgid, the head warm, and the carotids throbbing, ice-cloths or iced poultices may reduce the heat of the head and promote the coagulation of the effused blood.

It will be seen that the only routine treatment recommended for intra-cerebral hemorrhage is brisk purgation immediately after the occurrence of the accident, to which may be added the application of mustard plasters to various portions of the body. In the subsequent treatment, during the acute stage indications must be met as they arise. In the chronic stage electricity and strychnin must be used with judgment and great caution. The routine employment of these two agents to overcome the paralysis does much harm in causing irremovable contractures of the arm and leg of the affected side. In this stage strychnin should not be employed when contractures are present, or when the deep reflexes are greatly exaggerated. We must remember that no hard and fast rules can be laid down in regard to the use of strychnin. I have seen cases in the acute stage in which this drug, in combination with aromatic spirit of ammonia, has done good service. When electricity is applied, and, as a rule, it should not be before the end of the fourth or sixth week, the extensor muscles only should be stimulated, and during the application the extremities should be held in their normal positions. Massage, systematic exercise, Swedish movements, and time, do most to overcome the residual paralysis of intra-cerebral hemorrhage.

CHOREA.—I wish to limit my remarks to the so-called acute chorea of Sydenham, as distinguished from the chronic chorea of which much has been written of late, especially of the hereditary form, known as Huntingdon's chorea. It is useless, in an article of this kind, to take up time with the diagnosis of chorea, as but little difficulty is encountered in differentiating it from other forms of nervous troubles.

In two papers written a few years ago, in which I considered at some length the influence of the climate of Colorado in relation to mental and nervous diseases, I expressed the opinion that chorea is no more frequent, is no longer in duration, and is just as amenable to treatment in Colorado, especially at altitudes varying from five to six thousand feet above sea-level, as I had found it in Philadelphia. In a third paper, entitled "The Influences of Climate, especially the Climate of Colorado, on Chorea," I was forced to the same conclusion. After a more extended experience with the disease in Colorado, I still find no reason to change the opinion expressed in the papers just referred to. I see so many cases of chorea that have been under treatment from several weeks to three or six months, which on being placed on a certain course of treatment, yield in two, or, at most, in three weeks, that I believe it may be pardonable in me to give in detail the plan of treatment that I almost invarably follow in the management of chorea.

For a number of years I have refused to assume charge of a case of this disease if the parents and friends will not consent to follow my instructions. In the very mildest cases, in which there is only an occasional grimace of the face, or an infrequent twitch of the muscles of the hand or foot, I allow the patient to sit up part of the day, and spend the remainder of the waking hours on a lounge. No violent or exciting exercise, such as romping, running, etc., is allowed. The patient is placed on a nutritious, digestible, but non-stimulating diet. The stomach and bowels are kept in as good a condition as possible. The patient, to begin with, receives as many grains of antipyrin at bed-time as he is years old, and the dose is increased one grain each night until all twitching stops. At the beginning of the treatment of these mild cases I commence with one drop of Fowler's solution after each meal, and increase the dose one drop each day until the point of tolerance is reached; then the arsenic is discontinued for two or three days, or until all unpleasant effects of its administration have passed away, when the drug is again resumed at the dose reached when it was stopped. The dose is again increased one drop each day until tolerance is reached, when it is discontinued, and resumed after two or three days as before. As soon as the twitching ceases, the antipyrin at bed-time is discontinued, and the patient is given syrup of the iodid of iron after each meal, in from three to ten-drop doses, depending upon the age of the patient. The arsenic and iron are continued for two or three weeks after all symptoms of the disease have disappeared and the patient has regained considerable flesh.

In all except the mildest cases, to which reference has just been made, absolute rest in bed, day and night, is insisted upon from the first. If I had to rely upon one method of treatment in the management of chorea, to the exclusion of all others, I should unhesitatingly choose absolute rest in bed. When the little patient is placed in bed to begin its treatment (we will suppose it to be a child of a few years, or not more than fifteen years of age), I am in the habit of ordering as many grains of antipyrin,

three times daily, after taking food, as the child is years old, and increase the dose one grain each day until all violent movements stop, when I begin with one drop of Fowler's solution after each meal, well diluted in water, and increase the dose one drop each day, in the manner described. About the second or third day after the arsenical treatment has been added, the antipyrin is given only once each twenty-four hours, and the time for its administration is usually about 8 or 9 o'clock in the evening, thus securing a comfortable night for the little patient. After all but the most occasional twitching has stopped, the antipyrin is discontinued, and syrup of the iodid of iron is given in connection with arsenic. It seems a little heroic to give a child of seven years of age from ten to fifteen grains of antipyrin three times daily, yet I have given a child of eight years twenty grains of antipyrin three times daily, without the slightest apparent depression or untoward effect. Certain precautions, however, are necessary. In the first place, if there is any rise of temperature, perspiration will be free, and depression will result. I have learned to avoid antipyrin in cases in which there is much rise of temperature. In such, chloral hydrate takes the place of antipyrin. I have never carried the dose of the former to nearly that of the latter. When there is cardiac weakness, antipyrin and chloral should be given with great care, if at all. When such a complication exists, phenacetin, with a little cannabis indica, seems to quiet the patient. Valvular disease of the heart alone does not seem to contra-indicate the employment of antipyrin, but cardiac dilatation does.

Whilst antipyrin is being given the patient must be kept at rest in bed. I have seen considerable depression follow a large dose of antipyrin when the little patient has been allowed to run around. During the administration of large doses of antipyrin or chloral the patient should be seen at least daily, and the urine should be repeatedly examined.

The questions in regard to arsenic in chorea: How large doses may be given? How long should the drug be continued? Should it be kept at the point of tolerance for weeks without intermission, and what unpleasant effects are likely to follow its administration in large doses? are pertinent.

How large doses of Fowler's solution may be given? As a rule, children from seven to fifteen years of age will bear larger doses of arsenic than adults. So far I have never found it necessary to give very large doses to children under six years. In a number of instances I have given twenty drops of Fowler's solution three times daily to children from ten to fifteen years old, for a week or more at a time. In the majority of instances the point of tolerance is first reached when the dose has been gradually increased to some six or seven drops thrice daily. After stopping the arsenic for two or three days, or until all unpleasant effects have passed away, and resuming its administration at six or seven drop doses, as the case may be, the next point of tolerance will be attained when the dose has reached ten or twelve drops thrice daily. In most instances all twitching will have stopped at this time. If such be the case, the medicine is resumed after two or three days, at this dose, but now it should not be increased. It should be given at the dose tolerated when the twitching has stopped, for a week or ten days, then discontinued for two or three days, and resumed again at the full dose; the dose is now lessened one drop each day until four-drop or five-drop doses are reached; stopped again for two or three days, and again resumed at five-drop doses. Arsenic, as a rule, should not be continuously given in full doses for more than eight or ten days at a time. By observing this precaution I have been fortunate enough to avoid the ill-effects that some physicians have reported from the continuous use of full doses of arsenic.

How long should the administration of arsenic be continued after all twitching has stopped? As a rule, it should be continued for a month or more after all choreic symptoms have ceased, but not in full doses of toleration for more than a week or ten days, when it should be stopped for a few days; then the dose should be gradually reduced, as recommended.

The next question: Should the large tolerated doses be continued for weeks without intermission? has already been answered in the negative.

What unpleasant effects are likely to follow the administration of large doses of arsenic, even when the point of tolerance has been established by gradually increasing the dose from day to day? Seguin states that he has never seen any serious effects follow therapeutic doses of arsenic, although he gives some children as many as twenty-five drops of Fowler's solution thrice daily. Whether he takes the precaution not to use the drug continuously for more than a week or ten days at a time I do not know. So far, I have not seen any cases of neuritis following therapeutic doses of arsenic. Dr. Shattuck, of Boston, reports two cases of multiple neuritis following large doses of arsenic given for the relief of chorea. Dr. McGarvey, of San Luis, Colorado, informed me by letter a few days ago that he recently had two children paralyzed in the legs after taking large doses of arsenic for chorea. These were evidently cases of multiple neuritis. Neither Shattuck nor McGarvey states how long his patients had been taking arsenic without an intermission in the administration of the drug. Several other physicians have reported cases of

neuritis following the administration of arsenic for the relief of chorea.

In conclusion I will give brief reports of a few cases of chorea treated by antipyrin and arsenic in large doses.

CASE I.—Rose K., fourteen years old, of Austria, has been troubled with violent choreic movements (bilateral) for six months. She has been under treatment a portion of the time. The jerking of the limbs is so violent that it is difficult to keep her in bed. She is placed on fourteen grains of antipyrin three times daily, increased one grain each day. In four days, or by the time that eighteen grains of antipyrin are being given thrice daily, all violent muscular twitching is stopped. She is now given one drop of Fowler's solution thrice daily, and the dose is increased one drop each day, and the antipyrin is reduced to one dose of eighteen grains daily. In the meantime absolute rest in bed is insisted upon. At the end of the second week the choreic movements have nearly ceased, and by the end of the fourth week she is discharged, cured.

CASE II.—Helma B., thirteen years of age, has been suffering with violent choreic movements of the left side for three months. During this time she has been under treatment, but has been allowed to be up and walk around all day long. When she entered the hospital the twitching was violent. She is placed upon large and increasing doses of antipyrin and kept at rest in bed. In a week's time all violent movements have ceased. At the end of eighteen days she is now practically cured, under the antipyrin and arsenic treatment.

CASE III.—Charles R., fourteen years old, was admitted into the nervous ward of the County Hospital about two weeks ago. There was violent jerking of the muscles of all the limbs, and of the face. He had to be strapped in bed, as the irregular muscular action made it impossible for him, unassisted, to remain in bed. He states that he had been in this condition for six months. Articulation and deglutition are difficult. He is placed upon the same treatment given Cases I and II, with equally good results.

PRACTICAL REMOVAL OF HAIRS, MOLES, ETC., BY ELECTROLYSIS.

BY S. SORENSON, M.D.,
OF RACINE, WIS.

THE theory of the removal of superfluous hair by means of the galvanic current is comparatively simple; it is to insert the needle attached to the negative pole of the battery into the hair-follicle, apply the current, and dissolve the tissues, when the thing will be done. However easy this may seem, when the physician tries to make a success of it in his everyday practice he finds it by no means so simple.

I shall try to give my views of how to make electrolysis a practical success, and will not speak so much from theoretic grounds as from practical, almost daily, experience during a period of over two years.

I have used a McIntosh cabinet, and also a portable battery of the same manufacture. For some months past I have been using a ten-cell Flemming battery, and have found this very satisfactory. The dry chlorid of silver battery would no doubt prove very serviceable as a portable battery, but it has the disadvantage of being difficult to repair, so that should it get out of order when one is not near a place where it could easily be repaired, the inconvenience might be very serious.

I have used steel and platinum needles, and prefer the latter. For some reason the platinum does not seem to irritate the tissues so much as the steel; being also more pliable, it enables the operator to curve it as he wishes, and thereby more easily insert it into individual hair-follicles, which often curve so that they would be difficult to follow with a straight needle, this curving of the hairs being especially marked in certain parts of the face.

The holder I use at present is also manufactured by Flemming, and consists of an end-piece, cone-shaped, with a longitudinal slit to hold the needle; this part is turned into the end of the holder, which covers the slit and holds the needle. I consider this holder far superior to that class in which the needle is held by a set-screw, this screw obscuring the vision when the operator attempts to insert the needle. Some holders are made with an interrupter in the shape of a button which must be pressed by the finger of the operator when the current is to be stopped. This does not seem to me to be a good arrangement, for the time when the current is to be discontinued is the time during which the needle is being inserted into the follicle; when that is to be done the operator must have as much freedom of movement as possible, as no considerable force should be used, but the needle should insinuate itself along the opening until the bottom of the follicle is reached, which will at once be noticed by the experienced operator. If force be applied in inserting the needle, this will probably be driven in too far, or passed through the side of the follicle, with a poor result in either case.

Having, then, a battery of the proper kind, cords, a finger-bowl for water, needle and holder, a pair of small tweezers, and a comfortable arm-chair with some appliance upon which the operator can rest his elbow, one has the essentials for the work. The chair should be placed where a good light will fall on the patient's face, a towel placed in the patient's lap, and upon it a finger-bowl about two-thirds full of water, in which is a sponge-electrode connected with the positive pole of the battery. The cord

attached to the negative pole is fastened to the needle-holder.

Let us suppose that the patient has not been under treatment before, and wishes hairs of medium size removed from the chin. The operator will turn on two cells, seat himself with his back to the light, and sufficiently close to the patient so that he will not have to exert himself in reaching; he will then insert the needle to the bottom of the follicle, then tell the patient to dip one finger into the bowl and keep it there until asked to remove it. In inserting the needle the holder should be held with the same gentle firmness that a pen is held, the third and fourth fingers resting lightly on the skin near the hair to be removed, so as to gently steady the hand. The operator will also find it a great help if he will rest his elbow on the arm of the chair, or some other support.

The first indication of results is a white froth, which makes its appearance at the mouth of the follicle, around the needle. Depending on the strength of the hair and the force of the current, the operator will judge whether the hair is loose. When he wishes to attempt its removal with the tweezers he will ask the patient to remove her finger from the water, and will then seize the hair with the tweezers and make gentle traction; if the hair makes any appreciable resistance the needle must be reinserted and the current again applied. When the hair is entirely loosened by the current a good result may be looked for. Should the hair offer resistance, the physician may insert the needle into the follicle after its removal and continue the current, but, as a rule, I have found it more difficult to insert the needle after the removal of the hair than when it is in situ.

After one has had experience he calculates almost unconsciously the length of time the current is required. When this faculty is acquired, cognizance is also taken of the strength of current and the particular person upon whom one is operating. I have also found that the patient can leave her fingers in the water constantly, and need not remove them unless I experience difficulty in finding the opening of the follicle. These things must all be taken advantage of, for in the long run, if properly utilized, they save much time, and thus shorten an operation which must always prove trying to both operator and patient.

No hard and fast rules can be laid down for doing this work, and each individual operator will be called upon to exercise his judgment in the case of each one upon whom he operates, and much of the time upon the individual hairs.

After what has been said in a general way of the operation, I will attempt to notice some of the features that should be avoided or should receive special attention. In the first place, the part operated upon should be surgically clean. Next the needle should not be inserted more deeply than the bottom of the follicle. Experience will indicate when the needle is at that point by a slight sense of resistance. Should the needle be inserted too far, considerable tissue may be destroyed, and still the hair will not be loose. Another thing to avoid is passing the needle through the side of the follicle, something which experience also teaches one to recognize by the touch. If this be done and the current applied, a white spot will begin to spread around the needle; the result with regard to the hair will be the same as in the former case, and in both a vesicle may form, with some exudation of serum, and with the danger of subsequent pustulation, and formation of a pitted scar.

Another danger is that of operating during a given time on hairs too close to each other. Here again the operator must fall back on his judgment, and take into consideration the size of the hair and the amount of electricity it takes to destroy it; also the regenerating power of the patient's tissues, which will be learned by observation. This rule may be laid down, that, until the operator becomes acquainted with his case, he must be sure not to take the hairs out when they are too close together. This is a matter of a great deal of importance, for frequently patients whose time and money are limited will urge the doctor to take out hairs that are too close together to be operated upon with good results in one day, or even on two successive days.

Again, the temporary inflammation which always sets in does not fully show itself until after several hours, so that a patient may leave the office with a face that shows comparatively little trace of the operation, but will return next morning with that part of her face in a very sorry-looking condition. I repeat that the importance of what I have just said cannot be overestimated, for upon proper attention to this matter may depend the success or failure of the operation, at least so far as the question whether or not the patient will have a smooth face after the hairs have been removed is concerned.

How long shall a patient sit at one time? This will depend upon how sensitive she is to the current. To illustrate: I have encountered only two cases in which patients complained of being unable to undergo the operation. One of these had been in the chair for several hours, and was obliged to discontinue treatment for that day. The other complained at the beginning, but was able to endure having all her superfluous hair and a couple of moles removed at the one sitting. As regards the duration of the operation, the amount of time at the disposal of the patient, and the extent of surface covered by the growth, are factors.

As a rule, all things being convenient, the best plan would be for her to take treatment for an hour and a half at a time, two or three times a week. When necessary, however, patients will sit for hours at a time without complaint. I have operated as long as seven consecutive hours in one case, but three hours is about as long as any patient cares to sit continuously, and this length of time will also try the operator.

The number of hairs that can be removed in an hour must necessarily vary, depending on much the same conditions that have been mentioned; but I believe a fair estimate will be thirty per hour, all classes of patients considered.

Patients are of all kinds, from the girl of sixteen or seventeen, who has noticed a few hairs on her face —usually on the upper lip at the corners of the mouth—which she knows or imagines that people notice, and which she supposes give her a masculine appearance. Next comes the older woman, who, to a practised eye, bears the unmistakable evidence of having a tendency to a hairy growth on the face; this she is making desperate efforts to conceal from the public by the use of tweezers or depilatories. Then there is the older woman still, who has passed fifty, and even sixty years of age, who, perhaps, even used the razor. Young or old, life is made unhappy by the disfigurement, and in some cases it means a life of misery if it is not permanently removed. A number of men also want hair removed for various reasons, but they are few compared with the women, and, in my opinion, the physician need waste no sympathy on them. That the disfigurement is very prevalent one can easily convince himself by taking special notice of the faces seen on any fashionable thoroughfare, and such cases deserve the consideration of the intelligent physician.

Can these hairs be destroyed by means of the electric needle, and leave no mark on the face? To the first part of the question I believe my experience will entitle me to answer in all cases, yes. To the second part, no. I believe that every time a hair is destroyed a scar is left, for by this process some of the tissue surrounding the hair is destroyed, and, as a consequence, we have cicatricial tissue formed. But I will say again that by proper care on the part of the operator, the marks left will in the majority of cases be so small that no one who does not know what he is looking for will be able to detect them; so that practically the hairs can be removed without leaving scars. In cases in which the hair is coarse and thick there is, of course, greater liability to scarring, and it seems to me that a great deal also depends on the healing powers of the tissues of different individuals. A certain, or rather uncertain, number of hairs will return, though in what proportion I am unable to say. The smallness of the number of returns, I am led to believe, will be in direct ratio to the skill of the operator. The trying cases often take such a long time to finish—for reasons that will be plain to those who have read this—that it is difficult to follow them up. I have in mind four cases, three of which were very severe, the fourth one the worst I ever operated upon. Two of these are entirely cured, several months having elapsed since the last operation, with no return of the trouble. The third case, a very severe one, is also practically rid of the trouble, while the fourth is still under treatment, with every indication that her face will soon be in good condition. Perhaps the best criterion as to whether or not the work is a success is the fact that these cases persist in the treatment for months and years. The last case I mentioned has been under treatment, off and on, for nearly two years. Some idea of the amount of work a severe case requires may be gained from the fact that since the 25th of April, 1892 (now February 1, 1893), I have spent *eighty-six* hours operating on the face of the last-mentioned patient.

Another use to which I have put electricity in the form of the galvanic current is the removal of moles and enlarged cutaneous bloodvessels, such as are frequently seen on and around the alæ of the nose and also on the body of that organ. For convenience, I divide moles into two classes, not that the appliances for removing them are different, but that the *modus operandi* differs somewhat in each. The apparatus for removing moles is the same as that used for the removal of hair, with the exception of the tweezers.

The first class is the very common disfigurement called liver-spots, which are really pigmentary moles, or perhaps, exaggerated freckles. They are little, if at all, elevated above the surrounding surface. The method of procedure in the case of these is as follows: The patient and operator take the same positions as in the removal of superfluous hairs, the parts to be operated upon having been thoroughly cleansed The operator now inserts the needle at the edge of the mole, just beneath the epidermis, applies the current, which should be weak, and gradually passes the needle through the growth. As the electrolysis goes on it will be observed that a loosening of the pigment takes place, and it mixes with the froth around the needle. The needle must now be worked over the entire area of the mole, taking care to go no more than deeply enough to loosen the pigment. After a few seconds the burning sensation that accompanies the insertion of the needle ceases, in consequence of the local anesthetic effect following the application for a limited time of a comparatively weak current. The whole operation can be completed with only one puncture of the epidermis,

although in small moles that is a matter of little consequence. The pigment and dissolved tissue are now left to dry into a crust, which comes off in a few days, leaving a bluish-red spot, as always happens when a bit of the epidermis has been scraped off, and which later becomes the color of the surrounding skin.

The next class of moles includes those that are elevated above the surrounding surface, and which frequently contain a number of hairs. As a rule, the first thing to do is to remove the hairs, which, if few, can be done at the same sitting the mole is operated upon, and in the manner described in the first part of this paper. It is very essential that the surgeon, when operating on moles raised above the surface, should constantly bear in mind the object which he sets out to accomplish, namely, to bring the elevated spot down to a level with the surrounding surface. Great care must be exercised not to bring it below, for in that event a mischief is done which no method I know of can cure. The larger the mole the greater the liability to pitting if due precautions be omitted. In this class of moles the needle is inserted at the base of the growth and gradually passed through it, and may be passed out at the opposite side. This is repeated until the whole base has thus been treated, the object being to cut off the circulation by electrolyzing the blood-vessels at the base of the growth.

The first sign produced in the mole will be a gradual whitening of that part external to the needle, which finally reaches an appearance of complete anemia. The electrolysis must continue until the circulation is entirely cut off. Inside of twenty-four hours the whiteness will have disappeared and be replaced by a black color. There soon follows a dried, hard crust, the time depending upon the size of the mole, which falls off in a few days, leaving a discoloration that gradually disappears.

As a rule, it is not advisable to attempt to remove a mole at one sitting, unless it be quite small, for fear of leaving a scar. If moles be large there may be some oozing of serum during the operation, but that is a matter of little consequence, and a little dusting powder may be applied after the operation.

When it is decided that a mole is to be removed, the operator, before he begins, must fix in his mind how deeply he should penetrate, for there is likely to be some swelling around the margin, and he will have only his memory to rely upon to guide him. For that reason it is advisable not to attempt to remove the whole of the mole at one sitting, but to destroy a given amount. Then, after the crust has come away, the edges, or any part, may be trimmed down very easily, without any danger of going too far in, as might be the case did one try to remove a comparatively large growth at a single sitting.

Occasionally small pedunculated moles are found on the eyelids, which may be removed as the others are, and, if the operation be properly done, without any inconvenience to the patient.

I have occasionally been called upon to destroy enlarged bloodvessels in and around the region of the nose. To do this the needle is inserted into the vessels at their largest part, and the current turned on. Almost immediately a white substance will be seen to make its way along the vessels, distinctly outlining them. The vessel-walls must be destroyed throughout the whole extent, the needle being inserted at intervals along their course. The operator should experience little difficulty in doing this, as he can see his work. The greatest trouble he will have will be the extreme sensitiveness of the part, which frequently manifests itself in an uncontrollable desire to sneeze, though frequently the pain is severe in operating in the region of the nose, as also in removing hairs from the upper lip.

I applied cocain in one case when operating on the mucous membrane of the anterior nares, but it did not seem to deaden the sensation. I think, however, that cocain ought to be successful in these cases, and intend to try it again when the occasion arises.

In operating upon enlarged cutaneous vessels, it follows, as a matter of course, that the operation must be thorough; in other words, the current must be applied until the vessel-wall is destroyed.

I have also used electrolysis in two severe cases of ingrowing eyelashes — trichiasis-distichiasis — both upper lids being involved in one case, and one lid in the other. I cannot report on the ultimate effect of the operation, for I lost sight of both cases before sufficient time had elapsed to show definite results. I can say that the removal of the hairs may be accomplished more quickly than one would at first think. In one of these cases I removed all of the hairs from one lid at one sitting, with the result that when the patient returned a week later to have the hair removed from the upper lid of the other eye, he declared the eye that had received the first attention felt better, and he could see better with it than he had been able to do for a long time.

I used cocain, operated on the worse eye first, which, in consequence of the irritating hairs, was nearly blind. The patient was seventy years of age, and far from strong. I did not see him again after removing the hairs from the other eye.

In closing I will recapitulate as to certain things which must always be borne in mind in performing any of the operations I have mentioned:

1. Do not begin with too strong a current.

2. Apply the current for a sufficient length of time.

3. Always apply the negative pole to the part it is desired to destroy.

4. Do not have the circuit closed when you insert the needle until you have learned to know your patient *electrically*, if such use of the word may be permissible.

5. Always test the strength of your current before beginning. To do this I have found a convenient way is to touch the two poles to my tongue, having the points about an inch apart.

THE SURGICAL TREATMENT OF CHRONIC TYMPANIC VERTIGO, OFTEN MISCALLED MÉNIÈRE'S DISEASE.[1]

BY CHARLES H. BURNETT, M.D.,
AURAL SURGEON PRESBYTERIAN HOSPITAL, ETC., PHILADELPHIA.

CHRONIC tympanic vertigo, the most frequent form of aural vertigo, is one of the results of chronic catarrhal otitis media. It is always found in connection with tinnitus aurium and deafness, still commoner results of chronic aural catarrh. Unfortunately, chronic tympanic vertigo usually receives the very unjust and inaccurate designation of Mênière's disease.

The latter term, if it means anything—and it has but a very slender title to the wide acceptance it has met with in medical nomenclature—means a form of aural vertigo due to disease of the semi-circular canals. Disease of these canals, however, is very rare, and difficult to diagnosticate.

The name "Ménière's disease" is *inaccurate*, because it is indiscriminately applied to all forms of aural vertigo, regardless of the seat of the otic lesion, whereas Ménière attempted to prove the existenee of a disease of the semi-circular canals as the only cause of aural vertigo, an entirely untenable hypothesis. The name is *unjust*, because Flourens in 1822, and Deleau in 1836, described aural vertigo more acccurately than Ménière in 1861,[2] and Deleau came much nearer than any previous observer to the solution of the cause of most cases of aural vertigo in placing the origin *in lesions of the middle ear.*

Tympanic vertigo, due to lesions in the middle ear, is of frequent occurrence. It is often not recognized, especially by the general practitioner, as aural vertigo. It is not unusual for tympanic vertigo to be attributed to intestinal disturbance, or to "neurasthenia," instead of to an aural lesion. Hence, the diagnosis being erroneous at the outset, the treatment is wrong, and the patients do not recover.

True tympanic vertigo, due to a lesion in the middle ear, chiefly from chronic catarrh of the tympanic cavity, is paroxysmal in character, and attended with tinnitus and deafness in the affected ear. It is caused by the inward pressure exerted upon the labyrinthine fluid by the retracted and ankylosed ossicles. The foot-plate of the stapes is thus unduly pressed into the oval window, and there held by the force named, paroxysmally and for longer or shorter periods.

I have long maintained the tympanic or mechanical origin of most cases of aural vertigo, in opposition to the asserted neuropathic, or labyrinthine cause.[1]

In chronic catarrh of the middle ear there must always be, sooner or later, a disturbed tension in the conductors of sound, whereby at times the membrana tympani and the three auditory bonelets are carried unduly inward, and exert a morbid pressure by means of the impacted stapes upon the fluid in the labyrinth. This irritation in the labyrinth being communicated to the motor filaments of the auditory nerve is reflected by them to the cerebellum, and disturbed equilibration is the result.

This morbid retraction of the auditory chain, and resultant cerebellar irritation, are not constant, but vary with the state of the general health and the condition of the catarrhal middle ear. Hence all true aural vertigo of tympano-mechanical origin is paroxysmal in form.

If the theory is correct that the vertigo in chronic catarrh of the middle ear is due to the retraction of the conductors of sound and mechanical pressure upon the labyrinthine fluid, then the surgical removal of such retraction and pressure ought to relieve tympanic vertigo.

No opportunity to test the truth of this theory offered itself until May, 1888. Then, being consulted by a former patient with chronic catarrh of the middle ear, for the relief of constant tinnitus, and oft-recurring attacks of *severe tympanic vertigo*, which had been superadded to her deafness in the left ear within the previous two years, and finding that the malleus had become adherent to the promontory, I resolved to do what, so far as I know, had never been done for the relief of aural vertigo of a mechanical or tympanic origin, viz.: to cut out the membrana tympani and the malleus, in order to liberate the impacted stapes.

This case and the entire success attending the operation have been fully detailed in other places.[2] I would like to state here that the entire relief from tinnitus and vertigo, which followed immediately upon the operation five years ago, has continued to

---

the present time. All the operations referred to in this paper were performed upon the etherized patient, the ear being illuminated by a six-volt electric lamp, held on the operator's forehead.

The operation of excision of the membrana tympani with the malleus was applied in four succeeding cases of chronic tympanic vertigo with entire relief in all of them.[1] However, as in all of the cases more or less inflammatory reaction followed this operation, I concluded that removal of the incus alone, or of the incus and stapes, the membrana tympani and the malleus being permitted to remain in position, would liberate the stapes and the compressed labyrinthine fluid, as well as, or perhaps better than, total excision of the membrana and the malleus, and probably would not be followed by inflammatory reaction. And the notes of the following cases will show that I was correct in my assumption.

The first case to which I would call attention was described in detail as Case V, in THE MEDICAL NEWS, of March 13, 1893, not as one in which tympanic vertigo was at all prominent, or in which the operation was performed chiefly for the relief of that symptom. The prominent symptoms were dulness of hearing and annoying tinnitus, and to relieve these the operation of removal of the incus and stapes was undertaken. But as there had been some slight vertiginous attacks, and as the operation was successful in relieving the deafness and tinnitus, and preventing the recurrence of further attacks of even slight tympanic vertigo, it may be regarded in this instance as at least a prophylactic of pronounced tympanic vertigo.

The next case was described as Case VI, in THE MEDICAL NEWS of March 13, 1893.

This is the only case in the series in which the stapes was removed entirely. The result was so good —in fact, so much better than in some in which the stapes was only liberated or only its crura were removed, that I am inclined to think that in any case of tympanic vertigo in which liberation or partial removal of the stapes does not give as much relief as is desired, *puncture of the foot-plate* of the stapes, in order to relieve the labyrinthine tension, would be justifiable.

CASE VIII. *Removal of the left incus for aggravated chronic tympanic vertigo.*—Mrs. T. R. G., aged fifty-five, the wife of a physician, has had chronic catarrhal otitis media since childhood. The tinnitus has increased of late years, and she has been treated for years, by a prominent physician, for neurasthenia. Within a year or two marked tympanic vertigo has set in, and increased to *weekly* attacks, quite laying her up in bed when a paroxysm occurred. These attacks usually have come on in the house, sometimes in bed, but once lately the patient was attacked while out driving. The attacks of vertigo were attended with increased tinnitus, nausea, and vomiting, without loss of consciousness, the face and forehead being bathed with cold sweat. There has never been any rational aural treatment in this case. The patient has been treated with purgatives and alteratives for "neurasthenia," and has grown steadily worse.

Examination of the left ear revealed a retracted membrana tympani, with signs of sclerosis of the drum-cavity. The incus and stapes were visible through the membrana. No catarrh of the nares or naso-pharynx. Tuning-fork heard *per ossa* in the affected ear. Loud words could be heard near the ear. The right ear is good, but said to be failing lately.

As the attacks of tympanic vertigo had now become so well marked, and so distressing, her husband had determined to seek relief for her by means of the removal of the force impacting the stapes in the oval window. Therefore, on June 7, 1893, the patient was etherized, and after excision of the posterior, superior quadrant of the membrana, the incus, though held tightly in place by synechiæ, was quickly removed. The stapes was found firmly and immovably fixed in the oval window, and could not be removed, its head being broken off in the endeavor.

There was no reaction in this case, and the patient went home, a hundred and fifty miles away, on the third day.

On June 25, three weeks after the operation, her husband wrote that "she has been getting on so well that we have some how failed to report to you of her general improvement. The first week after the operation she had several very *slight attacks* of vertigo, but they passed off very soon, and of late she has had no trouble whatever." She has been able to go about the house attending to her duties, without the fear even of the hindrance previously experienced from the attacks of tympanic vertigo. The tinnitus became much less, and the hearing improved a little. But the great end had been attained, viz: the relief from the sickening and incapacitating tympanic vertigo.

On August 8, 1893, her husband wrote that there had been some attacks of slight vertigo since his last letter, but nothing severe. Before the operation the patient had been bed-ridden by the severity and duration of the vertigo. September 10th. The patient remains free from vertigo.

CASE IX. *Removal of the incus only.*—Sister ——, a nun, twenty-five years old, has for several years suffered from tinnitus, deafness, and tympanic vertigo, due to sclerotic otitis media of the left ear, following a chronic purulent otitis media, which latter ceased years ago. There was a perforation of the posterior inferior quadrant, with calcareous patches in the upper posterior and upper anterior quadrants of the membrana. The tuning fork was heard well *per ossa*, and isolated words were heard *close* to the ear.

June 28, 1893, the patient was etherized, and the perforation enlarged and extended into the upper posterior quadrant, exposing the incus lying high up in the attic. The incus was then removed.

[1] International Clinics, January, 1892.

The next day the hearing for isolated words in ordinary tone was two feet, and for whispered words from eight to ten inches. The patient was not seen again until July 20, 1893, when she reported that there was no more tinnitus or "swimming in the head." There had been no return of these symptoms by September 1, 1893. The result in this ear has been so good that a similar operation is contemplated for the relief of dulness of hearing and tinnitus in the other, the better ear.

Case X. *Resection of the long processes of both incudes for the relief of deafness, tinnitus, and severe chronic tympanic vertigo.*—Mr. Charles C. T., aged thirty-one, of Baltimore, Md., has been affected with chronic catarrhal otitis media in the right ear for eight years, and in the left ear for four years. Within a year the tinnitus has become severe in both ears, and the hearing has failed in both, the left ear being a little better for hearing, however, than the right ear. In addition to these symptoms there had been superadded the tendency to attacks of tympanic vertigo, with temporary increase of tinnitus aurium in both ears at the time of the vertiginous paroxysms. So severe have the latter been as to require the patient to hold on to the nearest objects in the street to prevent him from falling. He has never vomited, however, in any of these attacks, but their severity and frequency have dispirited him, and prevented him from attending to his duties. For many months past the patient has been treated for an *asserted* catarrh of the nares, naso-pharynx, and throat, but the deafness, tinnitus, and vertigo have grown worse rather than better. Examination, June 18, 1893, revealed the membranæ tympanorum slightly retracted, the incudes and stapes visible through the membranes. The nares, naso-pharynx, and fauces were not affected.

July 21, 1893, the patient was etherized, and I endeavored to remove first the right, and then the left incus, after their exposure by exsection of the posterior, superior quadrants of the membranæ.

The right incus seemed firmly held in the attic, and when traction was made on the long process it quickly broke off. No further attempt to remove the body of the incus was made, as the object sought, viz.: severance of the retractive power of the incus from the stapes, had been attained. I met with the same experience on the left side.

The next day there was a slight reaction in both ears, the tinnitus was no better, and the hearing was perhaps a little duller in the *left*, the better ear. There was no vertigo.

The patient returned to his home now, and reported to me in the course of four days that he had had no vertigo, but he felt worse in his ears, and that he had had some fugitive pains in them, with a little bleeding from one.

August 11th. The patient reported "a slight improvement in hearing in the left ear, but none in the right." The tinnitus still continued, but there had been "an entire absence of vertigo." The left ear had pained him "quite a good deal, and felt uncomfortable for the past day or two."

August 13th. The patient's sister, a physician, reported to me that there had been an "evident improvement in his hearing in the last ten days." Also a great improvement in his spirits.

September 3, 1893. The patient wrote that "the hearing in my left ear is much improved. I can hear conversation in ordinary tones about four feet, and if loud about ten feet. If the windows are open I can hear calls on the street. There is scarcely any roaring in the left ear, but in the right (the deafer ear), though diminished, there is quite a good deal. The hearing in the right ear seems to be about the same as before the operation." There has been no return of the attacks of tympanic vertigo. The perforations in the membranæ tympanorum persist.

It is noteworthy that in this case relief followed the severance of the retractive force by resection of only the long processes of the incudes; also, that most improvement in hearing and relief from the annoying tinnitus ensued in the better ear. This is due to the fact that greater mobility of the stapes has persisted in this ear than in the worse ear, and hence liberation of the freer stapes and the passive motion exercised upon it by sound-waves, have greatly improved the function of hearing in this ear. The result in this respect should encourage the surgeon to operate on both ears, or upon the better rather than upon the worse ear alone, when both are so profoundly affected as in this case. Most important is it to observe the *progressive improvement* in this case, as in some of the others. This must be due to the passive motion exerted upon the ankylosed stapes by sound-waves, which fall upon it more freely than before the operation.

From all the ten cases we may conclude:

1. That removal of the retractive force of the sound-conductors upon the stapes is the efficient means of relieving the tinnitus, deafness, and vertigo, due to the lesions of chronic catarrh of the middle ear.

2. That the removal of the retractive force upon the stapes can be accomplished efficiently and simply by removal of the incus alone, and even by resection of its long process.

3. That the improvement in these cases is due to the liberation of the stapes from the retractive power of the tensor tympani muscle, and the consequent unimpeded action of the stapedius muscle, which, relieved of the antagonism of the tensor tympani, tends all the more to draw the stapes from the oval window, thus aiding in the isolation and improved mobility of the bonelet, as well as in removing its undue pressure inward upon the labyrinthine fluid.

4. It would seem wiser, therefore, in most cases of chronic catarrhal deafness, tinnitus, and vertigo, not to sever the stapedius tendon and remove the stapes, but to be content with removal of the incus only.

5. The progressive improvement in hearing noted

in many instances, especially in Case X, must be due to the passive motion exerted upon the ankylosed stapes by sound-waves, which are enabled to reach this bonelet more freely after the removal of the incus.

PARESTHESIA OF THE PHARYNX AND LARYNX AS A PREMONITORY SYMPTOM OF TUBERCULOSIS OF THE LUNGS.[1]

BY JULIUS WOLFENSTEIN, M.D.,
OF CLEVELAND, OHIO.

PARESTHESIA of the pharynx and larynx is an affection often encountered by the laryngologist, and the etiology which suggests itself to his mind is, primarily, hysteria and hypochondria, and secondarily the results of injury to the mucous membrane from the swallowing of some hard substance. That these are etiologic factors in a large percentage of the cases of paresthesia of the pharynx and larynx is established beyond doubt; in fact, most of the modern text-books mention no other cause.

To cite but a few instances: Bosworth, in his late work on the *Diseases of the Nose and Throat*, has a very unsatisfactory, brief article on this affection, and he believes that most cases of paresthesia can be traced to some local pathologic condition. This same view is also most strongly upheld by Lennox Browne in his well-known text-book.

It is true, Bosworth does mention that the affection occurs in anemia and pulmonary tuberculosis, and in individuals of nervous temperament, but in such a cursory manner that the reader perceives that he lays very little stress on the subject.

As another example, take Schrötter's *Vorlesungen über die Krankheiten des Kehlkopfes*, etc., published within a year. This author states that most cases of paresthesia of the larynx are due to injuries produced by swallowing some hard substance; hypochondria and hysteria come next, and anemia is casually mentioned among the causes. Without quoting any more authorities, except to say that Mackenzie, with his wide experience, merely mentions a nervous and traumatic etiology, which would simply be a reiteration of what has been said before, allow me to call attention to but one more text-book on this subject. Gottstein, in his *Krankheiten des Kehlkopfes*, which by the way is certainly the most excellent treatise on this subject extant to-day in any language, calls attention to the fact that paresthesia of the larynx is one of the frequent symptoms of the early stages of tuberculosis of the lungs.

The first one to call attention to this fact was, I believe, Jurasz in his monograph on the subject of "Sensory Neuroses of the Pharynx and Larynx." This was published as early as 1881, but it seems that the subject has not received the attention which its importance demands.

In his monograph, Jurasz remarks that these cases of paresthesia are "relatively not rare complications of beginning tuberculosis of the lungs." As mentioned before, Gottstein's observations coincide with those of Jurasz, and as far as my personal experience goes, which I admit is not very extensive, I have seen at least half a dozen cases of paresthesia of the pharynx and larynx in the past three years, whose causation could be traced to no other source than probable beginning tuberculosis of the lungs. The history of several of the cases afterward positively proved the correctness of my supposition.

As regards the symptomatology of this affection I can be brief. Paresthesia of the pharynx and larynx manifests the same indefinite and varied subjective sensations that characterize this peculiar symptom as an accompaniment of so many nervous affections, such as tabes dorsalis, cerebro-spinal sclerosis, etc. The patients complain of pain, which they now locate in the region of the larynx, now in the tonsil, now in the tongue, now on one side and now on the other. The abnormal sensation is never constantly present in a definite locality. Again some patients complain of the most peculiar and unheard-of sensations of tickling, scratching, burning, pricking, numbness, dryness, etc. Schrötter mentions the case of a patient who said he had a sensation as though "a mouse had run through his throat." As is so universally the case in sensory neuroses of the body in general, the perverse sensations complained of are peculiar and preposterous in direct proportion to the morbid imagination of the patients. The only definite thing in the history of this class of cases is the indefinite character of the symptoms; that is, the uncertainty on the part of the patient of localizing and describing the perverse sensations and the oftentimes changing character of these sensations.

Besides these sensory neurotic symptoms, there are also present at times paroxyms of cough, in the vain attempts to remove the irritation felt by the patients. There are also present at times motor neurotic symptoms, like contractions of the laryngeal and pharyngeal muscles, which are very disagreeable to the patients.

Coming to the most important part of my paper, the differential diagnosis of the various kinds of paresthesia of the pharynx and larynx from the etiologic standpoint, I shall try to be brief and give you succinctly the most important symptoms that characterize this affection as an accompanying,

[1] Read in part before the Ohio State Medical Society, Put-in-Bay, Ohio, June 29, 1893.

and particularly as a premonitory, symptom of pulmonary tuberculosis.

In every case of paresthesia of the pharynx or larynx a most careful local examinaton must be made, to exclude any local pathologic condition as a cause for the paresthesia. It is hardly necessary to add that, particularly in nervous individuals, a naso-pharyngeal catarrh, a chronic pharyngitis or laryngitis, or even the tiniest of those almost universally-present granulations on the posterior wall of the pharynx, or hypertrophy of the lingual tonsil, may produce paresthesia. All local causes must therefore be first excluded.

The hysterical cases are generally easily excluded from the history, and from the fact that there is usually present in almost all of these cases the well-known globus hystericus.

The hypochondriac cases are more difficult of exclusion. They are generally found in otherwise healthy individuals who use their voices professionally, *e. g.*, teachers, singers, clergymen, etc. Another class of these hypochondriac patients are the syphilophobes who constantly imagine that syphilis is manifesting itself in their throats. I have under observation a very striking example of this kind. A patient visits me regularly several times a year, complaining of a peculiar train of symptoms—tickling, pricking, drawing, etc. Still I have never been able to find anything abnormal. The man is perfectly healthy, but he had a chancre several years ago. He is fearful that syphilis will "break out" in his throat, and he comes to me several times a year for consolation.

As regards the class of cases due to injury of the mucous membrane produced by swallowing some hard substance, when the patients complain of the sensation of a foreign body in various portions of the throat, the history of the cases will generally give us a clew as to the character of the paresthesia. The patient can generally state definitely when the peculiar symptoms were first noticed, and their beginning can then in most cases be traced to an injury produced by swallowing some substance which, by its irregularity or hardness, wounded the mucous membrane of the throat. This wound or injury, which may be so slight as to escape detection, on even the most careful examination, may give rise to the sensation of a foreign body in the throat. These painful or disagreeable sensations can, as a rule, be perfectly localized by the patient, and their locality does not vary. A most careful examination of the entire throat and naso-pharynx must be made, so as to be positive that there really is no foreign body present, and after this is done, appropriate measures should be used to remove as speedily as possible the inflammation and irritation following the injury. But there are cases of so-called imaginary foreign bodies in the throat, in which the peculiar sensations complained of by the patient cannot be traced to any injury of the mucosa or to the presence of a foreign body. These cases generally occur in anemic individuals, particularly women. They are very refractory to treatment. I am inclined to believe that the majority may perhaps be included under that category of paresthesia of the throat which is premonitory of tuberculosis of the lungs.

Allow me to give in brief the history of only two cases of this nature. I believe this will best bring out the points in the differential diagnosis that I wish to make. In the first case the paresthesia was an accompanying symptom, in the second case it was a premonitory manifestation of pulmonary tuberculosis.

CASE I.—About three years ago a man of twenty-five years of age was sent to me for treatment. For the preceding few months he had noticed the following symptoms: A peculiar, indefinite sensation of pain and burning in the various regions of the throat, now in the palate, now far back in the pharynx, now on one side of the larynx, now on the other. He could not state definitely either the cause or the time of the beginning of these symptoms. He also coughed occasionally. There was a history of tuberculosis in the family. A careful examination of the nose, naso-pharynx, pharynx, and larynx revealed nothing abnormal outside of a slight redness of the true vocal bands; but as the man used his voice considerably, this was not surprising. An examination of the lungs revealed a moderate degree of apical catarrh on both sides; there was also slight rise of temperature, 99.5° F., and some acceleration of the pulse—84. In view of the family history, the physical signs in the lungs, the elevation of temperature and acceleration of the pulse, a diagnosis of beginning tuberculosis of the lungs was made. The patient was given creosote in increasing doses, was ordered to take plenty of nourishing food, and was given the well-known instructions ordered to patients with beginning pulmonary tuberculosis. No treatment was ordered for the throat. In four weeks the paresthesia disappeared, and, except for some slight recurrences, has not returned for two years. The patient is now practically well.

CASE II.—A woman, aged about twenty-six, came to me about four months ago. She was sent for an examination of her throat. She complained of pain in the throat for about three months past, with some cough and occasionally spasmodic contractions of the muscles of the larynx and neck, so that she sometimes had difficulty in breathing. This was, however, only momentary. The pain and "drawing," as she termed it, were not constant, nor were they always on the same side. Sometimes these symptoms disappeared for a week at a time, when the cough also disappeared with the pain and contractions. The physician who had sent her to me had made an examination of the lungs, but had found nothing abnormal. I also

found no abnormality. The throat was absolutely normal; there was not even anemia of the structures. After much questioning the patient remembered that some distant relative of hers had died of tuberculosis. To do something I gave the patient creosote in moderate doses, four grains per day. So as not to prejudice her mind, I told her that her throat-affection was a nervous trouble and would probably last a long while. Two weeks later the patient informed me, without any interrogation on my part, that the paresthesia was considerably improved. I increased the dose of creosote to six grains daily, and four weeks later the patient informed me that while the paresthesia was still occasionally present, it was much improved. The patient has gained in weight, looks better, and has a better appetite.

In brief, then, the cases of paresthesia of the throat which are premonitory of tuberculosis of the lungs are characterized principally by uncertainty on the part of the patients as to the cause and the time of beginning of their symptoms. Then in cases of anemia of the throat, in combination with the paresthetic symptoms, this condition should be thought of, although, as I shall mention later, anemia of the tissues of the throat is not an absolutely necessary condition in this class of cases.

This condition should also be suspected in all cases in which the patient has the well-known *habitus phthisicus*, or in which there is a tuberculous family history, and finally in all cases which cannot be definitely traced to an injury of the mucosa, or which are not positive types of the hysterical or hypochondriac varieties.

As regards the pathology of this affection we must honestly say "ignoramus." We do not know the reason why in the beginning stages of tuberculosis of the lungs there should be these peculiar nervous manifestations in the throat. Jurasz has attempted an explanation and calls these paresthetic manifestations "reflexempfindungen" (reflex sensations). He explains their causation by transference of the irritation produced by the pulmonary changes on the sensory fibers of the nerves in the lungs to the centripetal fibers (*i. e.*, the sensory fibers) of the pharyngeal and laryngeal nerves. He says that this theory is rendered plausible by the fact that these fibers are branches of the same nerve, the pneumogastric, which, it is well-known, distributes sensory fibers both to the lungs and to the pharynx and larynx, and also motor branches to the muscles of the latter. This attempted explanation is still an unsubstantiated theory, and, while very probable, we must confess that we do not to-day know the true reason for the presence of paresthesia of the throat in the early stages of tuberculosis of the lungs.

Gottstein lays stress upon his observations that all of these cases occur in anemic conditions of the pharynx and larynx, and hence he considers the paresthesia as a tropho-neurosis. This certainly does not hold good in all cases, for Jurasz declares that there are cases of paresthesia of this kind in which there is absolutely no anemia, and that it occurs in the very earliest stages of tuberculosis of the lungs, in cases in which positively no abnormality can be detected by the most careful examination —and which later by their history proved to be cases of pulmonary tuberculosis—and in which there had not yet been sufficient time for the anemia of the throat to have supervened.

I can corroborate this statement, for in the second case here detailed there was absolutely no anemia of the throat and no apparent abnormality in the lungs. Still I am convinced that this is one of those cases of paresthesia accompanying the initiatory stage of pulmonary tuberculosis, in which the changes in the lung-tissues are so slightly developed as to escape detection by our present methods of examination.

If we feel convinced that the paresthesia is due to or accompanies the initiatory stage of tuberculosis of the lungs, the prognosis is generally favorable. That is to say, if the pulmonary pathologic conditions can still be inhibited or made to disappear by appropriate treatment, the paresthesia will in time disappear in the great majority of cases. Still there are some cases which will persist in spite of any and all treatment. As regards the treatment, local measures should be entirely discarded. They are of no avail, and it is simply a waste of time and energy to persist in their use.

It would be "like sending owls to Athens" were I to attempt to bring forward any arguments to-day in behalf of the employment of creosote in the treatment of tuberculous affections of the lungs, especially in the early stages. I have seen most excellent results in quite a number of cases of tuberculosis of the lungs in their early stage from the administration of creosote, and I consider it the remedy *par excellence* in these cases, both uncomplicated and complicated with throat-affections.

I consider the paresthesia of the throat as one of the complications of pulmonary tuberculosis, even in those cases in which no physical changes can be discovered in the lungs by auscultation and percussion, and I would advise the use of creosote in gradually increasing doses as the remedy that to-day gives the best results in these cases.

To recapitulate: Paresthesia of the pharynx and larynx is not a rare accompaniment of the early stages of tuberculosis of the lungs. In those cases in which no physical signs can be found in the lungs, it should be considered a premonitory symptom of tuberculosis of these organs: (1) if there is tuberculous family history; (2) if the paresthesia cannot

be definitely traced to a foreign body, or an injury produced by such an agency, or by the swallowing of some hard substance; (3) in the cases of imaginary foreign bodies of indefinite etiology, with the presence of anemia; (4) in all those cases which cannot be positively placed under the head of hysteria or hypochondria. Finally, these cases are best treated by the internal administration of creosote, without the use of any local treatment.

CLINICAL MEMORANDA.

PRELIMINARY NOTE ON THE PRONOUNCED EFFECT OF THE ENDERMATIC USE OF GUAIACOL IN CONTROLLING HIGH TEMPERATURE IN TUBERCULOSIS.

BY J. SOLIS-COHEN, M.D.,
OF PHILADELPHIA.

HAVING noted remarkable statements in the French journals as to the antipyretic and other effects of guaiacol used endermatically in tuberculosis, and having had my attention called to the statement about the same time by a medical friend with whom I was seeing a case in consultation, we determined to try the method in that instance. The result was marked, and the case will be duly reported by the physician in charge.

Then the same treatment was tried under my directions upon two of my cases in the Home for Consumptives at Chestnut Hill. The result was very encouraging, as will be seen from the following record, chiefly from notes by the resident physician, M. Hannah McKirachan.

CASE I.—Mrs. F. September 3d, 3 P.M., temperature 102.4°. Guaiacol, ℥xxx, was well rubbed into the skin over the cavities for eighteen minutes. 3.33 P.M., temperature 99.3°. 5.00 P.M., temperature 97.4°. The patient was perspiring copiously, especially in the groins. The pulse was good, the body warm. 6.15 P.M. The patient was chilly, the finger-tips blue and cold. Heat was applied to the extremities. 6.35 P.M., temperature 97.4°. Then the temperature gradually rose to a little above normal.

The patient felt well and looked well and bright when I saw her the next day. She had not been as near collapse as a patient in private practice had been reported a few days previously. She described the cold feeling as having been similar to that following the evaporation of the vapor of menthol from the skin. Her appetite was good. Her cavities, for the moment, were dry. The temperature did not rise to 102° again for several days, and when it was noted, September 9th, 3.00 P.M., it was 102.4°. Guaiacol, ℥xxv, was painted over the cavities with a camel's hair pencil for fifteen minutes until it was all apparently absorbed. 3.30 P.M., temperature 102°. 3.45 P.M., temperature 101°. 4.00 P.M., temperature 97.4°. Pulse was good. Perspiration was free. No sign of tendency to collapse. Again there was freedom from excessive rise of temperature for several days. September 14th, 3 P.M., temperature 103°. Guaiacol, ℥xxv, was painted over the cavities. 3.30 P.M., temperature 101.6°. Perspiration was free. 4.00 P.M., temperature 100.2°. 4.30 P.M., temperature 99°. 4.50 P.M., temperature 97.4°. 5.30 P.M. The patient was feeling comfortable, and went to the dining-room for supper.

CASE II.—Mary F. September 12th, 2.10 P.M., temperature 102.4°. 2.45 P.M., guaiacol, ℥xx, was painted upon the skin over the diseased portion of the lungs. 3 P.M. The patient was perspiring a little, especially about the head. 3.25 P.M., temperature 101°. 3.40 P.M. Perspiring profusely. 3.56 P.M., temperature 101°. 4.00 P.M., temperature 100.2°. 4.30 P.M., temperature 99.2°. 5.00 P.M., temperature 99°. 5.15 P.M. Slight chill. Heat was applied externally. Temperature 99.4°. 5.40 P.M., temperature 99°. Lips blue. 6.35 P.M., temperature 99.8°. Patient was very sleepy.

It is noteworthy that such marked effects are produced by the endermatic use of guaiacol, when its internal administration and its injection into trachea and bronchi are not followed by similar effects.

Its use should be studied, and studied with caution that protects the patient from neglect in case of too sudden reduction of temperature.

The nurse in charge of the two cases noted, and Dr. McKirachan also, painted guaiacol on their own bodies to note its effect on normal temperature in the healthy subject. There was a slight chilly sensation half an hour afterward, but no sensible alteration of temperature on thermometric test. The guaiacol used in these two cases was not Merck's, but of American manufacture.

IMPERFORATE HYMEN, WITH RETENTION OF MENSTRUAL FLUID.

BY ADOLPH KAHN, PH.G., M.D.,
OF SAN FRANCISCO, CAL.

ON the evening of July 4th, at 10 o'clock, I received a summons to attend Miss R. A., who, the messenger informed me, was suffering great pain in the abdomen, and also that something was protruding from her parts.

The patient, a well-nourished and vigorous girl of nineteen years, I was informed, had, about four weeks previously, a similar, yet not quite as severe an attack as the present one, for which she consulted a physician. The affection was pronounced "bowel-complaint," and the girl was ordered the "rest-cure" for one week, as she termed it—remaining in a recumbent position, subsisting on a diet of milk, rice, and toasted bread, with a tablespoonful of castor-oil each night. In a few days she felt comparatively free from pain, but the uneasiness in the abdomen and bladder still persisted, with frequent stools and painful micturition. On the 2d of July the abdominal pains returned, increasing continually, and while at

stool she became aware of the protrusion from her body. It was then deemed advisable on the part of the relatives to call a physician.

Upon examination, I discovered an abdominal tumor extending upward to the umbilicus, giving the girl an appearance of being about six months pregnant, and causing me to inquire when she had last menstruated. In reply, I was informed that she had never menstruated, and that late menstruation was a family feature. I then proposed to ascertain the nature of the protrusion, and found the anus in a normal condition. I endeavored to make a vaginal examination, but that was impossible, for the hymen proved to be imperforate, the membrane being distended and protruding, the labia separated to an extent of two inches, and the perineum bulging as if pressed upon by a fetal head.

The parents were informed of the nature of the condition, and that an operation would be necessary. For the night, the pains were calmed by an anodyne suppository. On the following day, at my request, Dr. C. E. von Hoffman saw the case with me. The membrane was anesthetized with cocain, and a small incision was made in the median line, giving exit to a dirty-brown fluid, of which about two quarts escaped, when it became semi-gelatinous, necessitating the removal of a piece of membrane to permit it to flow more freely, but it gradually became so gelatinous that it had to be carefully pulled out with forceps. At least two more quarts were removed by this process.

The operation was performed upon strictly aseptic principles. There was no subsequent elevation of temperature. The patient was kept in bed for a week.

The points of interest in this case are: The condition of the menstrual fluid evacuated, the gelatinous substance showing that absorption must have taken place; the rapid recovery of the patient, showing the small danger attendant upon the rapid evacuation of accumulations under strict aseptic procedure; and the mistaken diagnosis in the first place; also, the extreme thickness of the membrane—one-eighth of an inch at least, when distended.

The patient has since had a normal menstrual period.

430 Kearny Street.

MEDICAL PROGRESS.

A Case of Focal Epilepsy.—White (*British Medical Journal*, No. 1700, p. 225) has reported the case of a woman, forty-one years old, who two and a quarter years previously had had the left breast removed for malignant disease, and who for some weeks presented numbness in the right hand. The day before coming under observation she had a convulsion, and subsequently about fifteen severe and a number of slighter fits every twenty-four hours. The attack was preceded by a sensation of numbness and tingling in the fingers and thumb of the right hand. In less than a minute afterward there followed a series of rapidly repeated extensions of the right wrist and metacarpo-phalangeal joints. At the same time there occurred a series of rapid abductions of the hand to the ulnar side. The next stage consisted of rapid flexions of the phalangeal and metacarpo-phalangeal joints, so that the fingers were dug into the palms of the hands. Then there followed a series of rapid flexions and extensions of the elbow; after which the attack was over. Exclusive of the stage of numbness the whole attack lasted about ninety seconds. The minor attacks were much shorter in duration and consisted only in a little movement of the fingers. In a few, after the flexions of the elbow, the shoulder was, for a few seconds, rapidly adducted and abducted, and the head was jerked to the left. It was said that the woman was unconcious after the first attack, but in those personally observed consciousness was not lost. In the intervals between attacks, the right upper extremity was, in all movements, weaker than the left. The hand lay pronated and the supinators were unable to move it. With the right hand the dynamometer could be moved only to 50, while on the left it could be moved to 90. There was no paresis of the muscles of the head, face, eyes, tongue, trunk, or lower extremities. The knee-jerks and plantar reflexes were preserved and more pronounced upon the right than upon the left. There was no clonus at either knee or ankle. The elbow-jerks were abolished. The wrist-jerks were present, that upon the right being exaggerated. The woman was intelligent. Sensibility to touch, pain, and temperature was quite normal over the whole body. The muscular sense was normal. The fields of vision were normal, both for form and for colors. The pupils were equal and reacted well, and there was no ocular paralysis. There was optic neuritis at an early stage upon the right; the left fundus was normal. Smell, taste, and hearing were all normal. A diagnosis was made of a growth in the left cerebral cortex implicating the arm-area and secondary to the disease of the breast. The patient was willing to submit to an operation, and, accordingly, the middle of the fissure of Rolando was exposed. Over an area that, as nearly as could be judged, corresponded with the part of the arm-area in the ascending parietal convolution the cortex at one part was of a rather more brownish-green tint than normal. This part was cut away to such a depth that white matter was exposed. When frozen and cut this was seen to consist of new-growth. At the operation it was not definitely marked off from healthy gray matter, which it closely resembled. After the operation there was paralysis of the whole of the right side of the face, except the orbicularis palbebrarum and the occipito-frontalis. The tongue occupied the floor of the mouth and was quite motionless. The upper and the lower extremities upon the right side were completely paralyzed, but no sensory defect was noticeable. Aphasia was complete. After a time the right pupil became larger than the left, and there was sweating of the right side of the face, while the left side remained dry. The pupils later again became equal, and the ability to protrude the tongue returned, while the facial paralysis diminished somewhat. There was gradual diminution in the paralysis of the right side of the body. Some power of speech also returned. For the first three days after the operation the temperature was from 1° to 2½° above normal. Then it was normal till a week before death, during which it was from 1° to 3½° above normal; but at whatever figure it stood it was almost always higher in the right axilla than in the left. The difference was usually about 1°; on one occasion it was as much as 3°. Sixteen

days after the operation careful examination showed that tactile and thermic sensibility and the power of localization were quite normal. About a month after the operation drowsiness appeared, with slowness of the pulse and cerebral vomiting, and in a short time death took place. On post-mortem examination it was found that the gap left by the removal of the diseased structure was limited in front by the fissure of Rolando, while posteriorly it extended slightly on to the supra-marginal convolution, its long axis just crossing the lower interparietal sulcus. The floor of the excavation was constituted of white matter, soft and discolored here and there, with shreddy filaments of growth. There were secondary deposits (all of which evidently had recently grown very rapidly) in the upper part of the ascending parietal convolution, in the posterior part of the third left frontal, in the upper part of the left angular, and in the middle of the right ascending frontal convolutions.

Symphysiotomy.—EUSTACHE (*Nouv. Archives d' Obstét. et de Gynécol.*, 1893, No. 7, p. 318) maintains that symphysiotomy may be considered as belonging within the domain of legitimate obstetric operations. It should not, however, replace the induction of artifical labor if the pelvic narrowing is detected in the course of the pregnancy. During labor it should be performed at once if the conjugate diameter is narrowed to between 3.1 and 2.3 inches. If this diameter exceeds 3.1 inches the operation should only be undertaken if it is not possible to terminate labor by means of version and the application of the forceps. In cases in which the conjugate is between 2.7 and 2.3 inches symphysiotomy ought to be performed in conjunction with the induction of artifical labor; and in most other cases with the application of the forceps.

The Resuscitation of the Newborn.—OEHLSCHLAEGER (*Centralblatt für Gynäkologie*, 1893, No. 31, p. 718) points out that in many cases of asphyxia, especially in the newborn, the ordinary measures of resuscitation fail, because the entrance to the larynx is closed by the epiglottis from the falling backward of the tongue. If, therefore, under these circumstances the tongue be pulled forward the epiglottis is raised and air can enter the lungs. Such a result sometimes takes place spontaneously; at other times additional measures will be necessary. In cases in which the heart's action is embarrassed, compression of the precordium will sometimes stimulate the faltering organ. The skin may be pinched or the walls of the chest compressed rhythmically in synchronism with the heart-beat.

THERAPEUTIC NOTES.

A Case of Traumatic Tetanus Cured by the Antitoxin.—GATTAI (*Centralblatt für Bakteriologie und Parasitenkunde*, Bd. xiv, Nos. 4, 5, p. 108) has reported the case of a girl, fifteen years old, who, while engaged in drawing, accidentally pricked herself upon the palmar aspect of the extremity of the right thumb with the point of a pair of compasses. The wound, which was attended with little loss of blood and occasioned little pain, was at once treated with a 10 per cent. solution of mercuric chlorid and dressed with gauze and cotton. In the course of the same day and during the night the wound became painful, while the adjacent joint became stiff and a small pustule formed, while a line of bluish redness appeared on the dorsum of the hand. The pustule opened spontaneously, permitting the escape of a few drops of pus. On the following day the margins of the pustule were removed and the parts disinfected by means of mercuric chlorid. The pain, however, persisted and occasioned a good deal of annoyance, in the course of the next two days assuming a paroxysmal character. It was recommended that the hand be placed in a warm solution of mercuric chlorid with every exacerbation of pain, but on the following day the pain extended up the arm. An abscess formed upon the dorsum of the thumb and was freely incised, throughly curetted, and disinfected. Applications of cocain hydrochlorate failed to relieve the pain. In the course of the following days stiffness appeared, first in the lower jaw, subsequently to become general. Dysphagia and photophobia also manifested themselves and convulsions recurred paroxysmally. A diagnosis of traumatic tetanus having been arrived at, an injection of two drams and a half of blood-serum from an immunified rabbit was given, and subsequently upon the same day, at an interval of six hours, two injections, each of seven and a half grains of antitoxin obtained from the blood-serum of a dog, were given. These injections were continued in approximately like dosage for a week, amelioration in the symptoms meanwhile progressively taking place. On one occasion a dram of chloral was given by enema, and on each of several occasions fifteen grains. Under this treatment improvement steadily progressed, until on the nineteenth day after the puncture the patient got out of bed and resumed her ordinary pursuits.

Bismuth in Large Doses for Chronic Gastric Catarrh.—PICK (*Berliner klinische Wochenschrift*, 1893, No. 31, p. 761) maintains that, in order to be effective in the treatment of chronic gastric catarrh, bismuth should be administered in maximum doses. His own mode of procedure, which he reports to have practised successfully in a large number of cases, is to give a small quantity of a saline in about eight ounces of warm water before breakfast and half an hour later from three to four drams of bismuth subnitrate in two equal parts in cachets. Massage of the epigastrium is then practised for a short time, and in half an hour the patient is permitted to breakfast. Ordinary care is to be exercised with regard to diet. In mild cases decided improvement is said to follow after a week of this treatment; in the graver cases three or four weeks elapse before a similar result is obtained.

The Utility of Electricity in the Treatment of Hemiplegia.—RENZI (*Revista clinica e terapeutica*, 1893, No. 1, p. 1; *Gaz. hebd. de Méd. et de Chir.*, 1893, No. 29, p. 345) contends that electrotherapy is sometimes immediately followed by a restoration of the power of voluntary contraction in the paralyzed muscles. This restoration is not dependent directly upon the electricity, but upon the contractions induced, the memory of the defective motor mechanism being thus revived.

THE LAY-PRESS AND MEDICAL ETHICS.

CONCERNING questions of taste, the oldest proverbial wisdom tells us that dispute is useless. In reference to the criticism of MR. ERNEST HART'S recent American addresses it is therefore amusing to notice with what unanimity and avidity the quacks, potential or actual, and their lovers, seize upon possible errors of fact the most trivial in order to make them excuses for rage against principles they hate, but which they hardly dare confess that they hate. Among a certain class of physicians, stung by MR. HART'S truths, it is delightful to see how gossip and scandal and condemnation of matters of taste are rolled as sweet morsels beneath the tongue, and this by men whose urbanity of deportment and exquisite sense of the fitting are quite as wofully illustrated as by a freshly imported South Sea Islander.

There are few medical men so bold as to defend the newspaper doctor, the self-advertiser, the fellow who furnishes the reporters with his own photographs and reports of operations, or who goes into the secret-nostrum business. An occasional man, with a degree of M.D., may possibly become such an *advocatus diaboli*, but it would be altogether too ludicrous to call him a *medical* man. But the concealed malevolence can expend itself in well-simulated horror at supposed lapses of good taste and thus run tilt against the red-rag of manners in order to lose in mad action the pain of the deft matador's burning darts. The service MR. HART has rendered us, however indirect, is excellent: he stimulates the secret enemies within the profession to show themselves and to range themselves where they belong—that is, with their friends the patent-medicine-fed, notoriety-seeking, nostrum-loving newspapers. There is a deal of ducking and dodging about it, of course, and we have some fine farcical touches now and then—medical Falstaffs, for example, attempting the rôle of auctioneers of their own virtue, and not getting a single bid.

But there are friends who are not compelled to whip up subterfuge or factitious indignation: these are the dear newspapers whose pocket-books are touched, whose very financial existence, indeed, depends upon crapulous advertisements and the money of the nostrum-vender. These may loudly bawl their hatred of anyone who shall pretend to criticise the infamous traffic upon which depends their daily bread—*Wessen Brod Ich ess', dessen Lied Ich sing'*,—and so from one land's end to another the venal newspapers whose ten columns are filled with filthy advertisements of nostrums, "patent" medicines, and obscene literature, find room in the one or two remaining editorial columns of their space (also for sale, if desired!) to abuse MR. HART because he thinks the newspaper doctor and the nostrum-traffic quite contemptible. With editorial ink that stinks of the advertiser's skunkery, the didactic editor writes against the plucky Englishman, his antediluvian ethics, and his ancient prejudices.

One example of many such is an editorial in a recent number of the *Pittsburg Post*, entitled "Antiquated Conceits," in which MR. HART and the "old school" are lectured as if by a demigod of wisdom and virtue for their "intolerance," "medievalism," "obsolete traditions," "despotisms," and all that, and are told that all this has long since passed away with other thousands of effete superstitions and shams. "Professional etiquet and ethics" are spit upon quite contemptuously, and the day of progress, of money-making by medical trickery, by nostrums, and, egad! by the newspaper, is dawning, to the everlasting shame of worn-out and antiquated medicine.

Now, if a healthy stomach can control a healthy

tendency to vomit when compelled to smell such an odious mess as this, it is of course quite amusing —much as would be a sermon by Boss TWEED on civic virtue. But repeated from a thousand newspapers it grows too intolerably wearisome, and indignation wishes that a DANTEAN circle of the Inferno might be awaiting these righteous and progressive editors who thus prostitute their office for gain, and that for two eternities they had to swim in lakes of their advertisers' bitters, blood-purifiers, and panaceas, with no food but their advertisers' "little pink pills," and "Gentlemen's Friend" ("with a syringe free"), and no literature but their advertisers' "marriage-guides," and "retired clergymen's" secrets.

There are, thank Heaven! a few lay-journals that from principle and very shame refuse to fatten on humbug, and to sell their editorial souls, to the begulled public's undoing. To these honorable exceptions we would appeal that they seek by every means, and on every possible occasion, to arouse in the public mind some true conception of the real state of affairs as regards the animus and doings of the medical profession, and as regards the animus and doings of the foes it has to withstand. It is extremely difficult to maintain a pure ethical ideal, and unselfishly to devote life for the benefit of those who not only are ungrateful, but who spew malice and abuse on their would-be benefactors.

In individual medical ethics and in their application in private life by the great body of the profession, there is a clearness of intellectual perception and a heroism of patient endurance unequalled by that of any body of men. But it is the united and corporate action that fails. And never in history did the public welfare more clearly depend upon anything than upon this purity of medical character and conduct, whilst at the same time foes within and foes without the profession are insanely seeking to destroy what is infinitely precious to that profession, but more precious still to a public that is stupidly regardless of its own highest interest, and of its own best friend.

At a certain physiologic season the female canine sends her volatile messages through miles of air, and the responsive friends never fail. The newspaper reporters also never miss the challenge of the newspaper doctor. But the newspaper doctor knows no estrual season—which is equivalent to saying that he is the professional prostitute. If it be said that owing to his sex the simile does not hold, the answer is prompt that there is a terrible revival nowadays of pederasty.

It is as natural for a newspaper to espouse the quack's side of medical scandal as it is for a gambler to defend horse-racing. If a rascal concocts some dodge for making a fortune by "curing" drunkards, for reviving the waning powers of roués, or for giving brain-power to the brainless, nine out of ten newspapers will give thousands of dollars' worth of free advertising to the schemes, and laud the "gold cures," "testicle juice," or what not else, to offended heaven. A Philadelphia newspaper lately made itself the agent of some patent medicine cure-all, and distributed thousands of bottles over its counters.

There remains, of course, the humiliating confession that the existence of the newspaper doctor and of the newspaper debauch in quackery is indirectly and in large part the fault of the profession itself, dependent upon the fact that we are a non-organized profession, and that what organization we have is not used in the practical righting of medical abuses. Thus, again and perpetually, recurs the truth that every medical scandal and every aspect of our powerlessness resolves itself into our sins of disorganization and of non-interest in practical matters and in preventive medicine. Out of a hundred thousand physicians in America hardly a hundredth part are active members of the American Medical Association, and the section meetings of "congresses" of physicians could almost always be held in an ordinary private sitting-room of a workman's cottage—so slim is the attendance. And when we do meet we discuss the symptoms and treatment of individual cases of illness, leaving out of consideration the production of disease, the prevention of it, and the domination of legislation, the newspapers, and the lay-world by the quack and the pill-vender.

How can we bring any influence to bear upon the newspapers if we present the spectacle of a disunited and factional lot of scramblers and indifferentists? There are many of these newspapers that are simply ignorant and thoughtless as regards the disgrace of their advertising columns, and who could easily be shamed out of it if we were but united among ourselves, and would use our united strength for matters of practical reforms of medical abuse and preventive medicine. Organize, and use organization for the world's sake! is the command of professional honor and of benevolence.

It may be said by the lay-journal that we as a

profession have no right to complain so long as so-called medical journals trade in nostrums, and so long as once reputable medical journals loan their columns to the defence of masked quackery, and to the abuse of critics of medical disgrace. The retort is pointless. This is a question like one of national finance, outside of parties, and all good men of whatever calling must unite to crush the control of the press by patent-medicine syndicates, and to aid the better part (which, despite appearances, is by far the greater part) of the medical profession to keep its character and standards above the smirch of a rotten commercialism. Reputable and self-respecting newspapers should combine to limit the national crime and disgrace of the newspaper debauch in advertisement filth and fraud.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, held at Milwaukee, Wis., September 5 and 6, 1893.

FIRST DAY—SEPTEMBER 5TH.

Morning Session.

THE Association met in the club room of the Pfister House and was called to order by the President, Dr. George Henry Fox, of New York, at 9.30 A.M.

DR. R. B. MORISON, of Baltimore, Md., read a paper entitled "Cosmetics." Cosmetics, in a general way, may be divided into two classes, namely, those that are irritating and those that are soothing. For instance, if we wish to remove freckles or warts, a stronger application must be made than if we simply prescribe for a redness following an acne or an eczema. The patient, either through himself or his assistant, should be taught how to apply local remedies. Salves, plasters, lotions, and caustics are so often misapplied that experience had taught that an application from which one hoped to get the most good must be made by skilled hands. For the removal of freckles the following solution was recommended:

℞.—Corrosive sublimate	gr. vij.
Distilled water	℥vj.
Spirits camphor	℥ss.
Rose-water	℥v.

Three or four thicknesses of linen, cut to cover the seat of freckles, are moistened with the solution and placed upon the face at night until they dry, when they are taken off. Whatever remains on the skin is left there till morning and then washed off. After a few nights' application the face becomes red, and the epidermis begins to peel off in fine scales. Then an ointment is used night and morning, the application being made by gently rubbing it over the face for five minutes at a time with a clean finger.

In the removal of superfluous hairs, the author has given up electrolysis. He finds that the proper application of a good depilatory answers the purpose much better. There are many women who wish to get rid of the white lanugo down on their faces, upon whom it seems that electricity cannot be used for fear of stimulating the growth of the surrounding hair, and the appearance of permanent scars. If a preparation of yellow sulfate of arsenic and quicklime, of equal parts, made into a paste with hot water, be allowed to dry on the hairy skin, it removes the hair for ten to twenty days, and sometimes permanently. On the other hand, nothing seems to take the place of electrolysis when there are a few strong hairs growing from moles, in the removal of moles themselves, in angioma, or in permanent small red spots.

For the removal of warts the author prescribes the following:

℞.—Hydrarg. bichlor.	gr. v.
Acid. salicyl.	℥j.
Collodion	℥j.

He sometimes increases the mercuric chlorid to 30 grains in the same amount of collodion, if the milder application does not answer. It is applied every day once, the upper crust of the previous application being removed before a fresh one is made. Four such applications generally soften the wart to such a degree that gentle traction removes it painlessly, the further dressing being any simple ointment.

The author had obtained excellent results in cases of acne by the use of the galvanic current.

DR. GEORGE T. JACKSON, of New York, read a paper entitled "A Case of Rhinoscleroma," in which he said that in October, 1892, he had the pleasure of presenting to his class at the Woman's Medical College of New York Infirmary a case of rhinoscleroma. There have been only three cases of this disease reported by members of the American Dermatological Association since its foundation, in 1877. The patient, a woman fifty-four years of age, was born in Hungary. The disease began sixteen years ago as a slight thickening of the upper lip to the left of, and just under, the septum nasi. Since then it has grown slowly and without pain. During the past four years it has increased in size more rapidly than during the preceding twelve years. At present it appears as a hard, well-defined, elevated, old-ivory colored mass, located upon the upper lip, beginning at a point a little to the right of the middle line and occupying nearly the whole of the left side of the lip. It runs up upon the left side of the septum nasi to a slight extent. It is slightly lobulated, so that it has an uneven surface, and shows a number of dilated bloodvessels running over it, and a number of white points apparently representing plugged-up and dilated follicles. There is no history of syphilis, nor does it look like a syphilitic growth. There is no sign of ulceration and no tendency to break down. Only about 100 cases of the disease have been reported altogether.

No satisfactory treatment of the disease has been found. The best results so far reported have been attained by the use of salicylic acid, injected into the tumor daily, a 1 per cent. solution of the acid or a 2 per cent. solution of sodium salicylate being used, while ten grains of the acid were administered by the mouth three times daily.

"A Case of Circumscribed Scleroderma (Morphea)" was the title of a paper read by DR. W. T. CORLETT, of Cleveland, O. Mary M., ten years of age, an intelligent-looking girl, well nourished, although slightly pale, presented herself with variously sized and colored lesions on the left upper extremity. These were of two years' duration. The lesions were located on the extensor surfaces, the most typical lesion being situated on the middle third of the forearm. This was of oblong shape, four inches in length and two inches in width. It was slightly contracted, lessening somewhat the circumference of the forearm, and was somewhat depressed, resembling cicatricial tissue. The lesion presented a yellowish-brown central area, with a slightly uneven surface, slightly indurated, and non-adherent. There was no anesthesia. Hairs were absent. Outside the central zone was a bluish-white area surrounded by a lilac-pink border merging into normal skin. The veins about the lesion were very prominent. A second spot had appeared one year after the first on the back of the hand, the characteristics of which were similar to the preceding. During the four months prior to her first visit to Dr. Corlett seven other spots appeared on the arm and one on the shoulder. These were smaller than the original. Sharp pains were now complained of, extending from the shoulder to the hand. These were aggravated by writing, but lasted only a few days. Some itching around the margin of the lesions and, occasionally, frontal headache were complained of. There was tenderness over the upper dorsal and lower cervical vertebræ; but no motor or sensory impairment anywhere; nor was there any other evidence of cord-disease. There was no history which might possibly explain the lesions, excepting a fall upon the back at the age of five years. There was no history of nervous or hereditary disease of any kind in the family. The case was originally considered as a perfect type of morphea, but at the present time it presents a picture of the atrophic stage of scleroderma.

The points of interest are:

1. The changes of clinical form through which the disease has passed.

2. The predominance of the neurotic element, which is so often well-marked in morphea, and which points to the spinal cord as the most probable seat of the disturbance.

3. The confusion of nomenclature of morphea and its relation to scleroderma is of some interest. Modern treatises on dermatology by American authors are in the main inclined to consider morphea and scleroderma as distinct affections, while European authorities are rather inclined to the opposite view.

DR. W. A. HARDAWAY, of St. Louis, Missouri, read a paper entitled "A Case of Tuberculosis of the Skin Simulating Lupus Erythematosus." The patient was a pharmacist, twenty-eight years of age; whose previous health and family history were good, and who presented no history of tubercle. He is tall and spare, and of sallow complexion, yet a man of great endurance. In May, 1892, he noticed in his left malar region a small yellowish elevation the size of a pin-head. This was supposed to be a flesh-worm, and was squeezed, blood only being thereby obtained. The lesion gradually enlarged peripherally, becoming hard and red, but was unattended with subjective phenomena. He came under Dr. Hardaway's care in June, 1892, the lesion being now as large as a dime, and presenting an atrophic whitish center surrounded by a slightly raised infiltrated border of a dull-red color. The lesion was anesthetic, a characteristic which has been noticed in tubercular syphilides. The anesthesia was temporary. In a short time the patient passed from under observation and was gone for a month, during which time he was thoroughly treated for syphilis by another physician. The treatment simply aggravated the general and local conditions. On September 3, 1892, the original lesion was the size of a half-dollar, not raised from the surface, and moderately infiltrated. The center was still atrophic, and the same narrow dull-red line presented at the borders. In a few weeks several small acniform pustules appeared on the right temple, the side of the nose, and the inferior angle of the right eye. Others presented at the end of the nose, on the right ala, and left cheek. These lesions were not painful or itchy. Each lesion was surrounded by a red areola, which subsequently extended and became infiltrated, crusts forming over the centers of the lesions. The crusts were fatty or sebaceous in character, and with a dull-red surface beneath were suggestive of lupus erythematosus. As the borders of the lesions extended the centers cicatrized, presenting the same dirty-yellow appearance of the original patch. Early in January a small piece of skin was excised from the lesion on the right temple and examined microscopically. Electrolysis was tried upon the other lesions with an apparent cure, followed by a relapse after a few months, manifesting itself first by the formation of a scale in the center of the scar. Electrolysis was persisted in as fast as the spots appeared and with apparent success. In March a small patch similar to the others appeared upon the scalp, and this is now the size of a dime. The tendency to peripheral extension throughout has been a marked feature in this case. The whole nose finally became involved and became a continuous lesion of partly red and partly cicatrized integument, presenting a striking likeness to some forms of lupus erythematosus. At no time could nodules of lupus vulgaris be demonstrated, nor were the sebaceous plugs of lupus erythematosus seen at any time. The patient's general health has continued so poor that at one time general tuberculosis was considered imminent. A trip to Colorado brought about great improvement. At last accounts the disease was apparently quiescent, the patient's general health good, and no lesions of the lungs and larynx have been detected. Dr. C. Heitzmann reports, after microscopic examination of the excised piece of skin, that a moderate number of tubercle-bacilli were found. A large number of inflammatory corpuscles were also detected displacing the fibrous connective tissue. Nests of inflammatory corpuscles were seen in the arrangement characteristic of tuberculosis. The diagnosis was local tuberculosis of the skin, which was entirely in accord with the clinical diagnosis.

DR. H. R. CROCKER, of London, England, read a paper on "Lupus Erythematosus as an Imitator of Various Forms of Dermatitis." The author said that lupus erythematosus as an imitator of various forms of simple dermatitis was a formidable rival of syphilis itself. It was to this aspect of the disease that he desired to direct

attention by relating some cases and showing drawings which illustrated the points he wished to place before the Association.

The first drawing was an instance of a lupus imitating erythema tuberculatum. The patient was twenty-seven years of age. The lesions commenced on the right cheek. There was only one spot for the first two years; then others formed on the side of the nose, and they then became scattered irregularly over the face, but with the exception of a hempseed-sized nodule on the left ear, there was none anywhere else. The lobes of both ears appeared atrophied, but the patient said there had never been any lesions on them. All the lesions were exactly like those of erythema tuberculatum, varying from the size of a hempseed to a half-inch in diameter, quite smooth, except one on the side of the nose, which was scaly. They were of a uniform purplish-red, except one, which was whiter in the center.

Case 2 showed an advanced condition of the disease, which began in a similar form to Case 1.

Case 3 was one of lupus erythematosus like erythema papulatum. The patient, aged forty-two, was a cab-driver. Two years previously he had some rash on the cheeks which lasted only a month, and it was not until a year ago that the present eruption began on the sides of the cheek, and has gradually extended until it reached its present condition. The eruption when seen occupied the whole face below the eyebrows, the orbits themselves and the lower lip escaping, but the chin, except in the center, was affected. On the left side it extended above the brow, but below the orbits, and was remarkably symmetrical. The most recent lesions were on the lower part of the side of the face and below the jaw. In these positions they assumed the form of erythematous, slightly raised discs from a half to a quarter of an inch in diameter; the most recent were quite smooth and slightly convex; the larger ones were not prominent in the center and but slightly scaly.

Case 4 was like diffuse erythema, the patient being a lady, forty-three years of age. The disease had commenced three years previously as a small red spot on the side of the nose and had spread continuously. The whole nose was intensely reddened and slightly scaly; the skin thickened and infiltrated, but the orifices of the sebaceous glands were not plugged.

Another disease which lupus erythematosus imitates is psoriasis, and the author reported a case in point. A rarer imitation is that of lichen planus, of which the author has seen only two cases.

DR. CROCKER also reported a case of lupus erythematosus nodulatum. He had met with three or four other cases of this, but not with so many distinct foci of disease. In two cases there was only a single nodule in each. He also remembers a case in which there were even more foci of disease in a patient of the late Dr. Tilbury Fox. Cavafy also showed a case at the Dermatological Society of London, in 1892, but Dr. Crocker was not aware of any other cases having been recorded.

DR. E. B. BRONSON, of New York, followed with a paper entitled "The Treatment of Pruritus.". The author said that in the management of *pruritus essentialis*, as of any other disease, the first consideration should be directed to the cause. The adoption of measures tending to remove any accidental conditions or influences through which pruritus might be occasioned is important. Such causes include, besides various local sources of irritation, certain remote or general diseases and furnish the *indicatio causalis* in its more limited sense. This, however, states the scope of the problem only partially. What is of more importance is to establish principles of treatment fitted to those more special and more essential causes that constitute the necessary conditions of the disease and whence we derive the *indicatio morbi*. These causes are traced under etiology, and it is they which must afford the only intelligent basis for the therapeutics of pruritus.

The chief underlying condition in pruritus is hyperesthesia, whether in its common significance of an excessive irritability of the sensory nerves, or in the sense of an excess or engorgement of sensation. The prime indications then are to allay irritability and to divert or annul the excess of nervous excitement. Measures to remove local excitants include, first of all, such as directly tend to prevent scratching. To admonish the patient to refrain from this is usually of little avail. Restraint may be possible during waking hours, but at night, when the trouble is always at its worst, and especially during the state of somnolence midway between sleeping and waking, no power can prevent it. It can only be avoided by first mitigating the lesion through the aid of anti-pruritics. Sedatives used internally are likely to be disappointing. The degree of general sedation that is required to affect the nerves of the skin in so intense a disturbance as pruritis often is affords a sufficient reason why this method of treatment is usually objectionable. Further than this, the depressing and atonic after-effect on the nervous system tends to exaggerate the general hyperesthesia, which is already essentially an atonic condition, and thereby increases the tendency to itching. Especially objectionable are most of the narcotics. The bromids, on the other hand, are often indispensable and may be required in liberal doses. It is important to avoid the enervating effects of loss of sleep, and for this purpose sulfonal or some other hypnotic is occasionally needed. In connection with this, two internal remedies, which have been especially recommended by Bulkley, are worthy of mention, and they are cannabis indica and gelsemium. The former is known to be a cutaneous anesthetic as well as an analgesic, and by virtue of the former quality should be useful in pruritus.

Carbolic acid is the most reliable and most generally useful anti-pruritic which dermatologists possess. It was well named by Unna "the opium of the skin."

The following "anti-pruritic oil" has been much employed by the author for years both in local and so-called universal forms of the disease, with no more untoward results than now and then a trifling dermatitis, when through oversight the patient has been allowed to make the applications too frequently, or has continued them too long. The formula is:

℞.—Acidi carbolici . . . . . ℥j-ij.
Liquor. potass. . . . . ℥j.
Ol. lini . . . . . ℥j.—M.
Sig.—Shake before using.

To correct the disagreeable odor of the linseed oil a drop or two of the oil of bergamot may be added. Sali-

cylic acid and salol, though less energetic in their effects, act similarly to the carbolic acid. Thymol is also an admirable anti-pruritic, but on account of its irritating effect cannot be used when the skin is sensitive.

The author then dwelt on sensory stimulants, substitutive irritants, alteratives of cutaneous nutrition, and motor depressants. In pruritus hiemalis an all-important measure of treatment is protection against cold. The sole cause of winter pruritus, aside from a special predisposing hyperesthesia, is lowered temperature.

DR. JOSEPH ZEISLER, of Chicago, Ill., read a paper entitled "Angiokeratoma," and reported the following case: The patient was a German, and fifty-three years of age, butcher by occupation. Had never had any severe illness, but had had malaria once. His present illness began somewhat gradually about four years ago with red spots and verrucæ on the skin of different parts of the body. He was under medical treatment and says he improved for a time. He states that some of the red spots gradually disappeared at times, but returned, and new ones arose in different localitities. During all this period his general health had not suffered in the least. No anorexia, headaches, nor any other complaint existed. There is no pain or itching in the skin-lesions. Patches of vitiligo of large size are found on the front and sides of the abdomen and on the right side of the thorax, and some small patches in the right axilla, with faint patches on the right side of the chest posteriorly and on the neck. There are also large patches on the penis and scrotum and small ones on the inner surface of the thighs. There are some old marks of tinea favus on the scalp. Nevus-like spots and small tumors are scattered over the body. The patches vary in size from three or four inches in circumference to the size of a dime. They are red in color, vascular, and slightly raised above the level of the surrounding skin. On the right forearm are numerous small tumors, varying in size from minute spots to some the size of a hazel-nut. The larger ones are all pedunculated, firm, and vascular. There is considerable edema of the right hand and fingers. Microscopic examination was made by Dr. Zeisler. Some of these tumors sprang out from beneath the finger-nails. On the left hand the verrucæ were not so numerous and inclined more to the small vascular variety, with two exceptions. Large irregular red patches were also found over each patella, and a few smaller ones irregularly scattered over the anterior aspect of the legs and thighs; also a few smaller ones over the posterior aspect of the thighs and one on each ankle. Two small pedunculated warts were also found on the back of the right leg, another with some of the red patches on the nates near the gluteal fold. No patches or tumors were found on abdomen, thorax, or upper part of arms.

The author reported this unusual and interesting case to show that the clinical picture of the disease is evidently not yet quite complete, and hoped that new examples of the disease would arise which would throw more light on the pathology and etiology of the affection.

DR. J. A. FORDYCE, of New York, read a paper entitled "A Contribution to the Pathology of Acne Varioliformis (Hebra)." Dr. Fordyce called attention to the case described by Dr. Bronson and himself in 1891, under the title of "Acne Varioliformis of the Extremities," which was at that time shown to originate in or about the coil glands. This was identical with cases since reported by Politzer, Dubreuill, and others under the name of Hydradenitis, and should go on record as an example of that affection. While clinically it presented many points of similarity to acne varioliformis (Hebra), its pathologic anatomy was quite distinct.

The writer had examined microscopically a number of papules and papulo-pustules from two typical cases of the latter disease, and was able to trace its beginning to an inflammation about the middle and upper portions of the hair-follicles and their sebaceous glands, while the coil glands were shown to be outside the inflammatory area. Enormous numbers of staphylococci were found in sections from one of the cases examined which readily stained with Kühne's carbolic methylene-blue solution. These organisms were especially numerous about the middle and deeper portions of the hair-follicles, and were contained within the external and internal root-sheath, in the connective tissue about the coil glands, and in the subcutaneous connective tissue. In considering their number, distribution, and presence in the diseased area before the epidermis was involved, the writer was disposed to consider them a direct influence in producing the lesions. In a secondary infection they would scarcely be found at so early a period in the evolution of the papule.

As a result of his investigations, Dr. Fordyce concluded that acne varioliformis (Hebra) was an inflammation of the pilo-sebaceous system, of microbic origin, leading to destruction of these organs, and that Bazin was correct in naming the disease acne pilaris.

The members of the Association, at the close of Dr. Fordyce's paper, participated in a general discussion on pityriasis, rosea, and pemphigus.

The following officers were elected:

President—Dr. Robert B. Morison, of Baltimore, Md.

Vice-President—Dr. George T. Jackson, of New York.

Secretary and Treasurer—DR. Charles W. Allen, of New York.

Member-at-large of the Council—Dr. J. A. Fordyce, of New York.

On motion, the Association adjourned to meet in Washington, D. C., in connection with the Congress of American Physicians and Surgeons, in May, 1894.

FIRST PAN-AMERICAN MEDICAL CONGRESS,

Held at Washington, D. C., September 5, 6, 7, 8, 1893.

(Continued from page 364.)

SECTION ON GENERAL MEDICINE.

THIRD DAY—SEPTEMBER 7TH.

DR. H. A. WEST, of Texas, read a paper entitled "Abstract Clinical Notes on Amebic Dysentery," in which he spoke of the practical importance of the subject in consequence of the diversity of opinion in regard to the definition, varieties, and etiology of dysentery, and especially the non-recognition by the general medical profession of the causal relations of the ameba coli in the production of dysentery and the wide dissemination and frequent occurrence of this form of the disease.

Attention was called to the following points:

1. Importance of a correct definition. Dysentery is not, as is usually taught, a morbid entity, consisting of an inflammation of the large intestine, essentially the same in all forms and climates, varying only according to climatic and other modifying conditions; on the contrary, the term dysentery should be used in a general sense to designate a group of inflammations of the large intestine partly of specific and partly of non-specific origin.

2. The adoption of the following classification will do much toward dissipating the existing confusion, viz., acute catarrhal, acute diphtheric, amebic, and secondary dysentery.

3. Amebic dysentery is more widely disseminated and occurs with greater frequency than is generally supposed.

4. To emphasize the probable entrance of the ameba through impure drinking-water.

5. To note the characteristic and uniform symptoms of this form of dysentery.

6. The essential chronicity and difficult cure depending upon the character and location of the lesions.

7. The necessity of combating the excessive anemia and wasting by the use of a more liberal diet than is generally prescribed.

8. To urge the importance of cleansing and antiseptic irrigations as a rational method of reaching and destroying the ameba, and stimulating the intestinal ulcers to heal.

9. To note the fact that while solutions of quinin are destructive to the ameba, injections of the same fail to exercise any marked curative effect.

10. The author's experience going to show that mild injections of nitrate of silver, thirty grains to a quart, with occasional administration of salines and large doses of bismuth and salol constitute the best treatment.

The nature of the disease is such as to produce very rapid anemia and wasting. It is necessary to combat these results by the plentiful use of nitrogenous food—meat, fowl, eggs, rich broths, milk, etc.; if restricted to a milk-diet these patients will very rapidly fail.

The character of the lesions gives the key to the most successful treatment, viz., consisting of thorough irrigation of the intestine, first with simple warm water for cleansing purposes; second, with an antiseptic solution for destroying the organisms and stimulating the ulcers to heal. For the latter purpose Dr. West has tried solutions of quinin, creolin, and silver nitrate; the latter has given the best results; quinin, in his experience, failing to accomplish any permanent good. While not attempting to explain the mode of action, large doses of bismuth subnitrate and salol seem to have had a distinct effect in controlling the excessive frequency of the stools. Salines also at times are beneficial, their mode of action probably consisting simply in a cleansing effect, in sweeping out irritants of various kinds.

DR. CARMONA, DR. GARDINER of Indiana, and others participated in the discussion, which was generally confirmatory of Dr. West's conclusions.

DR. J. W. MCLAUGHLIN, of Austin, Texas, read a paper on "The Bacteriology of Dengue Fever," illustrated by photomicrographs of jelly-cultures of the dengue-micrococcus. In closing the discussion on his paper Dr. McLaughlin said:

There is a very strong distinction between dengue fever and influenza, although there is a strong similarity. The cold weather kills dengue fever, which is without the catarrhal symptoms of influenza. While there is a resemblance, there is a marked distinction in the cause and in the disease itself. Dengue fever is to be regarded as distinctly different from influenza.

DR. F. G. NOVY, of Ann Arbor, Michigan, read a paper on "The Culture of Anaërobic Bacteria," containing a brief *résumé* of the principles and methods employed in the culture of anaërobic bacteria.

DR. NOVY also read a study of "A New Anaërobic Bacillus of Malignant Edema." In several guinea-pigs which died after injection of an impure milk nuclein solution a marked edematous condition was observed resembling, and even more pronounced than, that of malignant edema. In the subcutaneous tissues, peritoneal exudate, heart-blood, spleen, liver, etc., were found enormous numbers of a long slender bacillus. This organism was found to be obligative anaërobic in character, and pure cultures possessed marked infectious and extremely toxic properties, producing death in from twelve to thirty-six or forty-eight hours, with a characteristic edematous condition.

This new, highly pathogenic, anaërobic bacillus is motile and the flagella can be readily demonstrated by Löffler's method.

The germ is readily stained by simple dyes and also by Gram's method. Spore-formation has not been observed, but the germ itself is extremely resistant.

CORRESPONDENCE.

DR. HAMMOND AND THE MEDICAL PROFESSION.[1]

To the Editor of the *New York Medical Journal*,

SIR: My respect for and my sympathy with the medical profession in America, and my knowledge of its sentiments, forbid me to regard Dr. William A. Hammond as its representative in the defence which he puts forward in your columns of September 16th, of the practices of publicity-hunting by newspaper interviews, newspaper portraits, and of the use of and traffic in secret preparations, etc. I have in the course of recent travel received personally from many hundreds of prominent and representative physicians in Milwaukee, Washington, Boston, Philadelphia, Chicago, Cincinnati, Detroit, and from all parts of the United States, their cordial congratulations on the tone and substance of the addresses which I had the honor to deliver at Milwaukee and Washington. I have been assured on all hands of the entire sympathy of the great body of the profession in the views therein laid down and discussed. I should have been surprised, however, and perhaps disappointed, if they had not elicited some expression of pain and anger from certain quarters. "Let the galled jade wince, the withers" of the great American medical profession are,

[1] From an advance duplicate of a letter sent to the *New York Medical Journal*, kindly furnished THE MEDICAL NEWS by Mr. Hart.

I am assured, "unwrung." Your correspondent, in an access of ethical agnosticism, assumes that the enumeration of ethical data as to medical conduct was or could be a reproval, direct or implied, to the medical profession of America. That is an unmerited insult which he addresses to his profession, and indicates a view which I apprehend to be special to himself. Let him enjoy the practices which he defends; I do not think that he is likely to find much support or sympathy in them from medical men in good standing. His account of the position of medical men in Great Britain is a parody undeserving of serious notice. So as to myself, whom he favors with some personal abuse, I have been avowedly the scientific adviser to, but it is untrue that I have ever held any of the stock of, the Apollinaris Water Company. As to his other trivialities, I was the guest of the Pan-American Medical Congress, and on entering its headquarters I registered in ceremonious form.

I have no desire to be honored amongst "the Pan-Anglicans," "the loyal legion," "the fat men of America," and the other objects of lay interest with whom Dr. Hammond puts medical men on a par, and I do not agree with him that medical men should desire to share with them the honor of newspaper notoriety. I do not believe any details of my medical career have ever appeared in any lay paper. I suggest that it might be desirable for Dr. Hammond to rely less upon his imagination for his facts, and not to assume to speak for a profession from which he has no sort of mandate, and which would, I am well assured, repudiate, if consulted, both his advocacy and his methods of action and of expression. I am assured that he utterly misrepresents that profession, both in his statement of principles which he ascribes to it, and in his abuse of myself.

I am, sir, yours faithfully, ERNEST HART.

CLINICAL NOTES ON RHUS TOXICODENDRON.

To the Editor of THE MEDICAL NEWS,

SIR: In an editorial comment in THE MEDICAL NEWS of September 9, 1893, attention is called to the use of rhus toxicodendron "in a large and ill-defined group of chronic rheumatic affections," and allusion is made to its usefulness in certain chronic skin-eruptions, in hemorrhoids, varicose veins, etc.

To Dufresnoy, of France, belongs the credit of first having observed the therapeutic effects of the drug. He quotes a case of a young man so severely poisoned by contact with the plant as to experience its constitutional effects, the result of which was the cure of an eczema of many years' standing.

From the time of this observation comparatively little account has been taken of its action by the regular profession, especially in this country. It is official in the German Pharmacopeia, and was recognized by the United States Pharmacopeia of 1830.

The "Eclectic" and "Homeopathic" schools seem to have retained it, and we find it and its ally, "rhus aromatica," entering into the composition of various proprietary eliminative mixtures.

A strange relationship seems to exist among its uses by the older men of the regular school, the eclectic, and the homeopathic professions. Among its "indications" in the therapeutics of the latter we find "*Rheumatic and gouty* tension, joint and tendinous lameness, urticaria, heat spots, vesicular and scaly eruptions, nocturnal incontinence, etc."

Dr. H. G. Piffard, in speaking of its use in skin-affections, says: "I have seen prompt change for the better, I might almost say abortion of the eruption, follow the uses of small doses of rhus toxicodendron."

Dr. Aulde, of Philadelphia, also speaks of the value of small doses.

My personal experience with the drug dates back two years, and although I have used much larger doses (five to ten drops of the fluid extract) than those recommended, I have seen no evil effects, and can confirm its usefulness in certain painful conditions.

My attention was called to its use by a man who had tried in vain the various "pathies," and who had spent much time and money at Hot Springs, Arkansas, in a fruitless endeavor to rid himself of what had been diagnosticated as chronic rheumatism, and who, at last, to use his own language, had "found something that had made a new man of him, and would knock the rheumatism out of any man." This "something" was the fluid extract of rhus toxicodendron in ten-drop doses. I determined to give it a trial. My first case was that of a lady, of distinctly uric-acid inheritance and diathesis, who had gone the rounds of the iodids, alkalies, and salicylates with but little effect, and who now keeps a bottle of rhus toxicodendron as a panacea, claiming that she can always control her pain by it, and that she does not think that she would have been able to be about the past winter had it not been for the relief afforded by the drug.

My second trial was in the case of a man suffering with cramps in the calves, some lumbar pain on motion, and numb spots along the terminals of some of the sciatic-nerve branches. Iodid with colchicum afforded little relief; tincture of rhus (five drops to the dose) was added, and relief was speedy.

My third case was in a man, over fifty years of age, who had suffered with rheumatism at intervals for years, and whose urine, at the time of employing the drug, showed a specific gravity of 1025, with excess of urates. He presented himself for the treatment of an eczema of the scalp and backs of the hands. The promptness with which the case responded to treatment (rhus toxicodendron being given internally) led me to attribute the results largely to that drug.

In a number of other cases I have *thought* that I derived benefit from its use, and I continue to use it as an ingredient of my prescriptions for rheumatism.

In one case of irritable bladder I have tried the drug with negative results, but in this case the specific gravity of urine was but 1010; and although no tube-casts were found in the specimens, the other symptoms all pointed to the case being one of primary chronic nephritis.

In glancing over the various conditions for which the drug has been particularly recommended, we get some order out of the chaos. The stiffness, the cramps, the rheumatic pains, the incontinence of urine, the scaly and itching skin-diseases, and even the hemorrhoids and varicose veins, are so often the results and the accompaniers of the uric-acid diathesis that it is probably in the cases depending upon such a cause that the drug proves useful.

One other very significant fact occurs as a suggestion, and that is the well-known efficacy of the allied species "rhus glabrum" in the local treatment of pharyngitis of rheumatic origin.

Respectfully yours,

FRANK W. THOMAS, M.D.

GERMANTOWN, PA.

THE TREATMENT OF CHOLERA MORBUS.

To the Editor of THE MEDICAL NEWS,

SIR: As in a great many parts of the country cholera morbus for the past few months has proved itself to be a disease of a most decidedly fatal character, I beg to suggest for the consideration of medical readers a treatment that, according to my observation, has universally been successful. I also wish to suggest that opiates, as they are generally used in this class of diseases, are, to a great extent, contra-indicated, and are frequently the indirect cause of fatal results. Only a few days ago I learned of a case, that of a young woman suffering with cholera morbus, which well demonstrated this fact. The pains and muscular contractions were very severe. Morphin was given and the doses repeated until relief was obtained. During the following day, as there was no pain, no more of the drug was administered, but the patient seemed to be sinking into a low septicemic state. During the second day she died, having rapidly developed symptoms of a ptomaïnemia. In this case there seemed to be no elimination, but consequent rapid formation and absorption of septic materials. Morphin was thought to be the cause of the stoppage of the channels of elimination, Such evidently is frequently the case in this class of diseases; ptomaïnes and like poisons are rapidly formed and absorbed, and in large quantities, as is evidenced by the conditions found: the extreme irritation of the alimentary canal, the rapidly destructive processes, the great amount of nerve-excitation, and the final collapse. Opiates should therefore be given with great caution, in as small dose as possible, and discontinued as soon as possible, because their tendency to arrest elimination from the body, especially through the kidney, is very decided. Many of us have heard physicians remark in speaking of a case of cholera morbus: "The pains and muscular contractions were so severe that I had to give several injections, each containing a large dose of morphin, before I could get any effect of the drug." If that physician had remained with his patient he would probably have found that after the pain (the antidote for opium) had ceased, his patient was in a condition of profound opium-poisoning, with tightly contracted pupils, scanty urine, a dry mouth, and slowed respiration. Such a condition in itself would require several days for the patient to recover from.

The treatment I wish to suggest for consideration and more general use is as follows: In the acute stage of the disease, given an ordinary dose of morphin hypodermatically; if, after a short while, this does not have the desired effect, administer chloroform to partial or complete anesthesia; keep the patient in a restful state for a short time, and then with perfect quiet allow him to recover from the effects of the chloroform. The morphin will, by this time, have had sufficient time to take effect, and in combination with the condition of exhaustion, will produce a state of ease or most frequently a peaceful sleep. Reaction will rapidly commence, profuse sweating, a changed condition of the entire system, and with a simple mixture of bismuth, mint, etc., the patient goes on to complete recovery. On the day following the attack, the lower bowel should be washed out by means of an enema consisting of a pint or a quart of warm water containing ammonium chlorid ʒj to the pint. The tincture of the chlorid of iron in 10 or 15 drop doses should be given three times daily following these attacks, as it seems to act in a most beneficial manner and frequently prevents relapse and inflammatory changes from taking place in the intestines. There seems to be no danger connected with the administration of chloroform in these cases, and the almost instantaneous relief given by it frequently shortens the disease and avoids a fatal termination, and, as by its use the spasmodic pains and muscular contractions are interrupted and the vomiting and purging checked, only a small amount of the opiate becomes necessary and the injurious effects of the drug are avoided.

Respectfully,

W. MAZYK MEMMINGER, M.D.

CHESTER, PA.

MORE ABOUT STENSEN.

To the Editor of THE MEDICAL NEWS,

SIR: The variations in the spelling of this anatomist's name are due to the fact that he lived in various countries and wrote or corresponded in various languages. *Stensen* is the original form, as he was born in Denmark. In Italy he was called *Stenone*. The French form is *Sténon;* the Latin form is *Stenonius*, or *Steno;* his German contemporaries used both the Latin forms.

The form *Stenonis* often occurs, and almost always in the genitive case, as, for example, on his tombstone in the church of St. Lawrence, in Florence: "*Nicolai Stenonis . . . quidquid mortale fuit . . . hic situm est.*" Hence it is clear that *Steno* is a correct form, being the nominative, third declension, like *Cicero, Ciceronis*. If Stensen ever signed himself *Nicolaus Stenonis*, it must have been according to Danish usage, the word *filius* being understood, as if he would say: *Nicolas, son of Steno*. In English we should use the original Danish *Stensen*, or else the Latin *Steno* or *Stenonius*.

It may be worth while to add that Stensen was a remarkable man, and led a very eventful life. He ranks high not only as an anatomist, but also as a geologist and as a theologian. Born in 1638, he became a Catholic in 1667 during a visit to Italy. In 1672 he was Professor of Anatomy in the University of Copenhagen. Two years later he resigned that post, returned to Italy, and, in 1675, became a priest. In 1677 he was made bishop, and placed in charge of Catholic interests in Northern Germany. There he labored till his death, in 1686. His life was that of a saint, his zeal untiring, his charity limited only by his means, his self-mortification and fasting excessive—in fact, he seems as worthy of canonization as any saint in the calendar.

As a matter of truth, the doctors *do* need a patron saint.

Very respectfully,

R. J. DOHERTY, M.D.

NEWS ITEMS.

Dr. Vignard has been elected professor of anatomy at the University of Nancy.

Dr. Tappeiner has been elected professor of pharmacology at the University of Munich.

Bayer has been made professor extraordinary of gynecology at the University of Strassburg.

Fr. Kraus has been made professor extraordinary of internal medicine at Vienna.

Paul Ernst has been made professor extraordinary of pathologic anatomy at Heidelberg.

Richard Neumeister has been made professor extraordinary of physiologic chemistry at Jena.

Podwyssotzki has been made ordinary professor of general pathology in the University of Keiff.

Oscar Loew, of Munich, has been called to Tokio to assume the professorship of botany in the University.

V. Noorden, assistant at the second medical clinic at the Charité at Berlin, has received the title of professor.

Mitropolski has been made professor extraordinary of special pathology and therapeutics in the University of Moscow.

Herman Oppenheim, formerly assistant in the department for nervous diseases at the Charité at Berlin, has received the title of professor.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee, will hold its fifth annual meeting at Chattanooga, October 17th, 18th, and 19th. An interesting program is in process of preparation.

The Southern Surgical and Gynecological Association will hold its annual meeting at New Orleans, on November 14th, 15th, and 16th. Members of the medical profession are cordially invited to attend. A successful meeting is anticipated.

Professor J. Sommerbrodt, well known for his work upon sphygmography and for the construction of a syphgmograph with regulable pressure, and for his work upon the treatment of tuberculosis with creosote, died on August 14th, at Breslau.

A New Medical School for Boston.—The trustees of Tufts College have decided to establish a medical department, to be located in Boston and to be opened during the current session to both men and women. Dr. Albert Nott is the dean and Dr. Charles P. Thayer the secretary.

The New York Medical Association will hold its Tenth Annual Meeting on October 9th, 10th, 11th, and 12th, 1893, at Mott Memorial Hall, in New York City. The program includes the following addresses, papers, and discussions:

Address of welcome by the Chairman of the Committee of Arrangements, Dr. John G. Truax; address by the President, Dr. S. B. Wylie McLeod; address, "The Medical Work of the Association during its First Decade," by Dr. John Shrady; address: "The Surgical Work of the Association during its First Decade," by Dr. Stephen Smith; "Report of Eight Cases of Placenta Praevia," by Dr. Zera J. Lusk; "Penetrating Wound of Anterior Fossa Through Orbital Plate of Frontal Bone—Recovery," by Dr. Zera J. Lusk; "The Treatment of Epithelioma and the Cancroid Ulcers by Topical Application," by Dr. Nelson J. North; "Prevention of Disease," by Dr. James G. Porteous.

"Lesions of the Pleura," to be discussed by Drs. John Shrady, Frank W. Ross, William McCollom, Edward F. Brush, J. Blake White, John G. Truax, M. K. Hogan, and Charles A. Leale; "The Surgical Treatment of Pulmonary Cavities," by Dr. N. P. Dandridge, of Cincinnati; "Remarks on Fermentative Dyspepsia," by Dr. Austin Flint; "Open Treatment of Tuberculous Diseases of the Joints," by Dr. T. M. L. Chrystie; "Bloodless Amputation at the Hip-joint," report of cases operated on by the author's method, by Dr. John A. Wyeth; "Report of a Case of Osteotomy of Both Femora for the Relief of Deformity following Ankylosis of the Hip-joints," by Dr. Reginald H. Sayre.

Address: "The Obstetric and Gynecologic Work of the Association during its First Decade," by Dr. George Tucker Harrison; "Rare Forms of Gout and Rheumatism," by Sir James A. Grant, of Ottawa, Canada; "Treatment Often Indicated after Trachelorrhaphy," by Dr. William H. Robb; "℞," by Dr. Henry D. Didama; "Ten Years' Experience in the Treatment of Cataract," by Dr. Alvin A. Hubbell; "The Treatment of Enteric Fever," by Dr. Gustavus Eliot, of New Haven, Conn.; "Voluntary Commitment of the Insane to Asylums," by Dr. W. D. Granger; "Surgical and Pathologic Memoranda," by Dr. Donald McLean, of Detroit, Mich.

"The Treatment of Appendicitis," to be discussed by Drs. Frederic S. Dennis, R. N. Cooley, Donald McLean, W. S. Tremaine, Joseph D. Bryant, and John W. S. Gouley.

"The Male Catheter, with Some Observations upon the Proper Mode of Introduction into the Bladder," by Dr. Douglas Ayres; "Researches on the Efficacy of Vaccinia after Typhoid Fever," by Dr. William Finder, Jr.; "Reflections on the Need of Close Observation of Disease and on the Value of Hygienic Therapeutics," by Dr. H. Ernst Schmid; "Unique Case of Traumatic Tetanus, with Generalization—Recovery," by Dr. John G. Orton; "A Case of Puerperal Blindness," by Darwin Colvin; "A Plea for the Non-operative Method of Treating Dysmenorrhea, Pelvic Inflammation, and Pelvic Abscess," by Dr. T. J. McGillicuddy; "An Additional Note on Nephrotomy and Nephrectomy," by Dr. E. D. Ferguson; "Fifty Operations for Laceration of the Cervix Uteri," by Dr. J. B. Harvie; "Brief Comments on the Materia Medica, Pharmacy, and Therapeutics of the Year ending October 1, 1893," by Dr. E. H. Squibb.

THE PRINCIPLES OF IMMUNITY AND CURE IN THE INFECTIOUS DISEASES.[1]

BY VICTOR C. VAUGHAN, M.D.,

PROFESSOR OF HYGIENE AND DEAN OF THE DEPARTMENT OF MEDICINE AND SURGERY, UNIVERSITY OF MICHIGAN, ANN ARBOR, MICH.

GENTLEMEN OF THE SECTION ON GENERAL MEDICINE OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS: I wish to extend to you a hearty greeting, and to thank you for your presence and for the interesting and valuable papers which many of you have prepared and which will make the work of this Section worthy of the profession of the New World.

In opening the labors of this Section, I have decided to bring before you for your consideration a theory concerning the principles of immunity and cure in the infectious diseases. I shall at first discuss the question of immunity and shall then endeavor to ascertain the differences, if there be any, between the fundamental principles upon which immunity is secured and those by which cure may be brought about.

Upon the subject of immunity many valuable contributions have been made, and theory after theory has been proposed. Both the researches and the theories have their value, that of the former being permanent and that of the latter consisting principally in suggestions that stimulate and systematize investigation. The value of a theory does not wholly depend upon its truth, but is rather to be measured by the fruitfulness of the lines of investigation that it opens. Indeed, a theory may be wholly erroneous and yet it may lead to most important discoveries.

It is not my purpose to assail or even to discuss the theories concerning immunity that have heretofore been brought forward, but to suggest one that, in my opinion, will harmonize the results already attained by scientific workers and which, I hope, will lead to other investigations.

Immunity may be natural or acquired. Natural immunity may be peculiar to the species or race, or to the individual. An example of natural immunity is that of the domestic fowl to anthrax. As has been shown by Lazarus and Weyl, the chick, even at the time of coming from the shell, is immune to the most virulent culture of the bacillus anthracis. It is true that this animal may be made susceptible to anthrax, but this is an artificially-induced susceptibility. The immunity is natural to this bird at every period of its life. Another example of racial immunity is that of the frog to anthrax. This animal can also be rendered susceptible, but again it is true that the susceptibility is artificial and the immunity is natural. Racial immunity must be inherent in the parent cell.

The natural immunity, which is peculiar to the individual, usually comes with adult life. The young are susceptible to a given disease, but adults of the same species lose this susceptibility and become immune. The young rat is susceptible to anthrax, while the adult is naturally immune, but can be rendered susceptible by exhaustive exercise. The child is highly susceptible to scarlet-fever and diphtheria; while the adult, though not wholly immune to these diseases, loses very much in susceptibility and is likely to become infected only when greatly reduced in vitality or after prolonged and aggravated exposure to the poison. The only reasonable explanation of this immunity is that it is inherent in the parent cell and comes on as naturally as do the changes in form and voice at puberty or the growth of the beard in early manhood. The evolution of the condition of immunity in these cases is due to the natural development of the functional activity of certain cells of the body. The cause of the difference in the effect of the anthrax-bacillus on the young rat and that of the same germ on the adult rat exists in the rat and not in the bacillus. A child and an adult are exposed to the Löffler bacillus from the same source; the former becomes infected, the latter does not. The germ is the same, but in the development that converts the child into the adult, the resistance with which the germ must contend has been strengthened. The immunity that comes with adult life must be due to altered cell-activity.

Ehrlich has shown that immunity from poisoning with the vegetable proteids, abrin, ricin, and robin, is transmitted from the mother to the fetus and retained by the latter for more than a month after birth, when it is quickly lost, and that the second generation fails to show any immunity. He concludes that there are two kinds of immunity: one he designates as active, the other as passive. The

[1] The President's Address, read before the Section on General Medicine of the Pan-American Medical Congress, held at Washington, D. C., September 5, 6, 7, 8, 1893.

immunity that he found to be transmitted, as already stated, from mother to child he classifies as passive, and thinks that it is due to the transmission of ready-formed antitoxins from the mother to the child and that these antitoxins being soon eliminated the immunity is lost. In active immunity he supposes that the body has acquired the property of manufacturing the antitoxins, but upon this point he is not clear. He also demonstrates that immunity may be transmitted from the nurse to the child, even when the latter is not the offspring of the former and has come from a highly susceptible mother.

This division of immunity into an active and a passive form is convenient and plausible, but Ehrlich's active immunity must be cellular in origin. Can any chemical products be elaborated in the animal body except by the activity, either direct or indirect, of cells? The most earnest opponent of vital energy—which now means cellular activity—admits that the active principles of the digestive juices are the products of specialized glands, and even the absorption of the products of digestion, which we once believed to be effected in accordance with the comparatively simple laws of osmosis, is now known to be dependent upon cellular activity. But can it be said that the temporary immunity that is transmitted from mother to child or from nurse to nursling is of cellular origin? The mother and the fetus are physiologically one, and the same is true of the nurse and the nursling. The blood of the mother flows through the fetus, and the products of the cells of the nurse feed the nursling.

Ehrlich made six experiments, in which it was found that the offspring of an immune father and a susceptible mother did not possess even a temporary immunity, and this forms another reason for his belief that immunity is humoral; but Tizzoni and Cattani have shown that an immunity to tetanus artificially induced in the sire is transmitted, though lessened in degree, to his offspring, although the mother remains susceptible; and Tizzoni and Centanni, that a like immunity to rabies may be transmitted from father to offspring. If these statements be true, the humoral theory of immunity must be modified so that the non-cellular elements can be considered as inducing immunity only by their effects upon the cellular elements. As is claimed by Ehrlich, immunity transmitted from the mother to the offspring may be explained by supposing the introduction into the latter from the former, through the fetal circulation or through the milk, of immunity-conferring substances in soluble form; but in the transmission from father to children, we can conceive only of the idea that the immunity must reside in the cellular elements of the spermatic fluid, because our knowledge of fecundation teaches us that the head of the spermatozoön fuses with the ovum and produces the child.

Artificial immunity may be induced by either of the following methods:

1. By an attack of the disease, ending in recovery. Until the discovery of Jenner, this was the only known cause of immunity, and even at present it is supposed to be, as far as man is concerned, the most potent cause. However, we now know that the period of time through which immunity thus obtained holds good has been overestimated. A man may have smallpox the second time, provided several years have elapsed since the first attack, and provided the second exposure brings him in contact with a highly virulent form of the infection, or the exposure continues through an unusually long period or happens at a time when the health is much reduced from any cause. Moreover, the period of immunity conferred by an attack of some of the infectious diseases is so short that many have reasonably questioned its existence.

It is true, I believe, that the more grave and virulent the disease may be, the greater and more persistent is the immunity that follows. I mention this in order to call attention to the fact that there is a quantitative relation between cause and effect in the production of immunity. Please bear in mind that in this method of inducing immunity the substance of the germ itself is introduced into the body. This method found a practical application in inoculation for the prevention of smallpox.

2. By vaccination with a modified and less virulent form of the infection, or by the introduction of at first a very small number of the virulent germs and successive inoculations with larger numbers.

The successful inoculations against chicken-cholera and anthrax made by Pasteur consist in vaccination with a modified germ, and the valuable investigations of Emmerich and his students in immunizing certain animals to swine-erysipelas have demonstrated the results that may be obtained by employing the virulent germ first in small numbers and then gradually increasing the dose. Again, it may be observed that the germs themselves are introduced into the body, and again it is also true that the more potent the cause the greater and more persistent the effect. The immunity that follows inoculation with a germ of full virulence is more marked and extends through a longer period than that which is induced by a vaccine.

3. By one or more treatments with sterilized cultures of the germs.

Immunity against the germs of typhoid fever, cholera, diphtheria, tetanus, hog-cholera, and several other diseases, has been secured by one or more treatments with sterilized cultures of these

germs. An interesting question arises in this connection: What constituent of the sterilized culture is it that confers immunity? All will agree that it is not due to the ptomaïnes that are present in some of the cultures. Another important class of substances present in these sterilized cultures contains the so-called toxalbumins, and to these we may possibly look for the cause of the immunity.

The teaching of some of the German investigators is that each pathogenic germ produces both toxins and a special immunizing substance. This is a very convenient theory. It supposes that each germ, while elaborating its harmful products, also produces a substance that will prevent its growth. Please bear in mind that this theory is wholly different from that which teaches that the germ may be finally killed by its own products. We know that many living things, both vegetable and animal, are killed by their own excretions, when the latter are allowed to accumulate about the former, but the theory of the production of a special immunizing substance by each specific germ is wholly different from this. The theory teaches that the germ produces a substance that confers immunity against itself and that the object in the production of this body is to confer the immunity. If we should find in nux vomica a substance that would render animals insusceptible to the action of strychnin, this fact would be analogous to the theory of the formation by each germ of a specific immunizing agent. This theory certainly presupposes a foresight and kindness on the part of the deadly germs of diphtheria and other infectious diseases which we hardly expected to find.

Fraenkel states that the toxic and the immunizing substances produced by the diphtheria-germs are two distinct bodies, the former being destroyed by a temperature of from 55° to 60° C., while the latter will bear a temperature of 70° C. or higher. He recommends that the cultures, sterilized by filtration through porcelain, be heated to from 66° to 70° C. and then be used in the production of immunity. However, he admits the possibility that the toxic substance may be converted into the immunizing body by the effect of the heat in lessening the virulence of the former, and there are many reasons for believing that this is the true explanation.

Brieger and Wassermann produced in guinea-pigs a certain degree of immunity from cholera by previous treatment with bouillon-cultures of the germ heated to from 65° to 80° C. Shall we conclude from this that the cholera-germ elaborates a special immunizing substance? Wassermann has shown that the immunizing substance in sterilized cultures of the comma-bacillus is contained in the germs themselves and is identical with the specific proteid poison of this germ. In other words, the substance that in larger doses kills, in smaller doses gives to the animal immunity from the living germ.

I think that we can answer the question as to which constituent of sterilized cultures gives immunity with considerable confidence if we recognize the following facts:

1. Marked artificial immunity to an infectious disease has not been obtained except by the introduction into the animal of the germ-substance, either enclosed in the cell-wall or in solution.

2. Sterilized cultures contain the germ-substance in one or both of these forms.

3. The same immunizing substance exists in the bodies of bacteria grown on solid media and killed by the action of chloroform.

4. The same immunizing effects, varying, however, in degree, are obtained with the bodies of dead bacteria morphologically intact or in solution, with living bacteria modified and reduced in virulence, and with very small numbers of the virulent germ.

With these demonstrated facts before us, I am ready to believe that the immunizing substance is a constituent of the bacterial cell itself; and as each kind of germ has its own peculiar poison (which in small doses confers immunity), this poison cannot come from the cell-wall; nor is it really a split product of the germ's action, but it is the essential characteristic part of the cell—that part which gives to the germ its distinctive properties. I believe that it is the nuclein.

The three methods of inducing immunity, which we have mentioned, reduce themselves to one and the same principle, *i. e.*, the introduction of germ-nuclein into the body.

The immunity that results from an attack of the disease is caused by the introduction of germs, living and more or less virulent; that which comes from vaccination is due to the introduction of germs, living but modified and reduced in virulence or administered in small quantity; that which is secured by one or more treatments with sterilized cultures is secured by the introduction of germ-nuclein so modified that it is no longer capable of reproducing itself.

Understood in this way, the production of immunity from disease becomes analogous to that which Sewall obtained with the venom of the rattlesnake, and Ehrlich with ricin and abrin.[1] Indeed, the venom of snakes, the poisonous vegetable proteids, abrin, ricin, and robin, and the cellular proteids of the pathogenic germs, have many characteristics in common. All are proteids, intensely

[1] Ehrlich tells us that one gram of ricin would be sufficient to kill one and one-half million guinea-pigs. The poison of tetanus can scarcely be more virulent.

poisonous; they lose their poisonous properties on being boiled in aqueous solution; different species of animals vary in their susceptibility to these poisons; they are much less poisonous when given by the stomach than when injected hypodermatically (the difference in the amounts necessary to produce fatal effects when administered by these different avenues being much greater than with either the vegetable or the putrefactive alkaloids). The immunity which is secured by all of these substances is gradually lost. A further resemblance between the vegetable and the bacterial poisonous proteids is to be found in the fact that immunity to one of these substances obtained from a given source does not confer immunity to another from a different source. An animal rendered immune to ricin is still susceptible to abrin, and one rendered immune to tetanus remains susceptible to diphtheria. Whether or not an animal made immune to the venom of one species of poisonous snake would still be susceptible to the venom of another species is not, so far as I have any knowledge, known.

The immunity obtained by Brieger, Kitasato, and Wassermann by inoculating with cultures grown in thymus-bouillon is due to the same principle that governs in the methods already discussed. Immunity was secured by the introduction of a modified bacterial proteid, the lessened virulence of the poison being due to a certain constituent of the thymus-extract. The nature of this constituent of the thymus gland will be discussed later. That the tetanus-germ is physiologically modified by its growth in the thymus-bouillon was demonstrated by the fact that it failed to produce spores in this medium, as well as by its diminished virulence.

Behring rendered about 40 per cent. of the animals experimented upon immune to tetanus and diphtheria by previous treatments with small amounts of cultures to which iodin trichlorid had been added. This is also most probably due to the fact that the chemical compound modified the bacterial proteid. Behring himself gives this explanation. He also states that it is a matter of indifference whether he employed cultures containing bacteria or those that are germ-free. By the latter he means cultures in which the germs have been deprived of their vitality or from which they have been removed by filtration. In either case the cell-proteid of the germ is present either in the form of cells or in solution, and this cellular proteid is the agent that induces immunity.

5. By treating a susceptible animal with the blood-serum of an immune animal.

Strange as it may seem, the principle upon which immunity is secured when the blood-serum of an immunized animal is injected into a susceptible one is essentially the same as that which holds good in the methods already discussed. A horse is rendered immune to tetanus by previous treatment with the modified bacterial proteid of that disease. As a result of these treatments a tetanus-antitoxin is generated in some organ or organs of the horse and circulates in its blood. When the blood clots this antitoxin is found in the serum, and if the serum be injected into a mouse in sufficient quantity, this animal becomes for the time being immune to the tetanus-poison, provided that the poison is not introduced in quantities so large that it will not be destroyed by the antitoxin that has been brought over from the horse.

The immunity actually does not belong to the mouse. It still belongs to the horse. It is stolen property, and will soon be lost. The cells of the horse, not those of the mouse, make the antitoxin. The mouse for the time being becomes physiologically a part of the horse, and it is by virtue of this relationship that the former is for the time being immune to tetanus.

The quantity of blood-serum that must in this supposed case be transferred from the horse to the mouse in order to give immunity to the latter will depend upon the relative weight of the animals and upon the degree of immunity possessed by the horse; and the degree of immunity induced in the mouse will be governed by these same factors.

Subsequent inoculation of the mouse with the tetanus-nuclein, in order to prove its immunity, may awaken the cell-activity of this animal, and then the immunity belongs to the mouse; but this is not true before the introduction of the germ. Behring has understood this point and has given this explanation.

We have seen that in all cases the cause that brings into existence the condition of immunity is a bacterial proteid. Now in order that this inciting cause may induce the condition of immunity, it must act upon something. We say that it acts upon the animal, but with this general statement we cannot be satisfied. Upon what organs of the body does it act? This question can be answered only tentatively at present, and the answer is founded upon the fact that we suspect that certain organs are acted upon, because certain results follow. Certainly, the cell-activity of the invaded host must be altered. The cells upon whose altered activity immunity depends are probably those of the spleen, the bone-marrow, the thyroid and thymus glands, and possibly other glandular organs. As already stated, this answer, which it may be noticed is given with reserve, is founded upon inference rather than upon direct demonstration. However, experimental evidence on this point is not wholly wanting. The disastrous effects that follow the removal or atrophy of the thyroid gland, and the wonderful alleviation

following the treatment of myxedema with extracts of this gland, are now well known to every member of the profession. These facts show that this gland must furnish an antitoxin, which is essential to the preservation of health and life. Lindemann has shown that the normal dog will bear doses of caffein which cannot be borne by the same animal after extirpation of the thyroid. Tizzoni and Cattani have found that rabbits from which the spleen has been removed cannot be immunized to tetanns.

These facts, together with others to be mentioned further on, render it altogether possible that the organs mentioned are concerned in the production of immunity.

Here an interesting question arises: In what way are these organs concerned in the production of immunity? Do they elaborate antitoxins, and if so what can be said about the nature of these antitoxins? These are questions in which I have been deeply interested for some time, and which I have attempted to solve. In this attempt I have borne in mind the fact that these organs are the sources of the nucleated white blood-corpuscles. Do these corpuscles contain a germicidal or antitoxic substance, and if so what is its nature? They differ from the red corpuscles in being nucleated, and from all other tissues in containing proportionally larger and more numerous nuclei. The chief chemical constituent of nuclei is a substance called nuclein, some of the general properties of which are known to physiologic chemists. Can it be that nuclein is the germicidal or antitoxic substance? Have the nucleins in general or as a class any germicidal action? As methods of isolating the nucleins are known, this question can be answered by experimentation. But before we begin with our experiments we will ascertain whether or not we can find that any such properties have ever been observed in the nucleins. I find that others have thought of the possibility that the nucleins may play a role in the production of immunity. In their very valuable paper, *Ueber Immunität und Giftfestigung*, Brieger, Kitasato, and Wassermann have the following to say:

"With the idea that the highly vitalized leukocytes or lymphocytes are concerned in the destruction of bacteria within the body, and that antitoxin substances are formed by the breaking down of these cells, we began our experiments with the best known and relatively most thoroughly studied decomposition-products of the white blood-corpuscles, the nucleins and the nucleinic acids, which we had prepared directly from pus. Later, Prof. Kossel had the goodness to make like preparations for us from pus and yeast, for which we again give him our best thanks. Cholera-cultures served us for the most part in these investigations. However, we found neither a decrease in the toxicity of these cultures on being treated with the nuclein bodies, nor could we render animals proof against the poison by previous treatment with cholera-cultures to which nuclein had been added.

"*A priori*, these negative results were probable because the preparation of the nucleins and nucleinic acids requires such powerful chemical manipulations that the resulting substances could only be such as would be devoid of all active energy. Moreover, we knew from previous researches with the bacterial poisons how susceptible similar compounds are to apparently indifferent chemicals, like alcohol, ether, etc. . . . . Therefore, we concluded to prosecute our studies with simple, aqueous, feebly alkaline extracts from organs rich in cells."

Having reached these conclusions, Brieger and his co-workers proceed to make their investigations with a feebly alkaline extract of the thymus gland.

This is the only instance, so far as I know, in bacteriologic literature, up to the time of the first publication of my results, in which anyone has even suggested that the nucleins might be germicidal or in any way concerned in the protection of the body against bacterial invasion, either in the production of immunity or in effecting a cure; and it must be admitted that this reference did not afford much encouragement to my theory. However, I was not altogether discouraged, because certainly no one should expect to find a highly active nuclein in pus-cells, the nuclein of which in the very formation of pus has been altered, probably more deeply and destructively than would result from "the apparently indifferent chemical reagents, alcohol and ether." As these German investigators failed to tell how the yeast nucleinic acids with which they experimented had been prepared, the hope was left to me that in this might rest the explanation of their failure. This hope found support in the fact that in the preparation of their thymus extract they heated it to 100° C., and certainly this temperature must have had quite as much effect in depriving the living nuclein of its energy as indifferent chemical reagents could have had. The fact that they obtained the results which they did with this extract after it had been heated to 100° is an evidence of the power originally possessed by the nuclein of this gland, for I think that it must be admitted, from the results which I have obtained, that the active agent in the thymus-extract with which Brieger and his co-workers experimented is a nuclein.

At first I tried to prepare an active nuclein from compressed yeast, but the results were not satisfactory. Compressed yeast contains a large amount of water and starch. The large proportion of the first-mentioned constituent caused a very small yield of nuclein, and there were many difficulties in the complete separation of the starch. There were, however, two other and more serious objections to the use of compressed yeast. The first of these is due to the fact that such yeast contains bacteria to begin with, and the task of preparing an active nuclein from it is similar to that of obtaining the same sub-

stance from pus. The second difficulty lies in the fact that compressed yeast contains many dead cells, and an active nuclein can be obtained only from living, healthy cells.

Next, I attempted to prepare an active nuclein from the ordinary brewer's yeast. But I found this also contaminated with bacteria.

At last, I was supplied, through the kindness of the Ann Arbor Brewing Company, and through Dr. Laasche, of Chicago, with unlimited quantites of pure cultures of yeast, without cost, and my thanks are due to the manager of the company named and to Dr. Laasche for this material.

With the aid of Drs. McClintock and Novy I have succeeded in preparing active nucleins not only from yeast, but from several organs of the body as well, and as the further elaboration of the principles of immunity and cure in the infectious diseases depends so closely upon the action of these nucleins, I must be permitted to go somewhat into detail concerning their preparation, their chemical reaction, germicidal properties, and physiologic effects:

YEAST NUCLEIN.—The cells from pure cultures of yeast are washed with sterilized water, then treated with a 5 per cent. solution of potassium hydrate, and filtered through paper (the Falten filter-paper of Schleicher and Schull being used for this purpose). Sterilization of the filter-paper is not necessary. The filtrate is feebly acidified with hydrochloric acid, and the proteid precipitated with 96 per cent. alcohol. The precipitate is washed with alcohol by decantation until the supernatant fluid remains colorless. The precipitate is then collected upon a filter, and, after all the alcohol has passed through, it is dissolved in very dilute potassium hydrate (0.25 to 0.50 per cent.). That this solution contains other proteid bodies besides the nuclein is shown by the fact that it promptly responds to the biuret, xanthoprotein and Millon reactions, but notwithstanding these impurities, solutions of nuclein prepared in this manner have markedly germicidal effects.[1]

A purer form of yeast-nuclein may be obtained by digesting out the other proteids from the alcoholic precipitate with hydrochloric acid and pepsin, in the manner which will be described in the preparation of animal nucleins.

The following experiments, in which the impure nuclein-solution was used, will illustrate its germicidal effects. In all cases the nuclein-solution was diluted with sterilized normal salt-solution, then placed in quantities of five c. c. in sterilized test-tubes, inoculated with the germs mentioned in each experiment; and plates made after varying intervals of the time show the germicidal effects. In making the plates, a platinum loop of constant size (with a diameter of two millimeters) was employed.

In the first four experiments, two c. c. of a 0.25 per cent. alkaline solution of nuclein, containing 0.9 milligram of impure nuclein per c. c. were diluted with three c. c. of normal salt solution, inoculated with the germ, and plates made as follows:

EXPERIMENT I.

Staphylococcus pyogenes aureus.

Time, . . .	5 min.	1 hr.	2 hrs.	14 hrs.	23 hrs.
No. of colonies,	1,110	0	0	0	0

EXPERIMENT II.

Staphylococcus pyogenes aureus.

Time, . . .	5 min.	1 hr.	2 hrs.	14 hrs.	23 hrs.
No. of colonies,	1,490	20	0	0	0

The strength of alkali in this dilute nuclein-solution, not taking into consideration the fact that some of the alkali is absorbed by the nuclein, is 0.1 per cent. The culture of the aureus used in these experiments grows abundantly in a 0.5 per cent. aqueous solution of potassium hydrate.

EXPERIMENT III.

The same solution nuclein as the preceding inoculated with the staphylococcus pyogenes albus.

Time, . . .	Immediate.	20 m.	1 h.	2 h.	17 h.	24 h.
No. of colonies,	680	0	0	0	0	0

EXPERIMENT IV.

The same solution of nuclein, inoculated with the bacillus anthracis without spores.

Time, . . .	Immediate.	20 m.	1 h.	2 h.	17 h.	24 h.
No. of colonies,	45	0	0	0	0	0

The total amount of impure nuclein in the five c.c. of dilute solution employed in these experiments was 1.8 milligram, or the strength of the solution was 1 part of impure nuclein to 2777 parts of water.

EXPERIMENT V.

The five c. c. used in this experiment contained ten milligrams of impure nuclein dissolved in 0.1 per cent. of potassium hydrate. The germ was the aureus.

Time, . . .	Immediate.	30 min.	1 h.	3 h.	5 h.	24 h.
No. of colonies,	Countless.	5,000	550	490	400	0

Many other experiments similar to this were made, but as the results were uniformly the same, repetition is unnecessary.

EXPERIMENT VI.

A loop of tuberculous sputum, showing from forty to sixty bacilli in each field when stained, was stirred up in beef-tea, allowed to stand for twenty-four hours, and injected into the abdominal cavity of guinea-pig No. 1. Another loop of the same sputum was added to a solution of thirty milligrams of impure yeast-nuclein in 0.08 per cent. of potassium hydrate, and this was also allowed to stand in the incubator at 38° for twenty-four hours, and then injected into the abdominal cavity of guinea-pig No. 2.

At the expiration of fourteen days both of these animals were killed. The omentum of No. 1 was a tuberculous mass throughout; while No. 2 showed not the slightest evidence of the disease.

The solutions of impure nuclein in dilute alkali may be kept at ordinary temperature in glass-stop-

[1] In fact, this is a nucleo-albumin rather than a nuclein.

pered bottles for months, without undergoing putrefactive changes. I have now one bottle of such solution, which was prepared on the 20th of December, 1892. One hundred and fifty milligrams—possibly a much larger quantity—of this nuclein may be injected, when properly diluted, under the skin, without any inconvenience, save slight pain at the time of injection and some soreness in the part, which disappears after a few hours. The last statement is true when the initial dose is small and the quantity is gradually increased. In one case, in which I gave an initial injection of twenty-five milligrams, an erysipelatous redness, as large as a saucer, appeared in a few hours. The temperature went up three degrees and the patient felt some nausea. The redness, however, rapidly disappeared, the temperature fell, and two days later I repeated the same dose without any ill effects. In some other instances I have noticed an elevation of temperature within an hour or two after the injection. This has happened only in those patients in which the size of the dose has been rapidly increased. Yeast-nuclein appears at times to have a cumulative action. When employed in large doses for several consecutive days the temperature may be markedly elevated.

Testicular Nuclein.—I have prepared this from the testicles of the bull, dog, guinea-pig, and rat. The testicles are stripped of their investing membranes as soon as removed, rubbed up and extracted repeatedly with a mixture of equal volumes of absolute alcohol and ether. Then the testicular substance is digested for some days (until the supernatant fluid fails to respond to the biuret test for peptones) at 40° C. with pepsin and 0.2 per cent. hydrochloric acid. The undigested portion, which contains the nuclein, is collected on a filter-paper and washed first with 0.2 per cent. hydrochloric acid, then with alcohol. Finally it is dissolved in a 0.5 per cent. solution of potassium hydrate and filtered through a Chamberland filter, without pressure.

This solution is clear, more or less yellow, and feebly alkaline. On the addition of nitric acid a white precipitate forms and dissolves colorless in the cold on the further addition of nitric acid. This nuclein does not give the biuret reaction, but does respond to the Millon test. The nitric acid solution of the precipitate becomes yellow on the addition of ammonia.

This nuclein also has germicidal properties, as is demonstrated by the following experiments:

Experiment I.

A solution of nuclein of unknown strength, obtained from the testicles of a bull, was diluted with four volumes of physiologic salt-solution, inoculated with the bacillus anthracis, and plates made, with the following results:

Time, ...	Immediate.	30 m.	1 h.	2 h.	3 h.
No. of colonies,	730	6	0	0	0

Experiment II.

The same solution inoculated with the aureus.

Time, ...	Immediate.	30 m.	1 h.	2 h.	3 h.
No. of colonies,	Countless.	2,850	0	0	0

Experiment III.

A solution of nuclein from the testes of a dog diluted with four volumes of salt-solution and inoculated with the staphylococcus pyogenes aureus.

Time, . . .	Immediate.	20 m.	1 h.	2 h.	17 h.	24 h.
No. of colonies,	680	0	0	0	0	0

Experiment IV.

Another solution from the same source diluted in the same manner and inoculated with the aureus.

Time, ...	5 min.	1 hr.	2 hrs.	14 hrs.
No. of colonies,	250	0	0	0

Experimemt V.

As several authors have reported the finding of a germicidal substance in the glycerin extract of certain organs, the following experiment was made: The testicles of a white rat were stripped of their tunics and extracted with glycerin. This extract, diluted with four volumes of salt-solution and inoculated with the aureus, gave the following results:

Time, ...	5 min.	1 hr.
No. of colonies, ...	1,240	75

I have used this solution of nuclein in doses of from five to twenty drops, diluted with saline solution, hypodermatically in one case of nervous exhaustion, and from the markedly stimulant effects observed, I conclude that it is to the testicular nuclein that the Brown-Séquard fluid owes its action. These effects, as I have observed them, with the very small doses given, soon pass away, but they are extraordinary.

Thyroid Nuclein.—The fresh gland is cut into fine pieces, extracted with alcohol and ether, and then digested with pepsin and 0.2 per cent. hydrochloric acid at 40° for two or three days, the digestive fluid being renewed several times and the digestion being continued until the supernatant fluid fails to respond to the biuret test. The undigested residue is collected upon a filter, washed with 0.2 per cent. hydrochloric acid, then with alcohol and ether, and finally dissolved in 0.25 or 0.5 per cent. solution of potassium hydrate.

This solution of nuclein gives a faint opalescence on the addition of nitric acid. It does not color on heating with nitric acid, but becomes markedly yellow on the further addition of ammonia.

A 0.25 per cent. alkaline solution of this nuclein dissolved with an equal volume of physiologic salt-solution and inoculated with the aureus showed a germicidal action as indicated in the following figures:

Time, ...	Immediate.	10 min.	1 hr.	20 hrs.
No. of colonies,	805	830	256	0

. I have not tested the effects of this nuclein on man.

EGG-NUCLEIN.—The yolk (two dozen eggs furnish a convenient amount of material to work with in the laboratory) is extracted with absolute alcohol repeatedly and until all the coloring-matter is removed. The substance is then digested for some days with pepsin and 0.2 per cent. hydrochloric acid. (In one instance I continued this digestion for four weeks, hoping to obtain a residue which would not respond to the biuret test, but this desire was not attained.) The undigested portion is collected on a filter, washed with dilute hydrochloric acid and subsequently with alcohol, and then dissolved in 0.25 or 0.50 per cent of potassium hydrate and filtered through porcelain.

This solution of egg-nuclein is colorless or slightly yellow. Nitric acid produces a slight, white precipitate, which dissolves in excess; this does not turn yellow on heating, but does so beautifully on the subsequent addition of ammonia.

EXPERIMENT I.

A solution of this nuclein in 0.25 per cent. potassium hydrate was diluted with four volumes of saline solution, inoculated with anthrax, and the following figures show the germicidal effect:

Time, ...	Immediate.	30 m.	1 h.	2 h.	3 h.
No. of colonies,	2,490	350	30	0	0

EXPERIMENT II.

Another portion of the same dilution, inoculated with the aureus, gave the following results:

Time, ...	Immediate.	30 m.	1 h.	2 h.	3 h.
No. of colonies,	Countless.	2,000	137	0	0

Besides the foregoing sources, I have obtained nucleins from the brain and the spleen, and these also are germicidal in their action. I have not tested the physiologic effects of the nucleins from the egg, brain, or spleen on man. I have employed the egg-nuclein on guinea-pigs, without any apparent deleterious effects.

I have introduced this sketch of some experimental work, illustrating a few of the many experiments that I have made bearing on this point, for the purpose of giving some correct idea of the ground upon which I make the assertion that nucleins are powerful germicides.

I think that all will now agree with me that the nuclein-forming organs of the body most likely have some concern in the production of immunity.

The nucleins formed by these cells or in these organs pass into the blood partly in solution and partly in the form of the multinuclear white corpuscles—the so-called phagocytes.

The germicidal properties of blood-serum are due to soluble nucleins. This statement rests upon work done by McClintock and myself, and the evidence upon which it is founded will be set forth in a paper to be read before this section.[1]

(To be continued.)

A PROBLEM IN ABDOMINAL SURGERY: WHY IS THE UTERUS RETAINED AFTER THE OVARIES ARE REMOVED?

BY HARRIS A. SLOCUM, M.D.,
PROFESSOR OF GYNECOLOGY IN THE PHILADELPHIA POLYCLINIC.

THIS question may at first seem to be a startling one and to savor of that ultra-radicalism which the more evenly-balanced minds in the medical profession are constrained to avoid, but a careful consideration of the facts that have been presented to my observation have led me, at least, to the conclusion that such is not the case; that, on the contrary, there are several good reasons for propounding such a query, and that our patients may be benefited in the future if we will take steps to inform ourselves upon such points as bear directly upon the subject.

This suggestion has been reached by observing the large number of women who have continued to suffer after the removal of the ovaries. On close questioning their pains are found to be just, or nearly, the same as before the operation. Sometimes they are described as being even worse, and, although we should use great discrimination in accepting the statements of a patient who considers herself to have been badly treated, yet I am sure that such suffering as remains is positive and great, while allowing for all exaggeration, conscious or unconscious, on the woman's part.

Having been assured by the operator, and honestly no doubt, that they would certainly be cured and freed from pain if they would consent to an operation, these women have submitted to it hopefully as the last thing to be done after weary months or years of treatment, and have too often failed to obtain the expected relief within varying periods of from six months to three years. These patients wander from one physician to another, and from hospital to hospital, with their pains not only unrelieved but gradually losing hope of relief; and as a rule, the physicians themselves, having learned that an abdominal section has been performed and the ovaries removed, yet the sufferings are just as severe, are often at a loss as to what should be done, and mentally consign the case to the class of "incurables," while they are writing a tentative prescription to afford relief for a time at least.

Continued suffering after removal of the appendages may depend upon a number of causes, and it is distinctly not claimed in this article that hysterec-

[1] To be published in THE MEDICAL NEWS.

tomy will prevent or remove them all, but, if performed under the conditions to be mentioned, I believe that it will certainly prove a legitimate and satisfactory method of dealing with one of the common sources of pain to the patient and disappointment to the surgeon.

Before determining upon the utility of the measure indicated in the title, a brief consideration is required of antecedent matters, the proper understanding of which will greatly influence us in forming our opinion regarding it.

First, as regards the physiologic relation of the uterus (and its appendages) to the body. The genital organism, considered in respect to the individual, is not at all essential to that individual's life. It is a specialized department designed for the purpose of continuing the species, and is not a vital part in itself. The function of the ovary is to to form the ovum; the *raison d'être* of the uterus is to receive and nourish the fecundated ovum; and menstruation is but a side-issue—the removal of furniture for a tenant that was not prepared to remain.

These organs contribute nothing to the maintenance of the body, and their removal, if not forbidden by danger to contiguous parts, evidently cannot affect the general nutrition, interfere with self-support, or lessen the powers of resistance to adverse influences.

To their tremendous importance as factors in influencing the moral life of an individual, and the latent influences that they exert over her equilibration and well-being, is given full recognition and acknowledgment; but these phases are not now under consideration, our only object at present being to determine upon the relative value of the procreative system as a vital part, or as necessary to the existence of the body.

Much testimony from various sources might be adduced to show the relative unimportance of the genital system *per se* to the general organism, but every physiologist will recognize this; and the physician, when recalling that we are dealing with a diseased and perverted system, will hardly fail to do the same.

The dominant nerve-supply of the uterus is that of the sympathetic, but it is probably of direct and physiologic use only during pregnancy, because the unimpregnated uterus is really an immature organ, and doubtless the nerve-fibers and ganglia are equally immature, so far as a correct performance of their duties is concerned, and this imperfect nerve-action may largely account for the predominance of the so-called hysterical element in women. It may be presented, in rebuttal, that pregnancy, when the nerves *are* developed, often causes still greater abnormal developments of mentality; but we should remember the artificial surroundings and accompaniments of the majority of gestations in civilized life, and the vast number of pregnancies that have for years been preceded by symptoms of uterine disease, permitting the inference that the muscular home of the fetus is in an imperfect condition for its work from the very beginning.

A complete knowledge of the power that this nerve-supply to the uterus exercises over the body in a healthy woman has not yet been demonstrated, but the untoward effects when these nerve-endings are disturbed are often manifest, and many cases in my experience present evidence that such disturbance exists in a large number of those who have already had their tubes and ovaries removed.

Let it be remembered that in the greater number of cases in the class to which I refer, inflammation has established itself not only in the tubes, but also in the lining membrane of the uterus, and in the canal tunnelling the uterus and leading to the tubes.

In the hands of the advanced operator of to-day this fact is recognized, and an effort is made to meet it. The uterus is curetted and drained and the appendages are subsequently removed, but the tunnel cannot be reached, and it remains to form a perpetual point of departure for subsequent attacks of endometritis, extending to an organ which is as disposed as ever to participate in such inflammation, whose nerve-supply is ever ready to indiscriminately affect the body adversely, causing the old pains and added reflexes, and which is yet deprived forever of its functions.

It is like an eye that cannot see, yet would bring about all the untoward results of a vicious refraction; like an ear that can no longer hear, yet tortures the body with vertigo and tinnitus; or like a brain that can no longer direct, yet brings to bear upon the body all the vagaries and illusions of an undeveloped or imperfect center.

The next question is: Would the removal of the uterus add to the mortality? Practical experience in this direction shows that the length of the operation is not greatly increased. If an operator begins an abdominal section with the direct intention of removing uterus and appendages, after having ascertained that the latter are irretrievably diseased, the application of another ligature to each uterine artery, the separation of the bladder from the uterus, and the severing of the latter according to Baer's method, with the subsequent attention to peritoneum and cervix, would take from ten to fifteen minutes. So much for the time. The testimony of many writers is to the effect that they are surprised at the small amount of shock sustained by their cases of hysterectomy. In the records of English and American journals, at the hands of many of my confrères and in my own experience, the same holds true.

It seems to shock the patient less to remove the uterus with its appendages than to remove the latter

alone, and I think the explanation lies in the fact that we at the same time remove the terminal nerve-filaments of the inferior hypogastric plexus of the sympathetic; that is to say, the active, working extremity of the nerve. A moment's consideration will recall the difference in receptivity to impressions between that possessed by the sensitive, developed nerve-ending and its trunk. A ray of light falling on an inflamed retina might cause agony, yet the cut end of the optic nerve might be exposed to ten times the amount without recognizing its existence.

Without doubt, the time required in operation is not greatly increased, while the subsequent shock appears to be really lessened.

Another danger that threatens is hemorrhage. In a paper read at the last meeting of the American Gynecological Association several deaths were reported from hemorrhage caused by slipping of the ligature, but one acquainted with the correct method of performing Baer's operation will readily see that if this is carried out as it should be, such a thing would be practically impossible, as the ligatures have tissue on both sides and cannot slip; they may become untied, and so might any ligature. Sepsis from the cervical canal, again, when the operation is rightly performed, is unknown to me. Reasoning from a knowledge of the condition of the tissues in the different parts, one would expect to have less danger from sepsis than if the cut ends of the tubes are presented to the peritoneum, for these are the very parts in which the disease is pronounced, while the cervix is generally healthy and would be far less likely to contain germs, and would, moreover, act as a far better drain than the occluded stump of tube and cavity of the uterus. When the uterus, tubes, and ovaries are removed *en masse* the infected cavity is not opened, the pus is sealed off in the upper part and cannot come in contact with the tissues.

Undoubtedly oöphorectomy has been performed, in many cases with subsequent cures, and my proposition is presented neither to disparage previous attainments, nor as a measure to be followed indiscriminately and without judgment, but because my experience with hospital and dispensary post-operative sufferers has led me to inquire into the causes of their sufferings, and I find that although some of these are due to adhesions, fistulæ, and hernias, the principal source of trouble is the persistence of a chronic metritis or endometritis, almost always involving the cornua, inaccessible, and practically incurable.

My proposition, therefore, is that we should consider the propriety of removing the uterus, as well as the appendages, in those cases in which both ovaries and both tubes are diseased beyond repair, and when their removal is clearly indicated; inasmuch as the uterus, if retained, is not only absolutely useless, but often becomes a menace to the system.

This measure has been advocated by other writers. Since beginning this paper my attention has been called to a statement made by Dr. B. F. Baer in an article in the *New York Journal of Gynecology and Obstetrics* for September, 1893; but my opinion has been reached almost entirely through my own observation.

I have said that this measure is not to be followed indiscriminately and without judgment. Cases will present themselves in which it would be unwise to carry it out, and each operator must exercise his judgment with each case; but the general proposition holds true, and one need but hear the symptoms and examine the tender, enlarged uterus in these barren patients to feel convinced that this organ should have been taken away when the abdomen was opened, as it has left the patient only a companion to her appendix vermiformis—useless, and possibly dangerous.

One question yet remains to be answered. Granted that patients are not having their lives risked to a greater degree than in oöphorectomy, have those patients who have already undergone hysterectomy given evidence of the benefit we are striving to obtain?

A just conclusion is difficult to reach for two reasons: first, because of the varied methods of performing the operation, and second, because of the character of the previous disease. The old method of constricting the cervix—a barbarous and imperfect surgical procedure in the light of to-day—often subjected the tissues to a painful and perilous tension and invited hyperemia; adhesions to the anterior abdominal wall were common, and we all know the malevolent influence of adhesions; the amount of uterine tissue requisite for the application of the *serre-nœud* was such that the endometrium was often encroached upon, and the stump that remained had poured into it the vast volume of the uterine artery—an inciter to riotous cell-action.

The greater number of hysterectomies have been performed by this or some similar method down to a recent date, and I think that a judicious observer would hesitate to draw a conclusion as to the results of an ideal hysterectomy from patients who had been subjected to one of the old methods of operation.

The character of the previous disease is so important a factor that it would be gross negligence to ignore it. A hysterectomy for carcinoma might readily fail to bring about such a restoration to health as one would desire. It is almost impossible to be sure that the whole of the diseased tissue has been removed. To give a just verdict, the operation should be the one approaching the nearest to surgical perfection, and the cases should be of the

character specified. Those that I have seen answer the question in the affirmative, *i. e.*, they *have* given evidence of such benefit.

An old Irish woman who was cleaning the clinic-room, saw a jar containing a specimen, and asked what it was. On being told that it was a womb with tumors attached, taken from a patient who was now well and working hard, she replied: "Well, well, she won't live long. Nobody can without their womb. Everybody knows that."

This dictum from an ignorant person is a faint reflection of the attitude of the medical world in general. The uterus has long been labelled *noli me tangere*, for reasons too numerous to be recounted here, and I am an advocate of such a policy so far as indiscriminate operation is concerned, feeling that it is our duty to our patients to make every effort to bring about a normal condition without recourse to surgery; but when the latter is shown to be inevitable, it is equally our duty to do the work as thoroughly as possible.

So far as I have been able to observe, removal of the uterus, when the ovaries and the tubes are doomed, does not lessen the feminine attributes of a woman. The knowledge that all diseased tissue has been removed and no useless organ allowed to remain is a comfort to the surgeon; its absence does not appear to predispose to vaginal descensus or other lower pelvic disorder, and, by allowing the minimum of blood to the cervical stump, just sufficient to nourish it, reduces the chances of epithelioma—the dreaded bane of so many women—almost to the vanishing-point.

ORIGINAL LECTURE.

LEPROSY.

Abstract of a Clinical Lecture, delivered August 9, 1893.

By ALBERT ABRAMS, M.D.,
ADJUNCT TO THE CHAIR OF CLINICAL MEDICINE, COOPER MEDICAL COLLEGE; PATHOLOGIST TO THE CITY AND COUNTY HOSPITAL, SAN FRANCISCO.

I WISH this morning to show you a few cases of leprosy. Before so doing, however, let me review some of the main points regarding the symptomatology of the disease.

In your text-books you will find many synonyms of leprosy; they are chiefly *Lepra Arabum*, *Elephantiasis Græcorum*, *Leontiasis* of the ancient Greeks, and *Zaraath* of the Hebrews. This multiplicity of terms subserves no other purpose than that of interfering with the proper study of the history of the disease.

Leprosy is a chronic infectious disease, presenting under the microscope essentially the same histologic elements as we find in the granulation-tissue of new-growths.

Two types of leprosy are usually recognized: tubercular and anesthetic leprosy. Both types present certain prodromal symptoms of an indefinite nature, such as languor, drowsiness, loss of appetite, chills, etc. Tubercular leprosy, as a rule, is preceded by spots which you see in this case, at first of a pale or bluish-red hue, while later the maculæ become pigmented. This macular condition may precede tubercular leprosy by many years. If, as often occurs, the maculæ become the seat of tubercles, the skin becomes thickened and raised, leading to the formation of nodules varying in size from that of a pea to that of a walnut. The most frequent seat of these nodules or tubercles is on the skin of the face or hands, although the subcutaneous tissues and the parenchyma of the viscera are not exempt from invasion. When the nodules develop upon the face they may be circumscribed or conglomerate. In the latter case they give the face a peculiar leonine expression, which is symptomatic of the name used by the ancient Greeks, viz., *leontiasis*. The tubercles may form on the mucous membranes of the eyes, nose, mouth, throat, and larynx. In the case before us you find the palate deformed by a dense infiltration of leprous new-formation. Like all new-formations the tubercles undergo certain retrograde changes. They may atrophy, soften, and form abscesses, or they may undergo ulceration; leading, in the latter instance, to what are termed leprous ulcers. In many instances they may remain stationary, and undergo no change for many years. When they soften or ulcerate, they are accompanied by all the somatic symptoms of septic infection.

The second variety is known as anesthetic leprosy, as well as by the terms, lepra mutilans and elephantiasis glabra; this type of leprosy may develop as such from the beginning, or it may follow or accompany the tubercular variety of the disease. The nervous symptom in the beginning is usually hyperesthesia, followed by anesthesia of the involved districts. Trophic changes of the skin accompany this type of leprosy. In this case you will observe nearly all the trophic changes. On the palms of the hands the skin is tense, glossy, and parchment-like, whereas on the dorsum of the hands the skin is wrinkled and bullæ are present. At certain points you notice the absence of pigmentation, whereas on the other parts the pigmentation is increased. On account of the trophic changes, coupled no doubt with traumatism, the fingers and toes fall off, leaving painful stumps; in many cases all the fingers and toes are lost in this way. Mutilation occurring after this manner is spoken of as lepra mutilans. The cases I now show you are of the anesthetic type. You will note that there is anesthesia as well as analgesia of the hands and forearms; there is no regularity in the distribution of this anesthesia; in other words, the distribution of the anesthesia does not follow the course of any particular nerve or nerves. If you palpate the ulnar nerve of this patient you will find it thickened and marked by nodosities.

These changes in the nerve are the result of a perineuritis. The nerves most frequently involved by perineuritis are the ulnar, the median, and the peroneal.

BACTERIOLOGY.—In the year 1880, Dr. Armauer Hansen, of Bergen, claimed to have discovered in the nodules of the disease the bacilli of leprosy. This observation was corroborated by Neisser, since which time these organisms have been generally recognized as the pathogenic microbes of leprosy. The bacilli of leprosy resemble the bacilli of tuberculosis, not only morphologically, but

in their reaction to the Ehrlich method of staining, thus differentiating both pathogenic microörganisms from all other varieties. Unlike the tubercle-bacilli, the bacilli of leprosy are as sensitive to aqueous anilin solutions as are the majority of all other microbes. Cultivation-experiments with the lepra-bacilli, as well as attempts at inoculation of animals have been practically negative. It is probable that the nodules and infiltrations of leprosy are a result of the specific action of the bacilli. We find them in the skin, in the connective tissue surrounding the nerves, in the lymph-glands, and in the viscera; they are practically absent in the blood.

DIAGNOSIS.—The difficulty in diagnosis is only encountered in the earlier stages of the disease, before tissue-changes have developed. At this period leprosy may be confounded with syphilis, lupus, vitiligo, multiple sarcoma of the skin, and syringomyelia. I cannot at this time enter into the points of differentiation.

Confined to the district of Brittany there is a peculiar affection known as Morvan's disease, so called after the physician who described it. It is a chronic affection, characterized by neuralgic pains, anesthesia, and painless whitlows. According to the recent observations of Zambaco, Morvan's disease is nothing else than lepra mutilans.

In April, 1891, as chairman of the committee on pathologic anatomy of the Medical Society of the State of California, I read a paper on "Parenchymatous Aspiration." I shall limit myself in describing this method of diagnosis in leprous lesions.

All that is necessary in carrying out parenchymatous aspiration is an antiseptic hypodermatic syringe. The syringe that I show you has a large barrel, the object being to secure better suction. The packing is made of asbestos, while the needle is of platinum. By washing the barrel of the syringe with alcohol and heating the platinum needle in the flame of a lamp, I reduce the danger of septic contamination to a minimum. By firing the ordinary hypodermatic syringe you can make it aseptic for all practical purposes.

This is done by filling the syringe with alcohol, and as you eject the fluid you light it as it escapes from the needle. We will now proceed to apply this method of diagnosis: You first render the arm of the patient in this case ischemic by the application of a rubber bandage, although this maneuver is not really necessary. You next introduce the hypodermatic needle into a leprous nodule, and by drawing the piston back you obtain a very small amount of serum. This serum will contain the bacillus lepræ, which you can demonstrate by appropriate staining. The same method is applicable in searching for the bacilli in infiltrations, lymph-glands, and in the viscera. You will find it difficult at times to remove any fluid from the leprous lesions, in which case you may have recourse to one or two maneuvers; first, if you can discharge nothing from the needle you may separate the latter from the barrel of the syringe; now draw into the barrel of the syringe one or more drops of distilled water; by discharging the fluid through the needle, in which are presumably lodged the aspirated products, you may get sufficient material for staining.

If this procedure does not suffice in securing sufficient material for microscopic examination, then the following method may be adopted: The syringe is partially filled with an indifferent solution of salt, which is injected into the diseased tissue, the needle remaining *in situ*; after waiting until the fluid has presumably taken up sufficient pathologic products, it is aspirated into the barrel of the syringe.

The method I have just described bears some resemblance to the procedure of Manson (*Lancet*, August 23, 1884). This observer recommended the following method of demonstrating the bacilli in leprous patches: The patch is compressed in the jaws of an ordinary thin-bladed pile-clamp. This has the effect of drawing out the blood from the occluded tissues, and then the patch is pricked with a needle, and the exuded fluid is stained for the bacilli. You will observe from the description I have given you of Manson's method that it is inapplicable in leprosy of the lymph-glands, nerves, and viscera.

ETIOLOGY.—The main question is whether heredity or contagion plays the chief part in the spread of the disease.

Arning, one of the most competent observers, denies that heredity is the sole etiologic factor. Leprosy is a disease, so he says, perfectly independent of climatic and telluric influences. He urges most strenuously that leprosy is introduced and spread solely by leprous individuals. It is exclusively a disease of mankind, thus differing from tuberculosis, which also attacks the common domestic animals. Under favorable conditions the disease is probably transmissible directly from man to man or through food; the latter, however, is not proved. The fish-diet theory of Hutchinson is untenable on account of its exclusiveness. Examinations made by Rake of the chief articles of diet among the negroes and coolies of Trinidad show no evidence of lepra-bacilli. The results of direct inoculation seem to demonstrate that leprosy in a practical sense is not contagious. The successful inoculation of the murderer Kearin cannot be regarded as conclusive in the light of contradictory evidence.

Thus, a Norwegian physician inoculated himself and twenty healthy individuals with leprous material, without result. The same negative results attended the experiments of Profeta in ten cases.

As Arning says, we shall never be able to decide the question of direct contagion, or of infection through the intervention of the ground, of water, or of food, till we are able to show a comprehensible difference between living and dead bacilli, either by culture or by constant successful inoculations on the lower animals.

TREATMENT.—There is no specific in this disease. Improvement of hygiene and dietetics will do much toward prolonging the life of the individual. The value of chaulmoogra oil has not been definitely determined. The oil may be administered in capsules. The dose is from ʒss to ʒj daily.

The treatment by excision of the tubercles in the early stages of the disease may prove of some benefit. Germicides are without practical value. Arning has caused a disappearance of the tubercles in many instances by the local application of an ointment composed of salicylic and pyrogallic acids.

PROPHYLAXIS.—There is no doubt that strict confinement of leprous individuals is of the same value in preventing the dissemination of the disease as would be the isolation of tuberculous patients.

CLINICAL MEMORANDA.

A CASE OF ABSCESS OF THE SPLEEN.

By WILLARD C. HOWE, M.D.,
of Hawarden, Iowa.

The occurrence of abscess of the spleen would appear to be of extreme rarity if the literature at my command is to be taken as a criterion. In the leading surgical works very little is said regarding this particular pathologic condition, and a careful search of the best journals fails to reveal the records of but few cases. Because of its obscure history and progress, and the difficulty of an early accurate diagnosis, it is very unfortunate, if it is at all common, that so few cases have been reported for the benefit of the profession. A painstaking examination of the books and periodicals at my disposal discloses reports of but nine cases of abscess, one of purulent cyst, and one of perisplenic abscess.

William H. Flint[1] mentions one case of supposed abscess of the spleen in which there was free expectoration of pus and final recovery. J. M. Flippen[2] reports one case in which he removed nine pints of pus by free opening. Recovery followed. Hodenpyl[3] presented to the New York Pathological Society a specimen of abscess of the spleen. Death was due to chronic nephritis. Joseph Levi[4] reports two cases. Mena[5] records a case in a boy sixteen years of age, in which the abscess was consequent upon traumatism. There was vomiting of pus and also its passage from the bowels. Recovery ensued in eighteen weeks. M. Chondhoory,[6] of India, observed among thirty thousand cases of malaria only three cases of abscess of the spleen. One freely opened and was treated by drainage, boric lint, and iodoform; and recovery took place. Porge[7] records a case of purulent cyst of the spleen, and Councilman[8] presented to the Johns Hopkins Hospital Medical Society a case of perisplenic abscess.

The following case was one of extreme interest to me, and because of certain points detailed in the history, would seem quite rare.

On August 7, 1892, I was called to treat C. C., an American, single, twenty-one years of age, by occupation a well-digger. For some time he had been working unusually hard, his ambition exceeding his strength. Up to within three weeks, his health had been good. Except for the usual diseases of childhood he had never known a sick day.

Two weeks before, he had consulted a physician regarding a pain in his left side. A "shot-gun prescription" was given, but as this did no good the man went to another physician who without making the least examination or asking any questions, except as to the location of the pain, prescribed a chloroform liniment for external application. After three or four days' use of this, with no improvement, the man sent for me.

I found him lying upon his right side, with the left limb slightly flexed, and complaining of a dull, heavy pain in the left hypochondriac region, with slight tenderness on pressure. His temperature was 102°; pulse 120; respiration 18; the bowels were regular and the kidneys acting normally. Careful examination disclosed the following condition: A slight bulging over the normal location of the spleen; the ninth and tenth intercostal spaces were obliterated; the area of splenic percussion-dulness was increased in a direction downward and forward for about two inches below the border of the ribs.

Palpation revealed a tumor arising from the left hypochondrium. It was superficial; its edges were rather blunt, and its anterior border was notched. With one hand behind and the other in front it was found to be mobile and tender on pressure. Deep inspiration was painful and occasioned a downward movement of the enlarged mass. Upon auscultation a distinct friction-sound was heard. The only sharp pain complained of was upon deep inspiration or when the tumor was moved during the examination or upon a change of position of the body. The erect posture caused the tumor to drop somewhat downward. Taking these points into consideration a diagnosis of splenitis and perisplenitis was made. The only conditions likely to simulate this and obscure the diagnosis would be fecal accumulation in the intestine (splenic flexure of the colon) and a floating or enlarged kidney. Fecal masses in the intestine could for the following reasons be excluded: The percussion-dulness did not correspond with the course of the colon; pressure left no depression, the enlargement being elastic, whereas fecal accumulations are not so. Finally, the bowels had been regular in action and the passages normal in appearance.

Tumors of the kidney are more fixed; they do not follow the respiratory movements, and are not displaced by changes in body-posture.

As ice was not to be obtained, I ordered cold cloths applied and changed frequently night and day. Quinin in four-grain doses three times a day, was given, and morphin sulfate, gr. ⅛ in pills, was left to be taken from every two to four hours, as necessary, to quiet pain. The spleen continued to enlarge until it filled nearly half the abdominal cavity. The temperature ranged from 100° to 103°; the pulse from 100 to 120.

The pain now became more severe, the countenance assumed an anxious expression, and there was rapid loss of flesh. No fluctuation was to be obtained, but thinking an abscess was forming I ordered hot poultices applied continuously. Small boils the size of a pea began to form in profusion upon the neck, face, back, and anterior aspect of the arms. The lymphatics of the groin and axilla became enlarged and tender. On October 6th a consultation was held with Drs. J. H. Brower and O. W. Phelps. Dr. Brower agreed with me as to the location and character of the trouble, but Dr. Phelps considered it a plain case of abscess of the kidney.

The urine being normal in quantity and appearance, and showing no sign of pus or albumin upon several very careful chemical and microscopic examinations, together with the fact that we had a tumor arising from the left hypochondrium that was superficial, movable, with blunt edges and a notched anterior border, confirmed our diagnosis at least as to the location of the diseased pro-

cess. The quinin was continued in two-grain doses during the entire time, and ferrum redactum in three-grain doses was given three times a day.

The diet consisted of milk and beef-extracts. No stimulants were used. On October 11th Dr. Brower again saw the case with me, and we decided to make a free opening into the spleen. This was accordingly done between the axillary lines and just below the border of the tenth rib. About two quarts of thick pus were evacuated, together with small particles of broken-down splenic tissue of a mottled-gray appearance; the cavity was washed out with a warm boric-acid solution, a drainage-tube was introduced, and the whole was covered with iodoform-gauze and proper bandages. The temperature declined to normal, the pulse to 90, and the pain was materially lessened, but not entirely removed. The cavity was washed out daily and the drainage-tube finally withdrawn October 18th, and the wound closed. The spleen was very perceptibly smaller. On October 22d the temperature again began to rise, and the pulse to run up, the pain to return, and by the 29th all of the symptoms had returned with the same intensity as they had presented before the abscess was opened. Thinking the old cavity was refilling it was reopened, with negative results.

The bowels moved naturally on the evening of the 28th, but caused great pain, and restlessness continued during the night. The morning of the 29th the man felt a sudden desire to go to stool. A large quantity of clear pus streaked with blood was passed. In the next four hours the bowels moved eleven times, the character of the discharge being the same; the movements then ceased, and from that day on were quite normal. On November 5th the man was seized with a hard coughing spell and expectorated pus freely. This continued for about four weeks, but gradually ceased; strength returned, and on January 15th he was discharged cured. He has worked hard all summer and is now in good health. The case was also seen by Drs. R. D. Clark and A. DeBey, who agreed with us as to diagnosis and treatment, the latter being tonic and supporting from beginning to end, with free opening so soon as pus was known to exist. In this case the cause was a bruise. No septic trouble of serious moment developed, and recovery was a very gratifying surprise, as a fatal termination had been predicted.

AMPUTATION AT THE HIP-JOINT FOR RECURRENT SARCOMA OF THE THIGH.

BY CLINTON B. HERRICK, M.D.,
ASSISTANT ATTENDING SURGEON, TROY HOSPITAL; PHYSICIAN AND SURGEON, COUNTY HOSPITAL, TROY, N. Y.

AMPUTATIONS at the hip-joint, with many others of the so-called major operations, have lost much of their formidableness through the efforts of surgeons to simplify the methods of operating, and to so carefully estimate all the factors in connection therewith as to render their performance much less of an undertaking than formerly. From the same causes the mortality records from this and other kindred operations are being constantly lowered. Not long ago this operation was regarded as a *dernier ressort*, and many times refused consideration by the surgeon, as offering too few chances for success. That such fears are ungrounded is undoubtedly true, and this is supported by the following case, which was looked upon by those in consultation as one which would result in death were the operation attempted.

The history of the case is as follows: Miss N. G., aged twenty-nine, in 1878 noticed a slight fulness at the middle third of the inner and posterior portion of the right thigh. Giving no pain, it gradually enlarged for a year, when it reached the size of an orange. It was removed, and consisted apparently of a simple fatty growth, enclosed in a distinct capsule. Six years passed by, when the cicatrix began to bulge, and soon afterward another growth made its appearance, being larger and more nodular. This was excised, and consisted of a number of encapsulated growths of a fatty nature, but containing more stroma. Care was taken to remove all traces of the growths and sacs, some of which were quite small. Recurrence took place in eighteen months, during which time the growth extended downward. Removal now showed softening in the structure of the growths, and many small ones rolled out in their capsules, looking not unlike eggs. Recurring after a year, the mass reached down toward the popliteal space, and assumed large proportions. The operation at this time was attended with difficulty, as the sheaths of the femoral vessels were involved and laid bare during the procedure. The neoplasm could not be entirely removed without ligating the femoral artery, and as this was not considered advisable, an early recurrence was anticipated, which followed in six months. As the mass had not extended any higher than the upper third of the thigh from the first, a high amputation was advised, but refused by the patient. An attempt was therefore made for the fifth time to remove as much of the growth as possible. Its character had changed decidedly, the mass having

become colloid and indistinct, spreading itself in all directions in and among the muscles. The wound, after this operation, never healed, but a large spongy mass protruded into the popliteal space, giving rise to considerable pain and numbness in the lower leg. The patient's condition had been very poor for some time. She was excessively anemic, had entire lack of appetite, was losing flesh rapidly, and had given up hopes of ever being relieved.

Advice was now given strongly in favor of hip-joint amputation as the only practical thing to do. It was accepted.

On July 8, 1893, the operation was performed at the Troy Hospital. The prognosis at the start was very unfavorable, as the pulse was feeble, high, and irregular. In this case it was very necessary that the operation should be so performed that the loss of blood would be reduced to the smallest possible quantity, and as well that the procedure should be completed as rapidly as possible. I had anticipated this by giving the subject careful thought and study for several days, and after going over the field of methods advised, discarded them all as too risky. I then planned and performed the operation as follows:

After anesthetizing with the Vienna mixture, I first ligated the femoral artery as it passed under Poupart's ligament, securing it above the profunda by the ordinary incision, which was closed at once with silkworm-gut sutures. There was no difficulty in performing this rapidly, although the presence of considerable adipose tissue necessitated a deep wound. Next, a longitudinal incision was made over the joint, *à la* Langenbeck, reaching from just below the spine of the ilium to below the trochanter. This was carried down to the bone. The soft parts being strongly retracted, all muscular attachments to the outer segment of the femur were severed. By rotating the bone first outwardly, then inwardly, the remaining muscles were cut away and the capsule exposed. Forced adduction of the leg gave room to open the joint, disarticulate the head of the femur, and divide the ligamentum teres. The separation of the soft parts from the bone was carried down, exposing the entire upper third of the femur, which was thus thrown out of the wound. This step of the operation, in all cases the most difficult on account of the many and close attachments of muscles to all sides of the upper part of the femur, was made more tedious by reason of the compression caused by an elastic band, which had been drawn around the highest point on the thigh as a safeguard against additional bleeding. As was afterward proved, however, this was of no value, and should be dispensed with, as it only hinders free access to the deep joint-structures. As the third step, a circular incision was made around the thigh, as high up as possible, and after the skin had retracted, a sweep of the knife severed all remaining tissues, removing the leg. There was but very little arterial bleeding, and but two or three small vessels needed ligating. The femorals were safe. After trimming up projecting muscular fasciculi, nerves, and tendons, intermediate silkworm-gut sutures were rapidly inserted and the stump dressed. Despite a rapid operation and little or no loss of blood, the patient's condition at the close was very poor.

Hypodermatics of brandy and nitroglycerin, hot bags, and other restoratives were administered, upon which the patient rallied. Lack of vitality evidenced itself by a breaking down of the fatty tissue in the stump, in the course of a few days, causing the flaps to separate. Supporting dressings were daily applied to the stump, and a slow but uninterrupted recovery took place.

In regard to the method of operating, the one employed in this case gave me the greatest satisfaction. The primary ligation of the femoral artery removes the necessity of considering the question of whether or not this very important factor in the operation can be met promptly and at the critical time. There certainly must not be any delay in so doing, for in a large majority of cases so advanced as to require the operation of amputation at the hip-joint, a few spurts from the artery would close the scene. So, to be assured of success as far as this factor is concerned, we should ligate the femoral artery first, and insure safety. The relief of mental anxiety should always be considered as an important duty.

As to the collateral circulation, there is fully sufficient to nourish the stump, and in this case no shrinkage or sloughing points were observed. To attempt by the old-time methods of operating to grasp the contracting bleeding mass and control the femoral is almost impossible, as is proved in less bulky stumps.

The use of needles and elastic bands and ligatures is, to my mind, equally dubious. The needles, although inserted presumably in a safe anatomic direction, may pierce the large vessels, especially if an anomaly exists, while in cases of emaciation of the parts or great swelling, difficulties immediately present themselves. Elastic bands passed around the entire circumference of the thigh in this locality do not carry any assurance of complete occlusion of the main trunks, as, lying so deeply and surrounded by so many projecting points of bone over which the bands ride, the pressure exerted by such bands is insufficient to shut off the current of blood.

The causes of death from amputation at the hip-joint are named as three: hemorrhage, septicemia, and shock. The primary ligation of the femoral artery removes the possibility of death from hemorrhage. The surgical technique of to-day presents the means by which we may remove the possibility of death from wound-infection. Giving the greatest care, by painstaking administration of stimulants and tonics, to the patient's system before, during, and after the operation, reduces to a great degree the liability to a fatal issue from shock. There are exceptional cases in which, through previous loss of blood from ulceration of growths, or systemic poisoning from absorption from ulcerated surfaces, or an exhausted condition from long-existing disease, these determining factors in a prognosis may be considerably influenced. However, even frequently handicapped by these, I believe that in primary amputations of the hip-joint we should confidently look for a considerable reduction in the percentage of mortality as at present rated.

RHYTHMIC TRACTIONS OF THE TONGUE IN ASPHYXIA FROM CHARCOAL FUMES, AND REPORT OF A CASE OF ASPHYXIA NEONATORUM REVIVIFIED BY LABORDE'S METHOD.

By ALBERT S. ASHMEAD, M.D.,
of New York.

There seems to have recently, and very seriously, come into vogue a system of revivification, proposed by Dr. Laborde, of Paris, which is called by its author *the method of rhythmic tractions of the tongue*. As early as 1874 rhythmic tractions of the tongue were performed at Tokio, for the resuscitation of persons asphyxiated by carbon. This was the method as I have seen it employed and have employed it myself at the Tokio Hospital:

The patient having been placed upon the operating-table, brandy, largely diluted with hot water, was injected into the rectum, as much as it would receive. The Sylvester method of artificial respiration was employed, and modified as follows: At each elevation of the arms above the head the tongue was drawn forward by an assistant, and rapid passes with paper fans, soaked in water and aqua ammoniæ, were made over the mouth, to get into the lungs as much vapor of ammonia as possible. The tractions were from 18 to 20 to the minute. In a very short time, in the successful cases, the return of the capillary circulation was noticed first in the toes and then to creep up the lower extremities.

The first case which I attended was in a Japanese child, three years old. It had been poisoned in the beri-beri season by the charcoal fumes of the *hibatchi*, the little Japanese stove. Carbonic poison is frequent in the summer months, owing to the necessity of keeping the sliding doors closed in the daytime on account of the wet weather. With us this kind of accident occurs more usually at night; but the Japanese stoves are always cold at night, because the people cannot then attend to the necessary ventilation.

It is therefore to the Japanese that the honor of originating the method of resuscitation would at first seem to belong. There is even in the use of the ammonia a scientific point very creditable to Japan. Ammonia furthers the separation of carbon poison from hemoglobin, and carbon greedily absorbs 90 per cent. of ammoniacal gases.

But it ought, in fairness to Dr. Laborde, to be added that, although his discovery would seem, by what I have said, to have been anticipated by the Japanese, it is really not so. Their method, based on another idea and aiming at another immediate action, is really another method. The Japanese doctor means to get ammonia into the lungs, and, with that object in view, he draws forward the tongue in order to clear the passage. It is evident by what will be said and quoted, that the object of Dr. Laborde's method is to incite respiratory movements.

Laborde's method of rhythmic tractions, as used by Dr. Ettore, of Rimini, Italy, in the case of stillbirth following uterine inertia and premature detachment of the placenta, the child having still hardly perceptible cardial pulsations, was as follows (he had failed in the attempt of catheterism as advised by Schroeder, and in the application of the methods of Schultze and Pacini):

"Having placed the newborn in a half-sitting position on the border of the bed, and having him held in that position by an assistant, I opened the buccal cavity, and taking the tongue between the thumb and index finger of the right hand, I began to perform on it tractions, at short and regular intervals, intensifying them gradually; and what was not my amazement and my delight when, after the time necessitated by about twenty tractions, the little thorax heaved, while at the same time the bambina uttered a faint squalling. Encouraged by this success, I continued the tractions and sousing simultaneously the little body with very cold water—a cutaneous stimulation, which, as I have said, had been ineffective in the first instance—I obtained after a short while a regular breathing, complete, with a wailing now quite vigorous."

Here is Dr. Roux's (of L'Orient, France) report of the use of the same method in another case: "When I came, the head was at the superior strait with prolapse of the cord. On auscultation the stethoscope indicated no heart-beat. The Tarnier forceps was promptly applied. The child did not breathe, the heart-beats were hardly perceptible to the hand, and very rare. The tongue-tractions produced a hiccough at rapidly decreasing intervals, followed by regular breathing. The first crying came after forty minutes."

The purpose of all attempts at resuscitation in case of any asphyxia is to arterialize the blood quickly. This can only be done by introducing oxygen and eliminating carbonic acid. The tractions open the aërial channels, and this is all that the Japanese method aims at producing. Laborde's method has for its object to call into existence respiratory movements.

The ammoniacal fanning is, however, an additional stimulant to respiratory movement—only its principal object is is to introduce a substance that will antagonize carbon.

The application of Dr. Laborde's method to the case of neonati shows most strikingly the difference of the principle on which it and the Japanese methods are founded. For in the case of the new-born there is no poisoning gas to be overcome, except what would be naturally developed in the organism, the object of this treatment being simply to establish respirations.

Two nights ago I myself made use of Laborde's method, with a modification borrowed from Sylvester's method, in conjunction with the Japanese fanning. In the child of a unipara, stillborn, after protracted labor, with a posterior position, and the application of forceps, thirty or forty tractions were followed by the first gasp, and gradual resuscitation followed. Household ammonia and water were used for the fanning. Terebinthinate preparations may be substituted for ammonia. Turpentine vapor is an oxidizing agent in the same degree as ammonia.

A CASE OF LEPTOTHRITIC PHARYNGEAL MYCOSIS.

BY JAMES WOOD, M.D.,
OF BROOKLYN, N. Y.;
ATTENDING PHYSICIAN BROOKLYN CENTRAL DISPENSARY, ETC.

DURING last winter the following rather rare affection of the throat presented itself for treatment. Mrs. A., twenty-seven years of age, said that she had been treated for several weeks by her physician for a "hacking cough and sore-throat." She was much alarmed about herself and feared pulmonary trouble. She remarked that something must be growing on the sides of her throat, as it felt rough and dry. Her voice was slightly changed, and an examination showed the tongue slightly coated with a white fur. The mucous membrane of the pharynx was somewhat congested and both tonsillar surfaces were thickly studded with white pyramidal bodies resembling the soft cheese known as "cottage curd." Similar bodies were scattered on the sides of the pharynx, and an almost solid mass occupied the depression between the anterior and posterior pillars of the pharynx. There were a few on the base and sides of the tongue.

The diagnosis of leptothritic pharyngeal mycosis, as

designated by Ruault, of Paris, was made, and subsequent resistance to all local measures confirmed the opinion.

The treatment was as follows: The excrescences were scraped off from the mucous membrane with a moderately sharp curet, and a strong solution of subsulfate of iron was applied. While this completely removed them, in two days the growth was as thick as before. Curetting was continued and different applications made every few days for several weeks, with no beneficial results. The condition was improved more noticeably under the use of sodium bicarbonate dusted over the areas. The improvement was, however, but transitory.

The patient refused to allow the use of the electric curet, knife, or strong escharotics, so that active measures were suspended.

As the remedial agents afforded by the materia medica had been exhausted, it is to be regretted that the woman would not consent to be a subject for further experimentation, and allow a test of surgical means. Dr. Dembicki's successful treatment with tobacco-smoke was not tried.

I believe that the electric curet, conscientiously used, and followed by the application of some astringent, would have effected a cure.

The case is reported because of its infrequency and lack of information as regards efficacious treatment.

MEDICAL PROGRESS.

Symmetrical Gangrene of the Feet in a Child.—Power (*Lancet*, No. 3648, p. 249) has reported the case of a girl, four years and eight months old, but looking much younger, who presented gangrene of both feet. Two winters before she had been greatly troubled with chilblains on both feet. A year later she was treated for wasting and swelling of the feet and legs as high as the knees. The feet and legs were said to become livid in the evening, and to be of natural color during the day. The child had never walked or crawled, but there was no paralysis of the legs, and the want of power seemed to depend upon simple weakness. She had been fed from birth on artificial milk, and had had an attack of measles at the age of eight months. There were no indications of syphilis. The little patient was pale-faced, dark-haired, and thin. The pulse was 144, regular, and of high tension. The radial arteries were tortuous, thickened, and readily felt. Pulsation could be felt in the dorsalis pedis artery of each foot and in both posterior tibial arteries. The skin appeared natural; the nails were cracked transversely, and the finger-tips beneath the nails were livid. Nothing abnormal could be detected in heart or lungs. The eyes were normal; there were no retinal hemorrhages. All of the toes on both feet were shrivelled and black, the gangrene extending as high as the metatarso-phalangeal joints. On the inner side of the left heel was a small patch of black skin, about half an inch in diameter, and at a corresponding point on the inner side of the right heel the skin appeared to be redder than natural. A generous diet was prescribed, with half an ounce of brandy every twenty-four hours. Small doses of tincture of opium and aromatic spirit of ammonia were given frequently. In the course of a few days a line of demarcation began to form along each series of metacarpo-phalangeal joints. The slough on the left heel had separated, leaving a small superficial ulcer, whilst the red patch on the right heel had completely disappeared. A little later the phalanges of the little toe of the left foot had completely separated, and at a somewhat later date the remaining phalanges on both feet were removed. The patient thereafter made an uninterruptedly good recovery, except for the appearance of a small black spot at about the junction of the upper with the middle third of the anterior aspect of the right tibia. The child was again ordered one-minim doses of tincture of opium, and the spot disappeared in the course of a few days. The urine, which was repeatedly examined, was usually neutral, or feebly alkaline, and it was at all times free from sugar, blood, and hemoglobin. On one occasion, at a late date, it was acid and contained a faint trace of albumin.

The Diagnostic Significance of the Gonococcus.—Neisser (*Deutsche medicin. Wochenschrift*, 1893, Nos. 29, 30) contends that there can be no doubt that the gonococcus is the cause of gonorrhea. The diagnosis of gonorrhea, in the male or in the female, can in many cases be made from the symptoms alone; but in a large number, particularly in cases of chronic course and attended with mild subjective and objective manifestations, the diagnosis will depend upon a demonstration of the presence of gonococci. Examination for gonococci is indispensable in cases in which a question arises as to the infectiousness of the discharge. As the therapeutic procedures to be adopted will depend upon the presence or absence of gonococci, the examination for the organisms is to be made not only before, but also during the whole course of treatment. In most cases a microscopic examination will suffice; on account of the imperfection of cultural methods, these will be employed only in exceptional instances. If gonococci be found, there can be no doubt of the diagnosis. Observations that yield negative results are not to be accepted as conclusive, as gonococci may be concealed in lacunæ or invaginations of the mucous membrane, or may be present in numbers so small as to escape detection. In such a case repeated examination, as well as cultural observations, will be necessary. The clinical manifestations will have to be studied in connection with the microscopic findings. If gonorrhea be found in a married person, both husband and wife should be placed under observation, and if necessary both should be subjected to treatment.

Immunization of the Fetus by the Vaccination or Variolization of the Mother.—At a recent meeting of the Paris Academy of Medicine, Hervieux reported the outcome of a study of the influence upon the fetus of revaccination of the mother. Of 152 cases in which the mothers were revaccinated during the last months of pregnancy and in which the infants were vaccinated soon after birth, in only 46 did the vaccination of the children fail. Experimental observations seem to indicate in a general way that immunization of the mother is only exceptionally transmitted to the offspring. Thus, 500 sheep were inoculated with vaccine virus and their offspring were also inoculated soon after birth, with positive results in

all but 35. In several cases an attack of variola in a pregnant woman did not render her offspring insusceptible to vaccination shortly after birth. In some instances, however, the infant for several months proved refractory. Recent investigation has shown that microörganisms may pass from the maternal to the placental circulation if there be an erosion of the placenta.

Diminution of the Electric Resistance in Cases of Traumatic Neurosis.—Mann (*Berliner klin. Wochenschr.*, 1893, No. 31, p. 749) has found that in cases of traumatic neurosis attended with cerebral manifestations (headache, vertigo, tinnitus) there is frequently a diminution of the resistance ordinarily offered to the passage of a galvanic current through the head. Such a diminution had previously been found to exist in cases of cerebral hyperemia, and it is believed that it is also this condition upon which the alteration of the resistance depends in cases of traumatic neurosis. The practical value of this knowledge resides in the fact that it may be of diagnostic significance in cases of traumatic neurosis in determining whether or not complaint of cerebral symptoms has an objective basis. A negative result, however, cannot be considered as excluding traumatic neurosis.

THERAPEUTIC NOTES.

The Physiologic and Therapeutic Activity of the Hot Bath.—At the recent German Congress for Internal Medicine, Baelz (*Wiener medicin. Presse*, 1893, No. 34, p. 439) pointed out the utility of the hot bath, the lowest thermometric limit for which should be placed at 104° F. The warmer the bath, the more important is it first to wet the head with hot water, in order to relax the cerebral vessels, so that, when subsequently the cutaneous vessels become filled with blood, there shall be no danger of cerebral anemia. The duration of the bath may be from five to twenty minutes; it should cease as soon as a sense of heat or palpitation of the heart is felt. Upon entering the bath, goose-flesh, contraction and pallor of the skin appear for a few seconds, to be gradually followed by relaxation and redness. The pulse, at first transiently slowed, gradually becomes quickened; the arteries become relaxed and the temporals appear tortuous. The pulse-wave is full, the curve high. The temperature, taken beneath the tongue, rises 3.6° or more. This elevation takes place not only in consequence of accumulation of heat, but also as a direct result of the absorption of heat. After leaving the bath the temperature usually rises rapidly from 0.2 to 0.4° additionally, to reach the normal again in from half an hour to two hours. On leaving the bath a sense of refreshment is felt and a copious perspiration breaks out. A gentle douche of cold water is agreeable. There is no danger of "catching cold"; on the contrary this danger is obviated by the hot bath, in consequence of the paresis of the cutaneous vessels from the effects of the heat, experiments and sphygmographic tracings having shown that for some time after the hot bath reaction of the vessels to cold is wanting. This is not the case if the temperature of the water has been at body-heat or lower. The prejudice that the hot bath is debilitating in any way is entirely unfounded; on the contrary two or three hot baths a day are exceedingly useful in mountain-journeying. Investigation has shown that, in contradiction of former belief, albuminous metabolism is not increased in the hot bath. The hot bath is therapeutically applicable not only in cases of nephritis, but also in cases of capillary bronchitis and broncho-pneumonia, especially in children. Its efficacy here depends upon the diversion of the blood from the pulmonary circulation to the cutaneous vessels. The temperature of the bath should be from 104° to 109.4° F.; its duration from five to fifteen minutes, the patient being removed as soon as the skin becomes reddened. If the body-temperature is high a half-bath may suffice; pyrexia is, however, not a contra-indication for the bath. Sprinkling the head or chest with cold water is to be recommended to stimulate deep inspiration. After the bath perspiration occurs; respiration is easier; the pulse better; and, as a rule, calm sleep follows. The hot bath also acts admirably in the treatment of rheumatism and of menstrual colic. Organic disease of the nervous system, particularly posterior spinal sclerosis, and atheroma of the bloodvessels, are contra-indications to the use of the hot bath, which must further be used with great circumspection in case of organic disease of the heart.

Venesection for Eclampsia Gravidarum.—Kirk (*Lancet*, No. 3648, p. 247) has reported the case of a woman who, in the eighth month of her first pregnancy, was seized with violent headache followed in two hours by general convulsions. Other convulsions occurred, loss of consciousness persisting in the intervals. Following a violent attack, a bleeding of 16 ounces was practised. Six ounces of pale urine were withdrawn from the bladder and found to be markedly albuminous. There was no anasarca and the ankles did not pit on pressure. Labor had not yet begun. After the bleeding the fits became shorter, though continuing with unabated frequency. Finally, however, labor set in and delivery was accomplished by means of the forceps. The child was stillborn. The woman made a good recovery. In a second case, in a woman in the ninth month of her first pregnancy, headache and vomiting were followed by convulsions. After a severe seizure a bleeding of 24 ounces was practised. In this case there was also no anasarca or pitting of the ankles. Some urine withdrawn by the catheter was markedly albuminous. Labor was progressing, the os being partially dilated. Four convulsions occurred within an hour, and upon their cessation the forceps was applied and a living child delivered. Six hours after delivery the convulsions recurred with their previous intensity, but finally ceased after four attacks within an hour. Recovery was thereafter uninterrupted. In both cases the blood-serum was examined for uric acid, but none was found.

A Depilatory.—

℞.—Iodi pur.	. . . . .	gr. xij.
Olei terebinthinæ	. . .	♏xx.
Olei ricini	. . . . .	f ℥ss.
Alcohol.	. . . . .	f ℥ijss.
Collodii	. . . . .	f ℥j.—M.

S.—Apply with a brush once daily for three or four days successively. Upon the removal of the layer of collodion the hairs will be found also to come away.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage in North America.

Per Annum, in Advance . . . . . $4.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, OCTOBER 7, 1893.

AUTOPATHOGRAPHY.

Von Ziemssen's *Handbuch der Allgemeinen Therapie* contains a noteworthy article by Oertel on the Therapeutics of Disturbances of the Circulation, etc., in which with great clearness and minuteness there are described the symptoms of a certain person afflicted with the disease-complications set forth by the learned author. It is an open secret that Oertel's patient was himself. And how often have such illustrations of autopathography occurred! Sydenham said of gout that "more wise men than fools are victims of the disease," and in writing of the physical disease his eye was also turned upon himself. Thomsen's disease was described by a sufferer in whose family the affection existed for five generations, and if we do not err, Salter, whose book on asthma is, perhaps, the best monograph on the subject written in England, spoke from much personal experience with the disease. Hay-asthma was first accurately described by an English physician, Bostock, in a report of "a case of a periodical affection of the eyes and chest," before the Medico-Chirurgical Society of London, in 1819. The "case" was himself. The sad illustration of Laennec is well known. His name is naturally associated in the same breath with pulmonary tuberculosis, of which he died at 45, from his epoch-making work, the affection having been discovered by his own methods and instrument—auscultation and the stethoscope.

Angina pectoris was described by Heberden in 1768. It is said that an unknown correspondent gave Heberden a description of his case and bequeathed his body for examination after death. John Hunter made the examination and was himself a great sufferer from the disease, and died in a paroxysm of it. Others have had scientific curiosity aroused as regards this terrible disease by their own anguish. The Medical News of March 26, 1892, contains an article on the subject, by one who suffered while he wrote and who died a year thereafter of organic heart-disease and angina.

The medical historian could multiply such sad instances many times. In literature hundreds of famous books are illustrations of the interest aroused in mental and social suffering by the bitter private experience of the writers with the ailments they set forth with a vividness and accuracy that naught else but personal realization could give. Perhaps all great writers have been great, and have so surely sent their words home to the hearts of their fellows only because the steel of pain had first penetrated their own souls. Dante, it was well said, had been in hell before describing it, and DeQuincey, Leopardi, and Heine spoke so convincingly because they spoke of what they knew by bitter experience.

But it is not only in writing that one's own pain may give him exactness and interest; it is also of greater use in teaching the physician to have that sympathy and accuracy of perception with the disease of his patient that shall lead him to treat disease there just as if it were in his own person. It is an often-noticed fact that opticians and oculists have been impelled to their specialty by their own personal ocular history—"they all wear spectacles"—but it is true, though less recognized, that the optician who has suffered from ill-made or ill-adjusted lenses is certain to do better work for his customer, and the ophthalmologist who has carefully studied his own optic defects will the more readily detect those of his patients.

Herein also lies the wisdom and propriety of women studying medicine, as all women-physicians so keenly recognize. When women rise to their opportunity there will be splendid examples of medical training and success in their ranks, because in treating the diseases of those of their own sex and of children we must expect great things of them.

In little things or in great the rule holds good; it is personal experience that makes the eye clearer to detect elsewhere what one has himself endured, and that innervates the emotions to cure in others what has been felt as so grievous in self. There are, therefore, numerous reasons why physicians should not neglect the intimations and the lessons derivable from personal illness. It was a myth of old-time folk-lore that pearls and diamonds were the crystallized tears of the child of Life cruelly whipped by the step-mother, Experience.

THE ETIOLOGY OF CHRONIC ARTICULAR RHEUMATISM.

IT has long been a matter of doubt as to whether or not any etiologic relation exists between the three groups of affections that are ordinarily designated acute, subacute, and chronic rheumatism, with a disposition to decide the question in the negative. Of the three, acute rheumatism is the only one at all well defined, from the standpoints of symptomatology, morbid anatomy, and therapeutics. Into the other two groups are usually cast all of the vague and uncertain painful conditions affecting musculofibrous and fibro-articular structures. The confusion attending the classification of these is eloquently indicated by the absence of a distinctive semeiology, by the want of a definite pathology, and by the lack of a distinctive therapy. There have even not been wanting observers that were willing to include some of the cases of chronic articular rheumatism among the tropho-neuroses, dependent upon changes in the spinal cord.

Little light has been thrown upon this obscure subject, but a recent communication by SCHÜLLER (*Medical Record*, 1893, vol. xliv, No. 13, p. 389) would seem to point the way for further investigation in at least one direction. This observer has made a clinical, anatomic, and bacteriologic study, embracing 116 cases of so-called rheumatic articular inflammations. In these he found hyperplastic inflammatory changes in the synovial membranes of the affected joints, and from the tissues and fluids of which he was able to isolate a peculiar bacillus, to which he ascribes etiologic influence. He was further able to transmit this organism to lower animals, inducing lesions in these comparable to those observed in man, and again to obtain from the lesions the specific bacilli. The organisms are described as being from 2.24 to 2.76 μ long, and from 0.75 to 0.95 μ wide; usually straight, though sometimes slightly curved or angular; presenting bright granules at either pole; staining readily with carbol-fuchsin; and decolorizing with acids, etc. In culture they grow best in the dark, at a little above ordinary temperature, forming opaque-white colonies that slowly liquefy gelatin.

These observations are not to be accepted as final, as the investigation has not been entirely completed. There is, however, no *a priori* ground on which to reject the conclusion to which they lead. On the contrary, there is growing evidence that acute rheumatism is of microbic origin (see THE MEDICAL NEWS, August 26, 1893, p. 247), and it is not too much to hope that before long we shall know more than we do concerning so-called subacute and chronic rheumatism, which, as has long been believed, are not at all rheumatic in nature.

Bacteriologic science has met with inevitable, and not unhealthy, antagonism, with the result of stimulating better work, with more reliable and more permanent results. As a consequence, it is likely that fewer mistakes will be made, and less hasty conclusions reached, than has been the case in the past, and we can look forward to the future of bacteriology with growing hope and confidence.

THE TREATMENT OF EXUDATIVE TUBERCULOUS PERITONITIS BY MEANS OF INTRA-PERITONEAL INJECTIONS OF STERILIZED AIR.

ALTHOUGH an adequate explanation of the sequence of events may be wanting, the now well-known clinical fact remains that in some cases of tuberculous peritonitis abdominal section is followed by a disappearance of the preëxistent symptoms. Many theories have been proposed to account for such an unanticipated occurrence, but none yet brought forward is entirely satisfactory. At one time it was believed that the antiseptic fluids used in irrigating the diseased peritoneal cavity were responsible for the fortunate result, but it was subsequently found that the outcome was the same when sterilized distilled water was employed, or even if the peritoneal accumulation was simply evacuated and no irrigation at all practised. Some authorities ascribed the result to the influence of light upon the disease-process; while others suggested exposure to the air as the cause; and yet others made the necessary operative manipulations responsible. From a number of

considerations, Nolen (*Berliner klinische Wochenschrift*, 1893, No. 34, p. 813) comes to the conclusion that the improvement must be due either to the changes in the circulatory conditions brought about as a result of the evacuation of the fluid accumulation, or to the contact of the air, in a chemic, physical, and bacteriologic sense. The first explanation is at once invalidated by the fact that recovery does not follow evacuation of the fluid by puncture. Now, it was reasoned that if the good result depended upon exposure of the diseased peritoneum to the air, that end could be attained by the injection of sterilized air into the peritoneal cavity through the puncture-opening necessarily made for the evacuation of the ascitic fluid. As the innocuousness of this procedure had already been demonstrated, it only remained to practise it in a suitable case. In three cases so treated the results fully confirmed every anticipation. In none did the ascites recur after a single injection of air. In two, permanent recovery ensued; the conditions in the third rendered such a result out of the question. The apparatus employed in the manipulations is extremely simple. After the fluid has been evacuated by siphonage, the air contained in a glass jar is expelled by means of hydrostatic pressure, and passed through sterilized cotton, and then through warm sterilized distilled water, and finally, by means of a rubber tube and the puncture-needle, into the peritoneal cavity. The insufflation is made gradually, the abdomen meanwhile being gently kneaded. It should cease when the abdomen commences to become tense. The air is aspirated by reversing the process, the removal of the hydrostatic pressure establishing a current in the reverse direction. No harm will result if a small quantity be permitted to remain. The operation has proved quite painless, and no unpleasant sequelæ have been observed. Some degree of meteorism persists for a day or two days afterward.

EDITORIAL COMMENTS.

Admissibility of Expert Testimony Not Based on Personal Experience.—Although it might not be admissible merely to repeat what a witness had read in a book not itself admissible, still, when one who is competent on the general subject accepts from his reading as probably true a matter of detail which he has not verified, the fact gains an authority which it would not have had from the printed page alone, and subject, perhaps, to the exercise of some discretion, may be admitted. So holds the Supreme Judicial Court of Massachusetts in the case of Finnegan *v.* Fall River Gas Works Co. (34 N. E. Rep., 523). This was an action against a gas company to recover for the death, by inhaling gas, of an employé of a city water board while in the gas company's cellar for the purpose of reading the water meter, pursuant to his duties. One of the doctors summoned as witnesses in the case testified that the deceased had a period of conscious suffering before death. To be sure, he had not had any experience of this kind of asphyxiation personally or with patients, but his general competency as an expert seems not to have been questioned. Therefore the court declared itself as recited, and said that it could see no sufficient ground for saying that the testimony admitted in the case could be treated as furnishing no evidence of the fact.

The Mineral-water Coöperative Business.—What fortunate men are physicians! All they have to do to make any amount of money—as it seems—is to enter into secret partnership with "enterprising hustlers," who will do all the work except a paltry word of advice to patients, and turn over to the physician most handsome profits. In so doing a man is not selling his professional honor, because the treatment advised is good! This is an extract from a "confidential" (the word slips with a wink and tells the story!) letter to many physicians:

Dear Doctor: I offer you a coöperative interest in —— Water, in the form of tribute to the amount of one dollar per dozen one-half gallons, when the prescriptions come to me direct, and half that sum when the business reaches me through druggists, providing you furnish me each week with the names of patients to whom you have prescribed —— Water, so that they may be credited to your account.

It is apparent from the above, that in this item a physician may find an income equivalent to interest at 6 per cent. on a real estate investment of thirty thousand dollars ($30,000), as —— Water may easily and properly be prescribed to one hundred families, who on the average may consume one and a half dozen per month.

100 at $18.00 = } $1800.00.
$30,000 at 6 per cent. = }

If you are favorable to this proposal, etc., etc.

Watch the Slaughter-houses.—The *Sanitary Inspector* says that one way in which filthy slaughter-houses are probably detrimental to health is this: Fresh meat is very absorbent of foul odors and is quickly tainted in an atmosphere laden with the germs and stenches of putrefaction. Tainted meat often gives rise to dangerous and sometimes fatal poisoning among those who have eaten such food. The whole idea is revolting—eating meat that has been dressed, and perhaps left to cool from six to twenty-four hours in a building which an ordinary person can hardly enter without suspended respiration and gastric insurrection.

So great an evil had these small and unkempt slaughter-houses become in England that a society was formed a few years ago whose object is to call the attention of the public to their dangers and to secure improvements in the arrangement and care of such places. The society, under the presidency of the well-known sanitarian, Dr. B. W. Richardson, has been doing good work in that country, and it would seem that some such effort is needed in this country, where the people are often too forbearing.

Appendicitis in the Negro.—From the correspondence presented in the present issue of THE MEDICAL NEWS it will probably be concluded, that while appendicitis is less frequent and less severe in the black man, he is by no means free from the disease. We have received a number of other communications upon the subject. Dr. E. R. Conson, of Savannah, Ga., writes that he has seen cases of appendicitis in the negro, but that they seem to be less frequent than in whites. He has noticed no difference in size or structure of the appendix vermiformis. Dr. James A. Turner, of Little's Mills, N. C., has seen and treated two cases in the last five years: one recovered without surgical aid, the other recovered after operation. Dr. Charles J. Aldrich, of Cleveland, Ohio, has had three cases, all of which recovered without operation. Besides these cases, Dr. Aldrich made an autopsy of a case in 1882 that was diagnosticated as one of appendicitis, but death was proved to be due to the fact that twelve inches of the ileum had passed through the ileo-cecal valve, whence resulted general peritonitis. We think the discussion may be closed.

Thyroid Therapy for Psoriasis.—Struck by the remarkable improvement observed in the condition of the skin in cases of myxedema treated by the administration of thyroid extract, Dr. Byron Bramwell, of Edinburgh, was led to try the same agent in the treatment of some chronic and obstinate cases of psoriasis, with results that were at once surprising and gratifying, as detailed at the recent meeting of the British Medical Association. A preparation of thyroid gland was the only medicament given, so that the possibility of doubt was practically eliminated. In some cases the subjective improvement was immediate, and was soon followed by objective evidence of improvement. The inflammatory redness of the diseased areas diminished, and there was considerable desquamation. One patient was made worse; in two the treatment was followed by no benefit; and in one case a slight relapse took place. The question at once suggests itself that if this method of treatment prove ultimately successful in psoriasis, why should it not be applicable to other diseases of the skin as well.

Should Doctors Charge Dentists? is a question the medical journals are trying to decide. The boot might be wisely put on the other foot: Should dentists charge doctors? If a dentist is a graduate physician, the "courtesies of the profession" should certainly be accorded each other by both physician and dentist—at least so far as service and advice. Why not just the same if he is not an M.D.? However, it wouldn't be advisable, as has been seriously suggested, to attempt making the doctors' drugs offset the dentists' gold plates and gold fillings. Hardly!

Figure-heads in the Programs of Medical Congresses.—Complaints are multiplying of the reprehensible practice of announcing as contributors to a proposed medical congress all or many of the great names that it would be desirable to have read papers, regardless of the fact that such persons have not proposed to do so, have not accepted invitations, or have even positively declined to contribute. It may show "enterprise," but "enterprise" is often a euphemism for very contemptible practices.

A Little Kindness Desired.—It has come to the knowledge of the Editor of THE MEDICAL NEWS that by reason of old age, illness, etc., a worthy physician is in want. He is struggling bravely against unmerited misfortune and, if he knew of it, would by no means allow such an appeal as this to be made for him. A little financial aid for a worthy member of our guild is needed, and we should be happy to make him happy by the transfer to him of the gifts of his unknown friends.

SELECTIONS.

FANTASTIC THERAPEUTICS.

THE fantastic character of recent therapeutic suggestions will, it is feared, cause a revulsion of feeling in favor of therapeutic nihilism. The science of therapeutics is particularly subject to the fluctuations imposed upon it by the idealism of its votaries. But, as Sir Thomas Browne somewhere observes, "every poison contains its own antidote," and the excesses practised by the insistent therapeutist engender a corresponding skepticism and mistrust, which ultimately save this much-abused science from the oblivion of ridiculousness.

These two traits, this confidence of the believer and the incredulity of the doubter, are admirably exemplified at the present time. On the one hand, it is found that the ideas which have resulted in the concoction of microbic and animal-extract panaceas for every ailment have devastated the reason of the therapeutist. The very reasonable hypothesis that the various glands supply an internal secretion to the blood necessary to its maintenance as a vitalizing medium has been twisted into the baseless fabric of a vision of every organ secreting or manufacturing specific nutritional substances. In harmony with this conception, a system of therapeutics is suggested which smacks of sixteenth century enlightenment; in which extracts of various organs are administered for diseases of homologous parts. On the other hand, we find a distinguished German observer carrying his nihilism to the extreme of contending that all the results of electro-therapeutics are those of suggestion. Between so much faith and so little, where do we stand? Shall we next hear that opium relieves pain and chloroform produces anesthesia by suggestion? or shall we learn that zygomaticin is extremely beneficial in melancholia?

One of the potent causes of this therapeutic befuddlement doubtless arises from the proprietary interest in remedies. The profession is perpetually deluded by those who claim to enlighten it by carefully prepared information of an unreliable kind, regarding the physiologic and clinical action of remedies. This makes it more and more incumbent upon the intelligent physician to limit his prescriptions to the actual materia medica, of which he possesses definite and reliable information.

It would be sad to think that nothing should result from this outrageous idealism in therapeutics. If it be that "the end of dreams is to break them," let them be broken rudely, provided this restore us to a fair degree of therapeutic sanity.—*The Physician and Surgeon*, August, 1893.

THE COMPOSITION OF QUACK-REMEDIES.

Signs are not wanting that the common-sense of a long-cozened British public is beginning to assert itself in the matter of quacks and their practices. For some time past a plucky little paper—*Hygiene*—has been publishing a series of articles with analyses of many popular patent medicines. It is astonishing to note the number of remedies which depend on the homely virtues of aloes, eked out by equally commonplace properties of such substances as treacle, hard soap, and powdered ginger. We may hope that the good seed of knowledge thus sown broadcast by that courageous editor will fructify to some future purpose in the minds of the community. One clear contributory force in the revolution will be the rousing of Englishmen to the way these charlatans have picked their pockets. The trial of the woman Ruppert a week or two since in the Irish courts showed that the poisonous nostrum she vended at half a guinea had a commercial value of about a halfpenny. The disclosure of the latter fact will probably deal a heavier blow at the pernicious system of patent and proprietary medicines than many years of journalistic agitation would be able to effect. Another hopeful sign is that the newspapers generally are beginning to seek for more light on this important subject. It is true that the leading papers, with some few honorable exceptions, have not yet had the courage to exclude the advertisements of proprietary articles, even when proved worthless in open court.—*Medical Press and Circular*, August 30, 1893.

REVIEWS.

Brain-Surgery. By M. Allen Starr, M.D., Ph.D., Professor of Diseases of the Mind and Nervous System, Medical Department of Columbia College. N. Y., etc. With fifty-nine illustrations. Pp. 295. New York: William Wood & Co., 1893.

This is the first distinctively American monograph on this fascinating subject, and pleases the reader not alone on account of its title, but because of the personality of its author. The translated monograph of Bergmann has until recently been the principal source to which students of this subject have referred. It is, however, not so comprehensive nor so suggestive as the one in hand, and it by no means does justice to the work of the American neurologists and surgeons, whereas this work of Dr. Starr is in large measure devoted to the labors of his *confrères* in this field. That he has been a careful student of the subject goes without saying, and that there is very little accessible literature on the subject which has not been referred to will appear from an examination of its pages. A large portion of the book is devoted to trephining for epilepsy and kindred disorders, to which about 130 pages are devoted. The author has studied the matter carefully, and apparently impartially, in the light of the experience of the last few years, and if not enthusiastic in favor of surgery in this condition, justifies this later by comparison of the results which he reports. We are pleased to see him emphasize, on page 27, the fact that when both medical and surgical indications for operation exist, but do not coincide, it is better to follow the medical indication, *i. e.*, it is better to trust to localizing symptoms than to the presence of scars or even depressions over portions of the cortex whose function is not known.

In the section devoted to the pathologic changes observed during operation he has been quite full, and as satisfactory, perhaps, as the subject permits. In speaking of the later results of excision of portions of the brain he quotes Coen, who says: "Should reproduction of brain-tissue fail to occur in the region where brain is destroyed, a connective tissue fills its place which forms a scar in the true sense of the word." In summing up results he aknowledges that in the majority of operated cases there has been a failure to permanently cure by operative interference. When we ask why, the answer must be that the original condition which gave rise to the effect has not been removed. While it is possible to elevate a depressed bone, to remove cysts, and take away the connective tissue, it is useless to simply break up adhesions, because they will always re-form. In this regard he seems to have taken no notice of the recent suggestion to insert gold foil between the dura and the cortex to prevent this very thing. He fears that excision of any portion will always be followed by the formation of a cicatrix, which in turn will act as an irritant. He does not argue that we should, therefore, be deterred from operating, but says, judging from general results which are unfavorable, that we should be inclined not to operate, but must take into consideration that in no case is it possible to predetermine just what or how beneficial the results of an operation may be. Some patients have undoubtedly been cured. It is here, we feel, that he has made an important omission in not referring to the necessity for a long-continued dietetic, hygienic, and drug treatment of these cases after operation, and he nowhere lays stress upon the so-called epileptic habit into which these patients have fallen, and which must be cured by these measures rather than by operation alone. Altogether he favors operation for selected cases.

With trephining or craniotomy for imbecility he deals very fairly, although not quite as fully as he might have done. For instance, he does not state the minimum circumference of the skull which makes a case hopeless for operation. This limit has been fixed by French authority at seventeen inches. And we look in vain through his pages for a description of that condition commonly spoken of as too early synostosis, due usually to rickets, which leaves a fairly normal brain in a condition in which expansion is impossible.

An interesting chapter is devoted to trephining for intra-cranial hemorrhage, which must for the most part be confined to traumatic cases, although success has followed the operation in cases of apoplexy of or near the cortex.

Of abscess of the brain and its operative relief he speaks at some length, and he gives a very compact summary of the symptoms due to abscess following ear-disease, with such directions as are necessary for the operator. Over fifty pages are devoted to the subject of brain tumors, including their symptomatology, with detailed reports of cases of his own. He advises, when brain-tumor is suspected or diagnosticated, if mercury and potassium iodid fail to relieve the patient within three months, or if during that time the symptoms rapidly increase, that operation should not be delayed. In

dealing with cysts he emphasizes the wisdom of removal of the cyst-wall, as otherwise it would probably refill and require further operation.

Due attention is devoted to trephining for hydrocephalus and for relief of intra-cranial pressure, and he appears to rather favor than discourage this operation. For insanity and headache, persistent and severe, the operation is occasionally to be recommended, but it is almost impossible as yet to formulate explicit rules; each case should and must be studied on its merits.

The final chapter is devoted to the operation itself, which is succinctly described and treated at sufficient length. This is, so far as we know, the first attempt by a neurologist to write a surgical treatise, and it has proved a success. In these cases, as well as in many others, the surgeon and neurologist must work hand-in-hand, and it is a pleasure to find a specialist in internal medicine who is quick to perceive the indications for operation, and so competent to judge of what ought to be done, and how. We congratulate the author very warmly upon his excellent work.

A CONTRIBUTION TO THE PATHOLOGY OF THE VERMIFORM APPENDIX. By T. N. KELYNACK, M.D. London: H. K. Lewis, 1893.

THIS volume embodies the results of the writer's evidently careful and extended personal observations upon the pathology of the vermiform appendix, as well as much useful information on the subject culled from the writings and reports of others.

There is probably no subject that has attracted more attention of late years, both from the medical and surgical standpoint, than that of disease of the appendix, and a systematic consideration of its pathology, especially by one who has had the opportunities for observation that Dr. Kelynack has, is a timely and welcome contribution to literature.

After discussing the development and physiology of the appendix, as well as the early references to appendicitis, the variations met with in the length and lumen of the appendix are taken up, and then follows a most interesting chapter on the pericecal peritoneal fossæ. Then in order follow chapters on variations in position, herniæ of the appendix, the histology, cystic dilatation of the appendix, and next its inflammatory affections are taken up. The writer makes some good criticisms on the complicated and uncertain terminology of affections of the cecum and appendix. In classifying the forms of appendicitis he adopts a very simple grouping, making three divisions: 1. Simple Appendicitis; 2. Perforative Appendicitis; and 3. Recurrent Appendicitis. The specific forms—tuberculous, typhoid, and actinomycotic appendicitis—are considered separately.

Upon the question of treatment, Dr. Kelynack's views, based as they are upon such extended observation, seem to us most fair and temperate. As he happily suggests, there is considerable difference of opinion between physicians and surgeons as to treatment in many instances, and the reason for this is obviously, as he points out, the fact that the medical men are likely to base their judgment upon the mild cases, which come under their care, and which recover with medical treatment, while the surgeons' experience is derived from the more severe cases, in which the occurrence of suppuration, or of peritoneal infection, demands operative interference. As the writer says: "Since the adoption of surgical measures may be demanded in what even seems to be a mild form of appendicitis, it is most desirable, if we are to live up to our knowledge of pathologic facts, that there should be free and early coöperation of physician and surgeon."

This book is one which will well repay reading; it contains much that concerns the general practitioner as well as the pathologist or the surgeon. The bibliography, with which the volume concludes, and the extensiveness of which will doubtless surprise not a few readers, will be appreciated by those who have occasion to write upon, or to investigate the literature of, disease of the appendix.

ABNORMAL MAN. (BUREAU OF EDUCATION, CIRCULAR No. 4, 1893.) Being Essays on Education and Crime, and related subjects, with Digests of Literature and a Bibliography. By ARTHUR MACDONALD, Specialist in the Bureau of Education. 8vo, pp. 445. Washington: Government Printing Office, 1893.

THIS report, just issued by the Government, is very valuable as containing the latest statistics and literature in the comparatively new science of criminology.

The author leaves aside all theorizing and devotes himself entirely to the arrangement of investigations and reviews of the latest writings, summarizing them so that the reader can familiarize himself with the best thoughts of the now famous criminal anthropologists of the Italian and French schools. He believes that "to experimental medicine scientific ethics will look for many of its basal facts."

The pathology of society must be studied experimentally, as the pathology of man is studied. Criminal anthropology is very closely connected with psychologic medicine; and one experienced prison-warden believes that the prisons of the future will be in charge of physicians.

Social diseases are intimately connected with physical disease, and the medical man is becoming more and more a factor in the efforts made to cure and prevent them.

To those who are connected with institutions for the defective and criminal classes this report is very essential, containing, as it does, an extensive bibliography of crime, alcoholism and allied habits, insanity, pauperism, and social pathology.

The most important contributions of the past few years are reviewed and a synopsis is given. Criminology, alcoholism, criminal and hypnotic suggestion, insanity and genius, and charitologic and ethical literature are some of the subjects treated in detail.

Just as pestilence and insanity are no longer considered visitations of an angry Divinity, so are crime and pauperism being slowly shifted away from the ideas of inherent depravity and original sin, and are considered diseases for whose existence society is chiefly to blame.

Expiatory punishment is no longer looked upon as the proper treatment.

Prophylaxis is the cry of the modern criminologist, and an asylum for chronic cases one of the methods of carrying it out.

Mr. MacDonald's report should be read by every physician, for his opinion may be sought any day in the discharge of his various duties.

Nursing: its Principles and Practice, for Hospital and Private Use. By Isabel Adams Hampton, Graduate of the New York Training School for Nurses, attached to Bellevue Hospital; Superintendent of Nurses and Principal of the Training School for Nurses, Johns Hopkins Hospital, Baltimore, Md.; late Superintendent of Nurses, Illinois Training School for Nurses, Chicago, Ill. Illustrated. Philadelphia: W. B. Saunders. 1893.

This latest nursing-book is well written and very readable, the best parts being those on "Observation of Symptoms" and "Obstetrics."

The remarks on page 58: "An intimate friendship between the head nurse and pupil nurse ought never to exist, if only for the sake of the patients;" and on page 342: "A well-trained nurse is never guilty of attempting a diagnosis of a disease even when invited to do so;" and those on economy on page 65 will, we hope, commend themselves to all.

The first chapter is not, we think, likely to be followed by any training school-head, unless it be one of the author's pupils, each one having her own preferred plan.

In Chapter II, the important duty of cleansing sputa-cups is given to an orderly, and yet in Chapter IX especial precautions are written as to their disinfection from a bacteriologic standpoint.

We cannot agree with the statement on page 55: "Hospital etiquette consists of nothing more than the continual and systematic observance of *every-day* courtesies"—a hospital having a code of its own, like to no other we know of.

The knowledge is distributed somewhat unevenly, nine pages being given to temperature, while two cover croupous pneumonia and one and a half smallpox.

Take it as a whole, the book is a valuable addition to a nurse's library. An excellent glossary is a commendable addition to the work.

The spelling is as rigidly medieval as possible, although at least one opportunity was missed—*perineum* is not spelled *perinæum*. The author, of course, spells *feces*, *fæces*, but why not logically also *defecation*, *defæcation*. In the index *Trommer* is repeatedly spelled *Trömmer*, and throughout the book *albumen* is written instead of *albumin*.

Heath's Practical Anatomy: A Manual of Dissections. Edited by William Anderson, F.R.C.S., Surgeon and Lecturer on Anatomy at St. Thomas' Hospital; Professor of Anatomy at the Royal Academy of Arts; Examiner in Anatomy for the Royal College of Physicians and Surgeons. Eighth edition. 329 illustrations. 8vo, pp. xviii, 744. Philadelphia: P. Blakiston, Son & Co.

Those familiar with text-books upon practical anatomy in general, and with Heath's *Practical Anatomy* in particular, will welcome the eighth edition in its new and reconstructed form. This edition has been subjected to an extensive revision in order to bring it to a level with current teaching and the present requirements of the examination boards.

The original plan of the work has been carefully preserved, but the more recent progress in topographic anatomy, involving, as it does, a greatly increased precision in description, especially in connection with the viscera, has necessitated an almost complete reconstruction of certain sections, and the addition of new matter to the extent of 150 pages, without increasing materially the bulk of the book.

The work of the editor is everywhere visible, without the unsightly and objectionable letter "E," so common in revisions. The reconstruction has been complete, and stamps the distinguished editor as in every way the equal of the celebrated author of this popular work.

In addition to the many valuable additions to the text everywhere throughout the work, the illustrations are particularly striking, clear, and forcible, and add much to the practical value of the book as a working dissector, in which capacity it has been so much employed. The editor has added no less than thirty-four original cuts, besides the large number selected from other recent works for this edition.

The new edition deserves, and no doubt will receive, even more liberal support than the past editions of this popular book have ever enjoyed. There is, however, one change which should be made to bring this work up to date—to have the parts on the illustration lettered and not numbered. This would be an expensive luxury to the publishers, but one which modern ideas demand.

Transactions of the Medical Society of the State of New York for the Year 1893. Published by the Society. Philadelphia: William J. Dornan. 1893.

Among many interesting papers, our attention has been specially attracted by those of Elsner, Einhorn, and Stockton upon "Diagnosis and Treatment of Disorders of the Digestive Tract." Bulkley's report upon "Chancre of the Tonsil" is an important contribution to a subject of perennial interest. "Carcinoma" is another topic that has received careful discussion; and we heartily commend the course taken by the Society to secure adequate presentation of vital topics. Dr. Pilcher's "Presidential Address" and its probable consequences, we have previously discussed.

CORRESPONDENCE.

IMMUNITY TO APPENDICITIS.

To the Editor of The Medical News,

Sir: In your issue of September 2d you quote one of America's foremost surgeons who cannot call to mind or learn of any of his Southern *confrères* who has seen appendicitis in the black man. This statement recalls two other immunities of the black race to which I referred in a letter published in the *Medical Record*, August 27, 1892: the immunity to scarlet fever and that to locomotor ataxia. These three immunities (assuming that the immunity to appendicitis is real) are common to the negroes, as to the Japanese. My own experience has been chiefly with the Japanese. One might be inclined to attribute the existence of these immunities in the Japanese to a fusion of negro blood some 1300

years ago. That such a negroid fusion took place is recognized by all ethnologists. The Eta, the distinctly leprous element, is decidedly a negroid race, of which we are forcibly reminded by some of their features—for instance, their curly hair, their pigmented sclerotic, etc. Baelz even thinks that the outcast Etas are descended from the ancient leper colonies. The isolation of this element, in consequence of its being a prey to leprosy, kept the negro characteristics from vanishing. That leprosy was rampant in that race is but natural, as leprosy is an African disease.

The occurrence of locomotor ataxia has been attributed to syphilis. Gowers has found 90 per cent. of his cases of ataxia to have originated in syphilis. Starting from this proposition, we should conclude that there is no syphilis in Japan, as there is no locomotor ataxia. But quite the reverse is true: the fact is that the race has been rotten with syphilis in the course of thirteen centuries; though the disease, being modified, is now less virulent. As we are not able to connect the immunity to ataxia with syphilis, it is natural, I think, to connect it with the negro characteristics inherited by the Japanese race.

However, I have been in the habit of taking quite a different view from the ethnologic one of the immunity to appendicitis. It seems to me that the diet has very much to do with it; temperance in eating, aseptic hot water (Japanese tea is drunk continually), vegetable diet (Japanese eat rice in enormous quantities, as all the world knows), absence of meat-diet (almost absolute in Japan), with its ptomaïnes and leukomaïnes, may be, after all, the cause, though indirectly, of the absence of appendicitis in Japan. A vegetable diet necessitates a large extent of intestine, and this extraordinary intestinal length belongs to the Japanese. The following passage from one of Dr. Scheube's articles will, I think, be interesting in this connection: "In my 'Remarks on Japanese Diet' I said that very probably the rice is better used up in the intestine of the Japanese than in that of the European, and I expressed a surmise that the Japanese intestine must be the longer of the two. I had before me, at that time, one single measurement, that of the intestine of an adult Japanese. The total length of the intestine amounted, in this sample, to 995.5, of which 183 belonged to the large intestine. The length of the body itself was 156.5.

"Mr. Taguchi, professor of anatomy in the Japanese Section of the Medico-Surgical Academy, in Tokio, has since kindly communicated to me the results of his measurements, both of body and intestine, on the corpses of 26 persons between seventeen and sixty years old. He made use of the Japanese measures, which I have converted into metric figures (1 shaku = 0.303 m.).

"These 26 cases give a length of intestine of 953.7 cm. The maximum was 1203, the minimum 0.667; only three times was the intestine less than 800 cm. in length. Hoffman, in his *Manual of the Anatomy of Man*, states the length of the intestine as from 8 to 9 m. Accordingly, even the absolute length of the intestine is greater in the Japanese than in the European.

"The differences are still more striking if we take into account the size of the body, and if we reduce the intestinal length to 100 cm. of the body-length. Hoffman, from whom I have quoted the foregoing figures as to the length of the intestine, found in men an average size of the body of 167.8 cm. Thus, 8½ m. being admitted to be the average length of the intestine, there are 506.5 to 100 cm. of bodily length. The average length of the body amounted in our 26 Japanese to 156.9,[1] so that to a body-length of 100 cm. corresponds an intestinal length of 607.8 cm. The intestine of the Japanese is one-fifth longer than that of the European. Whether further measurements will confirm these conclusions or not remains to be seen."

I must add here a few words explanatory of the manner in which, to my mind, the effect of the vegetable diet is produced. The vegetable or graniferous diet is gaseous. The gases, inflating the intestine, prevent the impaction of the appendix vermiformis.

But, however it may be explained, the fact remains that those people among us whose fare is the plainest and least concentrated (which is the nearest approach to pure vegetarian diet) are as exempt from appendicitis as any Japanese could be. The disease chooses for its victims only the highly fed, the great meat-eaters, wine-bibbers, and those that keep their blood in that plastic and consequently inflammable state which a meat-diet naturally produces.

Therefore, let anyone who has suffered from a first onslaught of appendicitis betake himself to a diet of hot water (omitting the spirit) and vegetables, and taboo the meat.

Yours truly,

ALBERT S. ASHMEAD, M.D.

NEW YORK.

APPENDICITIS IN THE NEGRO.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of September 2d the question of appendicitis in the negro is presented, with a proposition to record the results of experience in this connection.

It so turns out that a number of cases have been under my care, either directly or in consultation, in which there were well-defined signs of inflammatory action in the right flank of the negro. These cases were in most instances classified as typhlitis; but, with the light we have on the inflammatory troubles in this region, it is very probable that some of them originated in the appendix vermiformis. As they were not subjected to any operation and fortunately recovered without affording an opportunity for a post-mortem examination, there must remain a doubt as to the diagnosis.

There is, however, one case in the person of a negro, in regard to which all doubt was removed by an operation showing the existence of appendicitis. This was a patient of Dr. T. D. Longino, who saw the man first on April 23, 1891. Dr. Longino writes me that the patient complained of his bowels being cramped after drinking a quantity of ice-water. He was given a dose of morphin, which afforded little relief, and in about two hours the physician was called again, finding the man still in pain. The morphin was repeated, and more was left, to be taken during the night. Upon calling again before day, it was found that the patient had suffered all night, and morphin was given hypodermatically. The bowels being distended,

[1] The same figure is also given by A. Weissbach as representing the average size of the Japanese. I found by a large number of measurements a somewhat higher one—158.3 cm.

hot stupes of spirit of turpentine over the abdomen seemed to afford temporary relief during the 24th. Upon seeing the man again on the 25th there was still pain and the temperature had gone up considerably in the meantime. I was called by Dr. Longino on the morning of the 26th and concurred in his opinion that the patient was suffering from appendicitis, requiring operative interference without delay. Dr. W. A. Crewe was invited to examine the patient and fully acquiesced in the propriety of attempting to save life by an operation, though the man was then in a very prostrate condition and the abdomen enormously distended, indicating general peritonitis. In the presence of Dr. Butterfield, of Binghamton, N. Y., who was on a visit to Dr. Longino at the time, and, with the assistance of the colleagues named, I performed the usual operation and found the appendix vermiformis much inflamed and perforated by a fecal concretion. It was ligated near the attachment to the caput coli and excised. After washing out the cavity, I was proceeding to close the wound, when the patient ceased to breathe and died.

A case has been reported to me by a colleague, in the person of a negro woman, who was undergoing an operation for a different disease, in whom it was noted that the apendix was inflamed and contained what was supposed to be fecal concretions. But not thinking it proper to complicate the case by adding to the traumatism by the removal of the appendix, this was returned without interference, and the woman made a good recovery, illustrating that all troubles of the appendix do not require its removal. This observation, however, shows not only the existence of appendicitis in the negro, but also its occurrence in the female.

According to the records accessible to me, there are comparatively few instances of appendicitis among women, and it has not come within my experience to treat a single case in the female.

This observation may lead others to collect statistics bearing upon this point.

Respectfully,

J. McFadden Gaston, M.D.

Atlanta, Ga.

APPENDICITIS IN THE NEGRO.

To the Editor of The Medical News,

Sir: Is the negro subject to appendicitis? Yes. On June 21, 1893, I saw a full-blooded negro, about fifty years old, with undoubted symptoms of appendicitis. I operated on the 28th, and found the appendix perforated and gangrenous. The man died of septicemia about six days after the operation. I have seen only two other cases, both in white persons, however, and in both recovery took place after simply opening an abscess. A fistula remained for six months in one, but closed very soon in the other.

Respectfully, R. M. Hand, M.D.

Shubuta, Miss.

APPENDICITIS IN THE NEGRO.

To the Editor of The Medical News,

Sir: In response to your request, as expressed in your issue of the 2d inst., I will state that I have had two cases of appendicitis in the negro. Both were seen in consultation, and both occurred a number of years ago before we had heard much of operative interference. Both resulted fatally, and in both a post-mortem was secured, verifying the diagnosis. One was in a full-blooded negro, the other in a half-blooded one; the former was aged about thirty, the latter about forty.

I have had an unusually rich experience with appendicitis, and, considering the size of our colored population, if the foregoing cases are all that I have had (and they are all that I can now recall), I should regard the assumption justifiable that the negro is not as subject to this disease as the white man.

Very respectfully,

J. F. Baldwin, M.D.

Columbus, Ohio.

NEWS ITEMS.

The British Medical Association is to hold its next annual meeting at Bristol, under the presidency of Dr. Long Fox.

Dr. Herbert R. Spencer has been appointed Professor of Midwifery and Obstetric Medicine in University College, and Obstetric Physician to the University College Hospital, London, in succession to Dr. John Williams, who has resigned.

Graily Hewitt, for many years Professor of Obstetrics in University College and Obstetric Physician to University College Hospital, London, died recently at the age of sixty-five years. At the time of his death he was Emeritus Professor in the College and Consulting Physician to the Hospital.

The Army Medical School.—By direction of the Secretary of War, upon the recommendation of the Surgeon-General of the Army, the Faculty of the Army Medical School recently established will be made up of Colonel Charles H. Alden, Assistant Surgeon-General, U. S. A., President of the Faculty, and Lecturer on the Duties of Medical Officers; Lieutenant-Colonel William H. Forwood, Deputy Surgeon-General, U. S. A., Professor of Military Surgery; Major John S. Billings, Surgeon, U. S. A., Professor of Military Hygiene; Major Charles Smart, Surgeon, U. S. A., Professor of Military Medicine and Director of the Chemical Laboratory; Captain Walter Reed, Assistant Surgeon, U. S. A., Professor of Clinical and Sanitary Microscopy and Director of the Pathological Laboratory; and Captain Julian M. Cabell, Assistant Surgeon, U. S. A., Assistant to the Professor of Military Surgery and Instructor in Hospital Corps Drill.

The course of instruction will cover a period of four months, and will be given annually at the Army Medical Museum, in Washington City, commencing on the first day of November. It will include lectures on and practical instruction in: 1. The duties of medical officers in war and peace. 2. Military surgery, the care of the wounded in time of war, and hospital administration. 3. Military hygiene. 4. Military medicine. 5. Microscopy, sanitary and clinical; pathologic histology, bacteriology and urinology. 6. Hospital Corps drill, and first aid to wounded.

By permission of the Surgeon-General, medical officers of the Army who desire to avail themselves of the course of instruction, and who are stationed in or near the city of Washington or who have a leave of absence which

enables them to attend the course, may be admitted as pupils under the same regulations as apply to recently "approved candidates for admission to the Medical Corps of the Army."

At the termination of the course of instruction the "approved candidates for admission to the Medical Corps of the Army" will be examined by the several professors, and their relative proficiency in each branch will be reported by the president of the faculty to the Secretary of War through the Surgeon-General of the Army.

Regulations.—1. The president of the faculty will be responsible for the discipline of the school.

2. The junior professor will act as secretary and will be responsible for all property pertaining to the school.

3. A faculty meeting will be held in the office of the Secretary on the first Monday of each month from October to March, inclusive, and whenever called by the president of the faculty or the Surgeon-General of the Army.

4. Resolutions adopted by the faculty relating to the course of instruction, the purchase of books and instruments, etc., will be submitted to the Surgeon-General of the Army for his approval.

5. The president of the faculty will submit to the Surgeon-General of the Army, on or before the first day of April of each year, a detailed report of the condition of the Army Medical School, including an account of the instruction given, and the proficiency of the several pupils, as shown by an examination made by each professor at the termination of his course.

6. The hours of instruction will be from 9 to 12 A.M., and from 1 to 4 P.M., daily, from November 1st to February 28th, inclusive, with the exception of Saturdays, Sundays, legal holidays, and the week commencing December 25th.

7. Pupils will be required to be present during the hours designated, unless specially excused by the president of the faculty or by orders from the War Department.

8. When necessarily absent on account of sickness or other emergency, pupils will, as soon as practicable, send a witten statement to the secretary of the faculty, explaining the reason for such absence.

9. The laboratories and library of the Army Medical School will be open for the use of pupils during the hours of instruction designated.

10. Pupils will be held strictly accountable for all instruments and apparatus issued to them for their personal use during the course of instruction, and for any loss or injury to books or apparatus belonging to the Army Medical School, when such loss or injury is due to carelessness or neglect.

11. Pupils in the Army Medical School, during the hours of instruction, will wear the undress uniform of the grade to which they belong, except when engaged in laboratory work, when a black cambric laboratory gown may be worn.

THE PRINCIPLES OF IMMUNITY AND CURE IN THE INFECTIOUS DISEASES.

BY VICTOR C. VAUGHAN, M.D.,
PROFESSOR OF HYGIENE AND DEAN OF THE DEPARTMENT OF MEDICINE AND SURGERY, UNIVERSITY OF MICHIGAN, ANN ARBOR, MICH.

(Continued from page 400.)

THERE are three reasons (only one of which has heretofore been recognized) why the germicidal properties of blood-serum are greater than those of blood-plasma. These are: 1. The lessened amount in the serum of those substances that favor bacterial growth. 2. The concentration in the soluble nucleins that occurs as a result of clotting of the blood. And 3. The passage of the substance of the multinuclear cells into solution.

When I speak of the solution of the substance of the multinuclear cells I do not wish to commit myself to the theory that the entire cell breaks down. I refer simply to the fact—and I believe it to be a fact, as I have found nuclein in solution in blood-serum—that the nuclein passes from the cell into solution. Whether this process is due to the breaking down of the cell or to an active secretion on the part of the cell, I am as yet unable to determine.

As is claimed by Metschnikoff, there are obvious advantages to the animal in having the germicidal constituents of its blood (partly) in the form of ameboid bodies. Concentration at a desired place can be more easily accomplished, and the walls of the arteries and other tissues may be traversed without injury. But these cells do not eat and digest the invading bacteria. There are reasons for believing that they have no power to retard the progress of the invading bacteria until the constituents of the cells pass into solution. Germs often grow and multiply in these cells.

The fact mentioned by Metschnikoff as a proof of his theory that in the apyretic stage of relapsing fever all of the spirilla are found in the splenic cells, while in the pyretic stage they are free in the blood, is capable of a wholly different explanation from that which he attributes to it. It seems to me more likely that the spirilla seek the interior of these cells as a place of rest, where they reproduce themselves, and from which they go forth with renewed energy. In the monkey the splenic cells fail to afford this protection, and the pyretic stage does not return. Metschnikoff himself states that the malarial hematozoön, during the ameboid stage of its existence, finds its way into the corpuscle, and from the substance of this the parasite takes its nourishment.

The action of the soluble or alkaline nucleins on germs may be either inhibiting or directly toxic, or both. It is not necessary that the invading germ be killed in order to prevent its producing disease. If its growth and multiplication be inhibited the disease will not follow. Metschnikoff has shown that some of the germs taken even after many days from the local abscess formed in an immune animal inoculated with a pathogenic germ, and injected into a susceptible animal, may cause the disease. These nucleins are not only germicidal; they are also toxicidal. They render inert the bacterial nuclein, whether this be present in living or dead cells, whether it be in suspension or in solution.

In order to state my views upon immunity in a condensed form, and to bring this address within the limits of the time allowed, I will summarize as follows:

There must be three factors in the production of immunity in an animal naturally susceptible. First there must be an inciting or immunizing substance introduced into the body. We are acquainted in a rough manner with the nature of some of these substances, such as the venom of the snake, the vegetable proteids, abrin, ricin and robin, and certain bacterial proteids. I call these proteids, and I wish it to be understood that I do so tentatively, and that I recognize the fact that the exact chemical nature of none of them is known; but for the present we may call them proteids. For reasons already given, I believe that these proteids, which induce immunity, belong to the class of nucleins. I am aware of the fact that physiologic chemists do not always classify the nucleins among the proteids, but among the albuminoid bodies. These substances, be they nucleins, proteids, or albuminoids, have the property, when introduced into the bodies of certain animals, in certain amounts and under certain conditions, of so stimulating the activity of certain organs in the animal that these organs produce and supply to the blood an antidote to the substance introduced.

Secondly, the organs whose activity is stimulated by these immunizing agents are those, such as the spleen, thyroid gland, and bone-marrow, which manufacture nucleins.

Thirdly, the antidotal substance is a nuclein. The kind and amount of nuclein formed will depend upon the nature of the inciting agent and the condition of the organ or organs acted upon.

I use the word "nuclein" in a broad sense, including the true nucleins, nucleinic acids, and nucleo-albumins. By the term "nuclein" I mean that part of the cell which under normal conditions is endowed with the capability of growth and reproduction, which assimilates other proteids and endows these assimilated substances with its own properties. It is that part of the cell which gives it its individuality. Whether these nucleins, while in solution and devoid of morphologic unity, are still capable of assimilating allied bodies or not, cannot at present be positively determined. There is no *a priori* reason, so far as I know, for denying this. These different nucleins, that of the bacterial cell, and that of the blood, may be isomeric bodies, one of which may be designated as the α-compound, and the other as the β-compound, and one of these by simply causing a rearrangement in the atoms within the molecule of the other may assimilate the second. There are some good reasons for believing that certain proteid bodies contain a cyanogen-group, and Kossel has shown that nuclein contains a basis-substance, adenin, which has the formula $C_5H_5N_5$ and is a polymer of hydrocyanic acid, and Gautier has synthesized another constituent of nuclein, xanthin, by simply heating hydrocyanic acid in a sealed tube in contact with water and a little acetic acid. Indeed, the readiness with which cyanogen-bodies polymerize is well known to chemists. Thus, liquid chlorid of cyanogen C N Cl converts itself spontaneously, under certain conditions, into solid chlorid of cyanogen, $C_3N_3Cl_3$; cyanic acid into cyilid; methyl cyanic ether, C O N (CH_3) into methyl cyamin ether, $C_3O_3N_3(CH_3)_3$, and cyanogen into paracyanogen.

I do not mean to say that the process by which a nuclein assimilates another proteid is as simple as would be indicated by these examples, but they may suggest something of the nature of the chemistry of assimilation. We may suppose that when an alpha-nuclein and a beta-nuclein are brought together, one will assimilate the other; and which one will absorb the other will depend upon the relative strength or vitality possessed by them, and in measuring this strength several things must be taken into consideration. A vaccine has less of this power of assimilation than a germ of full virulence, and a nuclein in a sterilized culture less than either of the others.

An organ that has once been stimulated by a given excitant responds more quickly the second time to the same excitant, provided that the interval of time is not too great. This explains the gradual loss of acquired immunity.

Again, an organ that is stimulated by one excitant may not be responsive to another, and this accounts for the fact that an animal rendered immune to one disease remains susceptible to another.

The poison that is introduced is destroyed by the activity of certain cells. In order, however, to accomplish this destruction, it is probably not necessary that the poison should come in contact with the cells. For instance, the activity of the spleen has been found necessary, as the experiments of Tizzoni and Cattani have shown, to the production of immunity to tetanus. We can suppose that the process of immunizing an animal proceeds in something like the following manner: The modified virus of tetanus is introduced into some distant part, in some unknown way; the spleen is stimulated to action, and secretes a nuclein which is carried partly in solution, partly in the form of multinuclear cells, to the invaded part of the body, and the tetanus-poison is converted into the nuclein coming in contact with it, or is otherwise rendered inert. Later a larger quantity of the tetanus-poison is introduced, and now the spleen acts more promptly and energetically than before. This promptness and energy of action are increased by exercise, and finally an amount of tetanus-culture, of full virulence sufficient to kill an animal whose spleen has not been subjected to this training, may be introduced without ill effect. On this theory the production of immunity consists in a special education of certain cells, and artificial immunity becomes essentially cellular.

The difference between immunity and tolerance I conceive to be this: In the former the cells of certain organs become aggressive; a special function is developed; the poison introduced is destroyed. In tolerance, there is no aggressive action on the part of any organ; there is no development of special functions; the poison introduced is not destroyed; it only fails to kill.

Now, what can be said about the relation between the principles of immunity and those of cure? Are they the same? I think that there are essential differences. In the first place, the substances with which immunity is induced are not applicable in the production of a cure. They are already in the body, and have failed to stimulate the nuclein-forming cells in such a manner as to cause their own destruction. To introduce more of the bacterial poison after the invading virus has established itself in the system will only strengthen the invader. No disease, after being well developed, has been cured by the administration of the bacterial poison. I believe that vaccination, first performed after exposure to smallpox, may altogether prevent the development of the disease, or may modify it, but this is not cure. Of what service would vaccination

be when the body is already covered with smallpox-pustules?

Some experimenters have found that if a certain substance be introduced into the animal simultaneously with, or a few minutes, or at most a few hours, after the introduction of the virulent germ, the disease either does not appear, or it appears later than it does in control-animals, and they have claimed that these are instances of cure. Thus, Behring speaks of *curing* diphtheria in guinea-pigs with iodin trichlorid. He injected this "curative agent" immediately after inoculation, and at the place of inoculation, and found that, of the animals thus treated, some, although they sickened, did not die. He may have induced immunity in this way by the action of the chemical agent on the bacterial proteid, though this has been experimentally denied by Tizzoni and Cattani, but certainly such results do not deserve to be designated as cures.

Koch attempted to cure tuberculosis by introducing the proteid of the specific bacillus into patients. Theoretically this was a mistake, because this proteid in living, virulent form, is already present in the patient, and, indeed, is the cause of the disease. Immunity to tuberculosis has been tested by Nature in each tuberculous person, and has been found wanting. Some step in the process has failed. Either the poison was first introduced into the body in a form too virulent to be resisted, or the cells of the body have been unable to act with normal energy.

If I am right concerning this difference between the agents of immunity and cure, to what source shall we look for curative substances in the infectious diseases? Either we must introduce into the body some germicide formed by other cells, or we must employ other agencies for the purpose of stimulating the nuclein-forming cells. Blood-serum therapy offers the first of these alternatives, and now that we know that the germicidal constituent of the blood is a nuclein, blood-serum therapy will give place to nuclein-therapy, and with the latter there is more hope of accomplishing good results, because it reduces the size of the dose.

I say that the germicides from which we now hope for good results in treatment must be of cellular origin. The experience of the medical profession for the past twenty years has demonstrated that there is no known chemical substance which can be introduced into the animal body in sufficient quantity to effect a cure by its germicidal action without harm. Time after time the discovery of a non-poisonous, powerful germicide has been announced, but experience has invariably shown either that the substance is poisonous or that it is not germicidal. This universal experience of the profession has been scientifically demonstrated to be a fact by the researches of Behring, who after a large number of experiments came to the conclusion that, computed on the body-weight of the animal, antiseptic substances reach a fatal dose when injected in absorbable form under the skin in one-sixth the amount which is necessary to prevent the development of the anthrax-bacillus in the blood-serum.

Now that we have learned that the animal body itself generates a germicide more powerful in its action than corrosive sublimate, and since we know how to increase the amount of this substance in the blood, and can isolate it, and inject it into other animals, renewed hope comes to us.

I have stated that one advantage which nuclein-therapy will have over blood-serum therapy is to be found in the fact that it may enable us to employ the active substance in larger doses. We have seen all along that quantity as well as quality must be taken into consideration in the production of both immunity and cure, and that the effects are in proportion to the quantity. Even the ultra-bacteriologist does not now claim that a single bacillus of the most virulent kind introduced into the most susceptible animal will cause disease. The animal body is no longer to be regarded as a mere culture-flask, in which germs grow without meeting with the slightest resistance; and after the germs of tuberculosis have gained the ascendancy, and are multiplying by the millions daily, possibly hourly, we need not hope to find a tuberculin which in doses of the fraction of a milligram will, within a few days, or within any period of time, destroy this great mass of living, growing poison. The miraculous effects of small doses need not be looked for. These will have no place in the therapy of the infectious diseases.

If it be possible to kill the germs or destroy the bacterial poison after the development of an infectious disease by the introduction of a germicide or a toxicide formed by other cells than those of the infected person, then we may expect that cures for diseases of this kind will be found in the near future. Experimentation offers the only means of ascertaining whether or not this be possible. The recently reported cases of tetanus successfully treated with the antitoxin of Tizzoni and Cattani, obtained from the blood of animals which have been rendered immune to this disease, are in accord with this principle.

If nuclein-therapy fails us, we must strive to find agents that will stimulate the nuclein-forming glands. This probably is the chief factor in the climatic treatment of tuberculosis, but so far as our knowledge of medicinal substances that will accomplish this result goes, we are practically and wholly ignorant. The field of special cellular therapeutics lies before us a *terra incognita*. Im-

portant discoveries in this direction are not likely to be made soon.

I have used the word "cure," limiting its meaning to the destruction of the germs or other poison. If we could destroy all of the bacilli in the body of a tuberculous patient, would a cure be effected? If we ever reach this desideratum, Nature will probably do the rest.

I have thus imperfectly placed before you certain ideas that have for some years been slowly formulating in my mind. They have enabled me to demonstrate, first, that the nucleins are powerful germicides, and, secondly, that the germicidal constituent of blood-serum is a nuclein. Whether or not they will lead to further elucidation of the perplexing problems of immunity and cure I cannot predict.

EXOPHORIA CURABLE WITHOUT OPERATION.[1]

BY GEORGE M. GOULD, A.M., M.D.,
OPHTHALMOLOGIST TO THE PHILADELPHIA HOSPITAL,
PHILADELPHIA, PA.

AT the meeting of the Ophthalmic Section of the Pan-American Medical Congress, recently held in Washington, I said in the course of the discussion on Muscular Errors that operative measures for insufficiency seemed to me a very unphysiologic procedure; a hasty renunciation of distinctively medical or natural attempts at cure; without analogy in the treatment of similar incoördinations elsewhere in the body; requiring an impossible delicacy of execution; without definite prognosis; and very often utterly unsatisfactory as to results. Without offering anything to take the place of tenotomy, to which the whole ophthalmologic world seems committed, the statement may have appeared to some as absurd, and in the extemporaneous word then only permissible, I fear the plan of treatment I suggested was not clear to the members present. I have received so many inquiries as to the method that, although most of my cases are recent ones, I shall endeavor to make the matter plain by a few details and illustrative instances.

I now wish to go so far as to state that my experience shows that every case of exophoria (and possibly of divergent strabismus) is certainly and quickly curable by a rational and common method of ocular gymnastics—*of a certain kind, however, mark well!*—and absolutely without operation.

Let me first premise a few general statements that must have been apparent to candid investigators. The first is the absurdity of cutting a relatively strong, but in reality not over-strong muscle, in order to give its weak counteracting muscle more strength relatively, or what amounts to the same thing, more "purchase." This ridiculous procedure rests upon the more ridiculous assumption that the cause of the incoördination lies in the muscles alone, a fact that no one has sought to prove. And even if the assumption were admitted, it would not follow that tenotomy is the proper method of cure. A hundred facts must crowd to the attention of every careful oculist, going to show that, at least primarily, the fault cannot lie wholly, or chiefly, and generally not at all, with the length, strength, or weakness of the muscles, *quâ* muscles, but that it is largely, if not entirely, dependent upon innervation and innervational coördination. I need not repeat many evident reasons for this fact, but here are one or two. By prisms, for example, bases out, test the full power of weak internal recti "muscles" to adduct at twenty feet. Make these "muscles" exert every grain of power they possess, lifting the heaviest weight possible. Let us say they can only overcome 12°. Now put on, instead of 12° prisms (total), twice 12°, and fix the patient's gaze on an object twelve inches distant, then slowly carry the object away, while the gaze is riveted on the object, and in one minute or less you have carried the object twenty feet away, and without resultant diplopia. If one can only by the extremest exertion lift with one hand a dead weight of two hundred pounds, can one in half a minute lift four hundred pounds, by lifting it slowly, or by any method comparable to the foregoing method of ocular lifting?

Another proof is this: Fix the patient's gaze on a near object, and by extreme convergence put the supposably "weak muscles" on an extreme strain; then, while keeping up extreme convergence, and without movement of the head, move the object on which attention is fixed to one side of the field of vision. One of the "weak muscles" now doubles or trebles its contracting power—an absurdity according to the theory of muscle-weakness.

Take only one other example, an actual case: A patient with 18° of esophoria has both interni cut completely off—no "guarded" or "graded" tenotomy, but the tendon and adjacent tenon-fibers cut clean off—reducing the former high esophoria to a temporary exophoria. In ten days he has his original 18° of esophoria back again!

By their failures to get permanency and desired accuracy of result, or by many other such considerations as I have suggested, careful and conscientious ophthalmic surgeons should have been convinced that invariable tenotomy as a cure for heterophoria is a dismal failure. A few striking successes (readily explainable as due to changed innervation following tenotomy, or to the curative action of operations

[1] Because it conduces to clearness; because the majority of troublesome heterophorias are exophorias; and finally, because, though applicable to all kinds of heterophoria, the method requires some modifications in its special application to other varieties, I limit this article to a consideration of exophoria alone.

per se, or to mental effect, pure and simple) do not neutralize the many wretched failures, and do not establish the procedure on any philosophic or physiologic basis. And this is because the central innervational nature of the entire abnormality is overlooked.

In any myopathy that leaves the flexors of a part, say the arm or leg, relatively weak, do we cut the extensors? With a functionally weakened, paretic, or undeveloped leg, do we maim the opposite leg to bring both into coördination? Do not physiology, medicine proper, common sense even, counsel the development of a weak antagonist rather than the crippling of the stronger fellow?

I frankly confess that these and many other like considerations tormented me in former days, when I was blundering with doubts and authorities, and perplexed and tormented by every case of heterophoria—an ass between two or three bundles of poor hay, doubtful whether to choose the suspicious bundle labelled, *Prisms to be used as permanent crutches*, or that thorny, much-praised bunch, *Graduated Tenotomies—Look out!* or, finally, that malicious bundle ticketed, *For some other Fellow!* Prisms, correcting the insufficiency, to be worn all the time, are a sorry delusion. Temporarily they give relief, but in a little while the patient returns with the weakness of the "muscle" doubled, and successive pilings of prismatic Pelions on nasal ossa grow ludicrously disgusting to patient and to doctor. To proceed with tenotomies, graduate, undergradute, or post-graduate, is a good way to make money—so long as the patient will return for new operations and will pay—but unless one is determined to become a professional tenotomist conscience wearies with the load it must stagger under, and soon cries, Enough!

One ray of hope came to me in these dark days; but everybody did protest so loudly that ocular gymnastics was an utterly useless proceeding that I came near flinging it aside. That it was so rational and physiologic, so in conformity with all the laws of hygiene and health, is probably why I did not throw the suggestion away untried. As every success depends upon the method of carrying out treatment, quite as much as upon the means of treatment, I thought in this fact might be found the cause of failure in ocular gymnastics. A very little practice and observation have shown this to be true. To those who with more vanity than virtue always cry, *This is all an old story; nothing new about that!* I have nothing to say. There is nothing new about life or jealousy, but there are many new methods of making them practical and effective.[1]

It should be understood that a large number of cases of heterophoria are due to anemia, kidney-disease or cord-disease, tuberculosis, syphilis, or some other systemic or cerebral disease. To potter about the local symptoms of a general disease and not strike at the fundamental cause is professional incompetence, and worse.

Then, again, another large number of these abnormalities are directly caused by ametropia, and directly cured by curing the ametropia. The tenotomomaniac is wofully likely to ignore this highly important truth. Moreover, when an insufficiency is not progressive, and produces no troublesome reflexes, it is best left alone. But when one has a permanent heterophoria on his hands, not dependent upon ametropia or disease otherwheres, and a heterophoria that produces reflex symptoms—then he may and must go to work with the local condition.

In a word my plan consists especially in carrying the loaded or weighted stimulus of convergence slowly beyond near-range vision, or, in other words, carrying the weighted convergence-stimulus from the *punctum proximum* to the *punctum remotum*, and by repetitive gymnastics fixing it there. Half-jokingly I gave this equation to a student:

$$\text{Exophoria} + \text{C.-s.}^{\,weighted} + (p.\,p. \times p.\,r.) = \text{Orthophoria.}$$

This, of course, requires an explanation.

In near-range binocular vision, there is an extra power of innervation of the muscles gained by the stimulus of the presence of an object at the *punctum proximum* that at least temporarily enables the visual axes to meet more accurately and certainly upon the object. In exophoria this extra innervation may now be loaded or weighted by prisms, bases out, and by slowly and steadily withdrawing the object, one, two, three—twenty feet (the patient's gaze kept intensely fixed upon the receding object), the innervation of the weaker function is stimulated and increased without diplopia or relaxation of the muscular grip. This is what I mean by carrying the convergence-stimulus into the distance, or *p. p.* multiplied by *p. r.* Let me illustrate: A patient is before us in whom we have determined a power of adduction (at twenty feet) of only 10° instead of the 30° or 35° he should have, an abduction of 6° or 8°, and a manifest (twenty feet) exophoria of 6° or 8.° Put in the

[1] I have heard of a method as having been used by somebody, consisting in giving the patient single prisms to hold by the hand, and thus train the muscles to overcome stronger prisms. This would appear to me dangerous and ineffective. It is impossible for the most careful patient to hold such lenses accurately in place. The prisms must be put in "fronts" or spectacles, "divided," and their strength, method and length of application, accurately watched by the surgeon. I have had no time to examine the literature, if any exists. Mr. Funnyman will do this, doubtless, for me, and kindly inform the world how old the method is he never heard of or used before; but Berry, de Schweinitz, Fuchs, and Norris and Oliver, the latest books out, allude to no method of gymnastics in insufficiency, and least of all, none by carrying the weighted convergence-stimulus into the distance.

trial or spectacle frame, 10° prisms, each eye, bases out, and let the patient firmly fix upon a small, bright object or 20/40 test-letter, held at a distance of twelve inches from his eyes. Slowly recede, the patient keeping his gaze riveted on the object. If diplopia arise, return quickly to the patient and repeat. In normally healthy, young, or young adult persons, one will, usually, at once be able to carry the object twenty feet away without producing diplopia. Two or three repetitions of this will enable the patient in a minute or two to look all about the room without double vision.

The reaction (or strength of prism overcome without diplopia) varies according to the amount of the exophoria, and according to the hundred varying conditions of nervous vitality, length of duration of reflexes, idiosyncrasies, etc. In nearly every patient in whose case I have employed the method I have been able to double the power of adduction in five minutes, and often to reduce the manifest insufficiency proportionately. If the reaction is low, the defect high, the vitality asthenic, I then order prisms in "fronts," and instruct the patient how to carry on the gymnastic exercises carefully and intelligently at home, and to return at least once a week. If the reaction and vitality are high and the heterophoria low, a few daily visits, with exercise under my direction, soon reëstablish "muscular" balance and the normal relation between adduction and abduction.

I use the simple rod-test or prism-test at twenty feet to determine the measure of manifest insufficiency. This is accurate enough for all practical purposes, especially as this is not the chief test. It is the adduction-test that is important, and the determination of the relation between adduction and abduction. All tests and records are made at twenty feet. "Convergence-stimulus adduction" means the adducting power at twenty feet, after exercise, by carrying the weighted or loaded converging power from the near to the distant point. To test adduction and abduction I have had a simple "battery" of prisms made, running from ½° to 30°, arranged in progressive succession, each ⅝ in. by 1¼ in., bases laterad, the whole about a foot long—a device that greatly facilitates speed. The measurements of adduction, of abduction, and of manifest heterophoria are the first to be made, and to be daily retested, until normality is established. A proportion between adduction and abduction, of about 4 or 5 to 1, and an esophoria at twenty feet of from ½° to 4° or even 5°, I call normality.

Deficient adducting power is the source of trouble and the thing to cure. It is a remarkable fact, and one that often occurs, that we may have normality or balance of the muscles at twenty feet, together with a highly subnormal adducting power. I think this is the reason of failure sometimes to cure a case of asthenopia. No manifest or even latent heterophoria existing, the adduction-test is not made. But it is precisely this test that tells of the hidden weakness and cause of all of the trouble.

The essence of the treatment is to arouse innervation by the weighted convergence-stimulus carried into the distance, and to make the effect permanent by short periods of gymnastics. The length of each exercise-period depends on the peculiarities of the case. From five to ten minutes, I think about long enough, repeated several times a day. If given at the physician's office, several five-minute periods may be advised, with intermissions, and the strengths of the prisms varied with the reactions of the innervation. The patient should read a little each time, and be taught to carry the gaze slowly from near to distant objects, without diplopia, etc. When carrying the object away from the prism-handicapped convergence the patient must be taught and constantly warned to look intensely, and with riveted attention at the object. If diplopia supervene, and the patient cannot overcome it by strong-willed fixation, we must come back within the range of binocular fixation and repeat the recession. If still the grip slips, we have at first weighted the weaker function too much and must temporarily reduce the load. But in all cases there is a steady rise of the innervational centers to meet the demand, and I have in healthy people never failed to double and sometimes to treble subnormal adduction within two, three, or at the most five minutes. At the next period of exercise this gain has only in part been lost, and in the beginning of the treatment the gain in adducting power at succeeding visits is "by leaps and bounds."

The question arises as to the attainment of permanent or continual normality, and the ability to discontinue the method. Every case varies. A few days of "treatment" suffice in low degrees of defect, and with good health and nervous vitality, to bring about normal coördination and adduction. In the more chronic cases, or in those of high degrees of heterophoria, or again in those with subnormal vitality, the return to normal balance is slower, some requiring a week or two, others a month or two. But in every case, even the worst, there has been relief or improvement, and progressive approach to balance.

A highly important point is intelligent, accurate judgment in loading the convergence-stimulus. Success will depend upon precision in the amount employed. But response to surprisingly heavy loads is remarkable, and increase of the load is allowable with astonishing rapidity, while one established grade of strength must be quickly followed by an increase

of the load. Of course, one can go *too* fast and *too* far, although I have never had a patient complain of pain or even discomfort from the severest and most long-continued gymnastics. All this again illustrates the nervous origin, rather than the mechanically muscular origin of these defects.

As to the durability and perpetuation of once-gained normality, I have been delighted to find how steadily it is maintained. Nature may often be unable to rid herself of a vicious habit or abnormalism of function, but after one little wise "lift" from the physician's hand, with a word of thanks and a good-bye, she is off, and thereafter she will keep things straight herself. There is, indeed, a difficulty in getting patients to keep up the treatment long enough to reinstate complete orthophoria. They get relief before this is entirely re-established, and see no reason for continuance. I have had no relapses so far, although I frankly confess that my oldest cases cured by this method have been only a few months out of my hands. Their reflex symptoms, however, disappeared before the return of muscular coördination, and subsequent retestings show no tendency to revert to the old disorder.

All of my cases had previously not been subjected to tenotomy. I hardly doubt that such a surgical history, if present, would make recovery by this or any other medical treatment more difficult, if not impossible. Just as surgical help is excellent beyond all things when it is needed, so when hygiene and rational therapeutics are alone required then surgical meddlesomeness and impertinence are most pernicious.

I append brief epitomizations of a few typical cases out of many that have been treated or that are still under observation:

Case I.—Miss H., fifteen years of age, had much headache, despite correction of the ametropia and of the internal insufficiency by prisms, bases in. There was from 2° to 4° of exophoria, with adduction 22° and abduction 6°. Prisms, 10° each eye, were ordered and in ten days there was an esophoria of 2°, an adducting power of 32°, with ability to read as desired and no headache. The exercises were discontinued.

Case II.—Mr. V., twenty-five years of age, had a vacillating exophoria, varying from 4° to 8°, and an adducting power of 18°. The adducting power increased steadily to 33° under gymnastic exercises with prisms, but the manifest exophoria showed no sign of lessening for two months. Finally, on September 23d, two and one-half months after beginning the treatment, muscular balance was reëstablished; adduction was 35°, and all headaches had entirely disappeared.

Case III.—Mr. S., twenty years old, had received little benefit at my hands from glasses and prisms during a year previous to May 6, 1893, at which date my notes say there was exophoria 8° and adduction 12°. Gymnastics with six-degree prisms each eye, bases out, gave him on July 6th an adducting power of 23°. The exophoria still remained the same, but all pain had disappeared. I now ordered prisms, 10° each eye. On August 27th he overcame 35° prisms, total, bases out, but his insufficiency still remained about as high as before beginning the exercises. There was entire freedom of all previous ocular and cerebral distress. The gymnastic exercises were continued, and on September 30th I found muscular balance and a steady adducting power of from 30° to 35°. The patient was discharged happy.

Case IV.—Miss S., twenty years of age, had on August 12, 1893, an exophoria of 12°, adduction 6°, abduction about 10°. Prisms, 8° each eye, were ordered, and in three weeks there was a desired but astonishing esophoria of 2°, and an adducting power of 28°, with much relief from headaches, etc. On September 1st the manifest esophoria was 3°, adduction 30°, with entire disappearance of headaches. Gymnastics were discontinued. At later visits the good conditions were still present.

Case V.—Mrs. C., thirty-one years of age, had not had much relief from ocular distress and headaches with all the glasses and prisms I had ordered since 1891. On July 20, 1893, she had a manifest exophoria of 7°, an adduction-power of 8°, and abduction 10°. I ordered prisms, 8° each eye, bases out, in fronts, and taught her how to use them. In two weeks her exophoria was 2°, and adduction 30°. The headaches, etc., had disappeared.

Case VI.—Mrs. T., aged fifty, had on July 25, 1893, an adduction of 6°, an abduction of only 3°, and at different examinations a vacillating high degree of exophoria of from 12° to 20°. Careful gymnastics in the office and at her home by the methods described had in three weeks halved the manifest exophoria, trebled the adducting power, and doubled the abducting power, with a complete cessation of the headaches.

Case VII.—Miss S., twenty-five years of age, had been under treatment by several physicians prior to coming to me in 1891. For one year my attempts to relieve her reflex symptoms and absolute inability to use her eyes ten minutes in reading were as resultless as those of others. There was a fluctuating exophoria varying from three to eight degrees, and every device I had tried proved a sorry failure. On May 5, 1893, I gave her prisms, 6° each eye, bases out, in fronts, and with these she carried out ocular gymnastics several times a day as ordered. In one week her adducting power had increased from 10° to 25°, and the manifest exophoria had fallen from 7° to 3°. On July 10th all exophoria had disappeared, adduction was 30°, her reflex symptoms had disappeared, and her greatly increased power of reading was a delight to her. I have not heard from her since, and as she was a very faithful patient and visitor I think the cure permanent.

Case VIII.—Mr. T., forty-seven years of age, had great redness and congestion of the eyes after he had read a little while. On September 2, 1893, he was found to have a manifest exophoria of 8°, ad-

duction 10°, and abduction 12°. On October 2d, after daily exercises with 10° prisms, bases out, his exophoria was 2°, adduction 28°, and no conjunctival congestion followed reading. He is still using the prisms, as I wish to produce an esophoria of about 2° and an adducting power of 35° before discontinuing the treatment, though he does not feel the need of improvement. Doubtless this has already been gained, but the patient lives at a great distance and can visit me but seldom.

CASE IX.—Mr. L., a young man of twenty-two years, came to me on July 14, 1893, with a simple hyperopia of 1.00 D., a manifest exophoria of 12°, and adducting power of 16°, abduction 5°. In one week's use of gymnastic prismatic exercises his adduction was 25°, his insufficiency 8° or 9°. On August 26th there was muscular balance and an adducting power of 35°. The gymnastic exercises were discontinued.

CASE X.—Mr. B., twenty-six years of age, had muscular balance, but an adduction-power of only 8°. In one week he could fuse prisms aggregating 27°, holding the image single at all distances and as long as desired, and his former trouble of headache, nausea, and dizziness had disappeared. I saw this patient three months later, and his adduction was 25° or more, and his convergence-stimulus adduction was 37°.

CASE XI.—Mrs. K., forty-eight years old, had been wearing, from another oculist, prisms, 4° each eye, bases in, for reading, divided for distance, but had constant diplopia. I found 4° of exophoria, an adducting power of but from 2° to 4°, and an abducting power of from 7° to 10°. After daily exercises with prisms for two weeks, 8° each eye, bases out, there was no manifest exophoria to be found, but I could develop 2° of latent weakness; the adducting power had increased to 12°, and, under convergence-stimulus carried to 20 feet, she fused 22°, bases out. One week later there was still the 2° of latent exophoria, but adduction had now become 20° and, with C.-s., 32°. The diplopia had ceased troubling her much. A week later no latent exophoria could be developed, the diplopia had disappeared, and the adduction-power was normal.

CASE XII.—Miss H., at her first visit had 8° of manifest exophoria, adduction 8°, abduction 8°, and a convergence-stimulus adduction developed in a few minutes to 25°. In two days the exophoria was 6°, the adduction 20°. In three days more the manifest exophoria had disappeared, but I could, with patience, bring out about 4° of latent. The adduction was about 30°, and the convergence-stimulus adduction over 35°. This patient was treated daily by myself, and illustrates the rapidity with which some cases react.

CASE XIII.—J. H. W., a lad of fifteen, had long had much trouble from blepharitis and conjunctivitis, despite the best correction of another oculist, and later of myself. I found a mostly-latent exophoria of 7°, adduction 11°, and abduction 7°. This was in my pre-gymnastic days, and I applied prisms, 2° each eye, bases in, together with the ametropic correction, and much attention was ordered as to school-work, exercise, the general health, etc.—all in vain. Gymnastic exercises, according to the foregoing method, were ordered, with weak prisms (6° each eye), and in three days his manifest exophoria was 2°, and adduction 22°. His constant prisms, bases in, were now replaced by his simple ametropic correction, and exercises continued at home. In two months there was orthophoria, adduction 27°, C.-s. adduction 35°. The result, I think, could have been reached in a week or two if I could have seen the patient often, exercising with heavier prisms, etc. His blepharitis and conjunctivitis had long ceased troubling him.

CASE XIV.—To illustrate the fact that even the highest degrees of insufficiency will react to this treatment, I will allude to a case that is yet incomplete, but which is steadily gaining ground every day. The patient is a little girl of seven, who had habitual alternate divergent strabismus, except when fixing an object attentively. From another oculist she had been wearing hyperopic lenses doubly over-correcting her ametropia, thus increasing the exophoric tendency. She kept the left eye closed a great deal. There was, on September 23, 1893, as near as I could estimate it, about 25° of exophoria, a power of adduction of only 2° or 3°, abduction 12°. I treated the child in my office for a while, and in three days she was able to fuse a total of 12° prisms, bases out, and with convergence-stimulus she could hold 20° at 20 feet. A week later she could at first fuse prisms bases out aggregating 27°, and after a few minutes' gymnastics she could hold 35°. The left eye was now kept open, the strabismus had disappeared, the exophoria was reduced to about 16°, and habitual binocular fixation reëstablished. The case, I judge, is proceeding to a perfect cure.

RUPTURE OF THE MALE URETHRA.

BY R. W. STEWART, M.D., M.R.C.S.,
SURGEON TO MERCY HOSPITAL, PITTSBURG, PA.

BY far the most frequent cause of rupture of the urethra is falling astride a resisting body, the weight of the blow being received on the perineum, and the urethra being forcibly crowded against the sharp edge of the triangular ligament, or against the symphysis or ascending ramus of the pubes.

Fracture of the pelvis, or even temporary dislocation of the pubic bones without fracture, is a frequent cause of rupture of the urethra, a fact that should always be borne in mind when one is confronted with these injuries.

Being thrown forward on the pommel of a saddle, or against the front wheel of a bicycle, or the old-fashioned treatment of breaking a chordee, may be included in the category of causes of rupture of the urethra, without by any means exhausting the list.

A discussion of the disputed theories of the exact mechanism of rupture of the urethra would be futile, as we have a condition to deal with, in determining

the means to be adopted for the relief of which no amount of theorizing from an etiologic standpoint would be of the slightest assistance.

The location of the rupture has a certain bearing on the prognosis and treatment, because, in a general way, the deeper the rupture is located in the urethra the greater is its gravity. Thus, ruptures of the pendulous portion usually owe their origin to but slight degrees of traumatism, such as the breaking of a chordee or the unskilful use of instruments. In these cases the rupture is rarely, if ever, complete; retention of urine is seldom a disturbing factor, catheterism is usually a very simple matter, and the liability to infiltration of the tissues by urinary extravasation is less serious than in deeper injuries. These cases form the mildest grades of ruptured urethra with which we have to deal, and they may be disposed of by briefly outlining their treatment. This consists in periodically withdrawing the urine by means of a soft catheter until such time as the rent in the urethra has become sealed. This may take place in a few hours, or at the longest in two or three days.

It is difficult to conceive of a rupture of the prostatic urethra other than that produced by the surgeon in attemping to remove a foreign body or new-growth from the bladder through a perineal incision, and as such cases plainly do not come within the scope of this article they shall receive no further consideration.

Rupture of the bulbous and membranous portions of the urethra may be classed together, as it is frequently difficult or impossible to determine the exact site of the rupture, because the symptoms of both are often identical and but seldom distinctive enough to be of much localizing value. However, if a tense, fluctuating tumor has formed in the perineum, and the scrotal tissues are intact, we are justified in holding that the extravasation is confined within the layers of the triangular ligament, and that the rupture is necessarily limited to the membranous portion of the urethra. Conversely, if the perineum is intact and the scrotal tissues are infiltrated, we may hold with equal propriety that the rupture is anterior to the membranous urethra. This, however, is a distinction without a difference, when we come to consider the treatment of these injuries, and it frequently happens that the traumatic cause of the injury has been so severe as to break down the dividing barriers of fascia, so that a rupture in either situation, if the extravasation be unrelieved, may be followed within a day or two by most extensive urinary infiltration. In severe cases the urine may infiltrate the perivesical, the perineal, and the scrotal tissues, and travelling still further it invades the loose tissues of the penis, pubes, and abdominal wall. In one case I have seen it invade the subcutaneous tissues of the thigh, from Poupart's ligament to the knee. The aspect of such a case is a most striking one: the bulging perineum, the enormously distended scrotum, the distorted phimotic penis, and the thickened belly-wall—all blackened by the infiltrating bloody urine, together with the agonizing distress of the patient suffering from the worst of all tortures, retention of urine, make an impression at once as lasting as it is unmistakable.

This is a picture of the worst cases with which the surgeon has to deal, but it should not be forgotten that it not infrequently happens that the rupture of the deep urethra is so slight, and the amount of urine extravasated is so small, that Nature is enabled by means of inflammatory exudates to limit the extravasation to narrow bounds, the extravasated urine, if not interfered with, either undergoing absorption, with a return of the parts to their normal condition, or if the urine undergoes decomposition, setting up a destructive inflammation with, at the worst, the formation of a perineal fistula.

Cases of extensive extravasation of urine, if left to the unaided efforts of Nature, are as surely fatal as would be the uninterfered-with course of a strangulated hernia. It is true that in extremely rare cases a strangulated hernia may by sloughing and abscess-formation find a safe exit for the intestinal contents; it is equally true that the vesical contents may find a similar exit by sloughing of the infiltrated tissues; but the chances in either case of the patient surviving until Nature has brought relief are so slight that no hope should be entertained; nor should a minute of precious time be wasted on the illusory efforts of Nature to effect a cure.

In the treatment of a rupture of the urethra with urinary infiltration we must promptly meet two urgent demands: First, to give free vent to the urine which has escaped from the bladder and permeated the loose connective tissues; and second, to relieve the distended bladder and afford a natural exit to the vesical contents.

In regard to the method of relieving the tissues of the extravasated urine there need be no controversy—early and free incision has been the recognized treatment in the past, as it will be in the future. In making these incisions it should be borne in mind that if ammoniacal decomposition of the urine has not set in, the urine has but slight irritating properties, and Nature may, as a rule, be safely left to take care of the tissues, provided free drainage has been afforded through perineal and scrotal incisions.

The best method of accomplishing the second indication, namely, to afford an exit to the vesical contents through the natural channel, is still in some respects a debatable question. The ideal method of accomplishing this would consist in passing a cath-

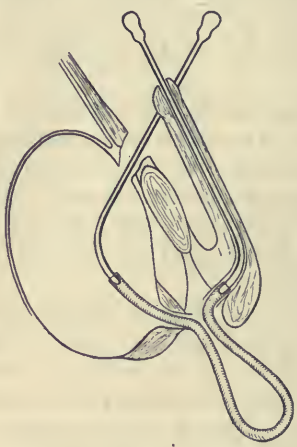
eter through the anterior urethra past the rupture and into the urethra beyond to the bladder, and retaining it there until the wound in the urethra has become sealed. A diligent, but not too protracted effort should be made to accomplish this end, and it will often meet with success, but in a large proportion of the serious injuries to the urethra, especially when the rupture is complete and the torn ends are separated by from half an inch to an inch and a half, it is simply impossible, even with the greatest skill and care, to introduce a catheter into the bladder. In these cases we are confronted with what has proved to be one of the most difficult problems in surgery, the ultimate solution of which, if treated according to the methods laid down in the standard text-books of surgery, is, to say the least, problematic.

The recognized treatment of the past has been either to resort to supra-pubic aspiration for the relief of the distended bladder and to trust in Providence for a cure, or else to boldly attack the situation by attempting to find the proximal end of the torn urethra through a perineal incision—a feat which may be easy on the cadaver, but is usually difficult and often impossible on the living patient, owing partly to the depth of the wound, but still more to the impossibility of recognizing the disorganized tissues in which the urethra lies. The history of such cases often is, that the operator blindly gropes his way in a deep wound, the bottom of which he cannot see, in search of a urethra he cannot feel, until, goaded to desperation by the futility of his efforts, he does by foul means what he cannot do by fair—he forcibly thrusts a catheter, regardless of the urethra, into the bladder with results that are, to say the least, disastrous. I have twice seen this done by competent surgeons, death resulting in one case and all but death in the other.

Difficult, dangerous, and uncertain as is the perineal method of attempting to restore the continuity of a ruptured urethra, it has the weighty endorsement of such text-books on surgery as Holmes, Bryant, Gross, and Moullin. Ashhurst's *System of Surgery* recommends opening the urethra through the perineal wound at a point beyond the rupture and performing retrograde catheterism—a feat which would be just as difficult and uncertain as finding the torn end of the urethra. Even the most modern text-book of surgery in our language, the *American Text-book of Surgery*, gives but a half-hearted endorsement of a method infinitely superior to the one we have been discussing. It says: "If persevering and careful search fails to reveal the proximal end of the torn urethra, supra-pubic cystotomy for the purpose of retrograde catheterism is justifiable, the distal end of the torn urethra being almost always easily discoverable."

The comparative advantages of the perineal and supra-pubic methods of treating rupture of the urethra are overwhelmingly in favor of the latter, a fact which will become obvious when we consider the technique of the latter operation.

The method I have adopted is as follows: The scrotum and perineum are first incised, to give vent to the extravasated urine; the incision in the perineum will enter a pocket containing bloody urine. The distended bladder is opened above the pubes by an incision just large enough to admit the index finger, which should at once feel for the vesical orifice of the urethra. A medium-sized steel sound is insinuated by the side of the finger and into the vesical orifice of the urethra; the finger should then be withdrawn from the bladder and the sound thrust along the deep urethra until its tip appears in the perineal incision previously made for the relief of the extravasated urine. Over the projecting tip of



the sound a rubber tube or, more conveniently, a soft catheter with its blind extremity snipped off, is forcibly thrust, and the sound, carrying the catheter with it, is withdrawn from the deep urethra into the bladder. The catheter is then detached from the tip of the sound and the latter is passed through the anterior urethra, until its tip likewise presents in the perineal incision; the end of the catheter which projects from the perineal wound is fitted over the tip of the sound which is withdrawn from the urethra, as is shown in the accompanying diagram, thus threading the catheter through the entire length of the urethra, where it is retained *in situ* by thrusting a safety-pin through it and one of the lips of the meatus.

If desired, the torn ends of the urethra may be approximated over the catheter by means of catgut sutures. The catheter should be retained in the urethra for from four to six days, after which the periodic introduction of full-sized steel sounds should be practised to prevent stricture-formation.

Of six cases of rupture of the urethra which I have treated I have succeeded in passing a catheter without resorting to operative interference in three. In two of these catheterism was only accomplished after it was thought impossible to do so, and the patients were placed in the lithotomy position preparatory to incising the scrotum and perineum.

In the three remaining cases I failed to pass a catheter and resorted to retrograde catheterism in the manner described. In one of these cases I attempted to find the torn urethra through a perineal incision, but failed. In one case there was slight leakage through the supra-pubic wound for eight days, in another for three days, and in one not at all. I may add that in all six of the cases recovery was satisfactory.

When we consider that in rupture of the urethra the bladder is distended from the associated retention of urine, facilitating its opening through a supra-pubic incision, and that the perineal incision for the relief of the extravasation is available for the threading of the catheter along the urethra, and also that no unforeseen circumstances can mar the success of the operation, the steps of which are as definite as those of an amputation, there can be but one conclusion: that the supra-pubic method should relegate the uncertain perineal method of treating this dangerous injury to the same obscurity that the supra-pubic method has relegated the perineal method of extracting stone from the bladder.

Westinghouse Building.

OXALIC ACID AS AN EMMENAGOGUE AND OXYTOCIC.

By HOMER C. BLOOM, M.D.,
of Philadelphia;
Instructor in Gynecology in the Philadelphia Polyclinic;
Outdoor Surgeon to the Gynecean Hospital.

It has been denied that there are such agents as emmenagogues, because "the discharge from the uterus is not one of the excretions through which medicinal agents pass out of the system."

This is but one of many theories which practice proves to be false. There is not an organ in the body that responds to medication more promptly than the uterus. Trousseau asserts "that all general excitants may be emmenagogues," as the uterine system does not escape the stimulation which these agents produce throughout the entire organism. I wish to call attention to one emmenagogue that I believe worthy of special confidence—oxalic acid.

How it acts, or why it acts thus, I am not prepared to say; theoretically I can give no explanation, and, indeed, no one seems to understand its peculiar action in this direction; but from practical observation it acts, in a large majority of cases, as the surest emmenagogue we can employ.

It is two years since I first observed a little article taken from some foreign medical journal relative to the possible value of oxalic acid in amenorrhea. I made a note of it, and in a short time found an opportunity to prescribe the drug.

Case I was in a girl, eighteen years of age. She was well developed, and for three years she had had all the premonitory symptoms of puberty—a monthly periodicity of associated symptoms characteristic of commencing menstruation; peculiar sensations, such as lassitude, pains in her back, gastric disturbances, irritability, flushes, with at times severe hypogastric pains. Frequently, at these periods, sympathetic breast-soreness occurred, in which the mammary glands were so irritable that the slightest pressure of the clothing gave pain.

I ordered the following prescription:

℞.—Acid. oxalic. . . . . gr. viij.
Aquæ } . . . āā f℥ij. M.
Syrup. limonis }
Sig.—A teaspoonful four times a day.

After taking the medicine for three weeks the girl reported that during the previous week she had seen her menses for the first time. They had lasted one day and a half, were free from pain, the flow soiling three napkins.

She was asked to continue the prescription as before ordered. At the expiration of five weeks she reported that her sickness had come on at the expiration of twenty-eight days, lasting three days, and being perfectly normal.

The drug was discontinued and the girl was requested to report in three months, which she did, saying that her sickness had returned every twenty-eight days, and that she was in excellent health and had no symptoms.

I might add that in this case all the regular routine treatment for amenorrhea, or retarded or delayed puberty had been employed, such as hot douches, sitz-baths, and drugs many and various.

Case II was in an unmarried woman, twenty-five years of age, a native of Ireland. She had been perfectly regular in her menses prior to coming to this country, but never saw them after leaving Ireland. Her general appearance was fair; she had a good physique, was well nourished, and was a bright and intelligent girl. Her symptoms were flushes, with headaches, in which she complained of her head having "too much blood in it," with backache, etc.

I ordered the oxalic acid in quarter-grain doses, four times a day, requesting her to report from time to time, which she faithfully did, and after taking the drug for four weeks she reported that her monthly illness had come on for the first time, and she was entirely relieved of her symptoms, being "regular" thereafter.

This patient gave a history of having gone from one dispensary to another without any improvement.

Of twelve cases similar to the foregoing in which I have prescribed oxalic acid, and in which amenorrhea has existed for from six months to three years,

there were only two failures, and in both of these there was evidence of pulmonary trouble. I believe oxalic acid to be a drug that can be relied upon as an emmenagogue in all cases purely dependent upon some functional disturbance, of course bearing in mind that amenorrhea is not in itself a disease, but simply a result of some morbid condition affecting either the system at large or some part of the genital apparatus.

Probably there is no other disease in which the function of menstruation is interfered with to the same extent as in chlorosis, and it is in the treatment of this condition that I would ask for a more extended trial of this drug. I have had only three cases in which there was marked chlorosis. In two of these cases the drug acted quickly and promptly. In the other case, I found the anemia to be so profound that it was necessary to use iron in various forms before any improvement took place.

In several cases of scanty menstruation the drug has effected very good results. In others it has had no effect whatever. For example:

CASE III occurred in a married woman, thirty-three years old, sterile, with a history of the menses growing less in quantity and at greater intervals for the past three years, with lassitude, headaches, general irritability, nervousness, etc. Her menses last but a day and are very scanty and often six weeks apart. I ordered oxalic acid, in quarter-grain doses, four times a day, continued for six weeks, and normal and regular menstruation was reëstablished.

As to the action of oxalic acid, at or near the menopause, in those cases in which we find an absence of the menses for three, four, five, or six months, together with all of the phenomena attending menstruation, as well as the flushes and nervous condition incident to the climacteric period, I have in several cases seen decided benefit attend the increased menses, but in the large majority of cases the action has been negative.

As to the action of oxalic acid as an oxytocic I can positively say that it has decided ecbolic properties, having acted decidedly as an abortifacient in several cases.

CASE IV was in a woman, aged thirty, married six years, with three children, the last one born eighteen months ago. The menses appeared for the first time after the birth of her last child six months ago. They had been less in quantity than after previous pregnancies. She had flushes, nervous headaches, pains in her back, and constipation.

A saline was ordered and she was requested to report again. No examination was made. In the meantime her menses came on, but merely a show, with all of the phenomena and symptoms of the unaccomplished function.

Without any examination, I ordered oxalic acid in quarter-grain doses, four times a day. I had the mortification of being told by the same patient six days afterward, that she miscarried promptly after taking the medicine two days, and that she had had no untoward symptoms.

From the description of the products, as she gave it, I should think that she had been about two months pregnant.

A few days after this occurred, in speaking of it to my chief, Dr. Baldy, he told me of a similar case occurring in his own experience at the Pennsylvania Hospital dispensary, in which the patient returned and kindly requested the same prescription, "as it was one of the best she had ever taken to get rid of the unwelcome products of sexual intercourse."

The two cases just mentioned, with several others that I shall note, prove the ecbolic influence of oxalic acid in perfectly safe doses.

Probably the safest procedure for securing a miscarriage when medically necessary is operation, yet there are contingencies likely to arise which could best be subserved by the action of a reliable and safe oxytocic. This is my excuse for calling attention to the power of oxalic acid in perfectly safe doses as an abortifacient. The first case in which I prescribed it, as an ecbolic, is as follows:

CASE V.—Mrs. D., aged twenty-seven, had been married three years. She had had repeated miscarriages, at periods ranging from six weeks to three months. She had not seen her menses for six weeks, had obstinate nausea and vomiting, frequent desire to pass water, some mammary symptoms, constipation, etc. She was greatly reduced in strength and in the first stages of chronic pulmonary trouble. Her husband, also a patient of mine, is in the advanced stages of pulmonary tuberculosis. The woman had pulmonary hemorrhages, obstinate cough, a pronounced hectic condition, with other rapid progressive pulmonary symptoms. My efforts in the way of local applications to the cervix and uterus, as well as means directed to her digestive organs, and constitutional measures, availed nothing in the way of relieving her most obstinate nausea and vomiting.

The case was a desperate one. There were two results that seemed inevitable. First, the possibility of a miscarriage from an exhausted condition, and from the fact that she had had repeated miscarriages. Second, the death of the mother before the viability of the product of conception. To take the risks of the first was a course not only fraught with too much danger, but entailing the loss of valuable time, most likely the balance between life and death. The second was out of the question, for upon the life of the patient, however short, depended much.

With the certainty of either of the two inevitable results just mentioned, I hesitated no longer as to what was right; and there was every reason why this should be carried out with as little nervous shock as possible. With this before me and the fact of my previous unintentional experience with oxalic acid as an oxytocic, I made up my mind to try the drug. The patient was put upon quarter-grain doses

every four hours, in solution. After three days' use it had the desired effect, bringing on a miscarriage, followed by no untoward symptoms, but on the contrary complete relief from the nervous reflexes of pregnancy.

The remaining case, in which the ecbolic power of oxalic acid was proved, is as follows:

Case VI.—Mrs. H., aged forty-two, the mother of seven children, had the last pregnancy eighteen months ago. Menstruation was regularly reëstablished twelve months after the birth of the child, until eight weeks ago, when it ceased. The woman was sure from past experience that she was pregnant. Frequent desire to pass water, morning sickness, a bluish tint of the vagina and of adjacent soft parts existed. The cervix was soft, the uterus enlarged in its antero-posterior diameter, and the uterine arteries were easily felt.

The woman was nervous and anxious about her condition, for she was suffering from a large suppurating carcinoma of the left breast, involving the axillary and contiguous glands.

Here was a case that, in a few short months, would prove fatal. The history of her past pregnancies was such that additional suffering was more than she could bear.

There was no hope of her living until the viability of the product of conception, and there was every reason why she should be spared the additional suffering incident to her condition.

With this excuse, and the hearty coöperation of the patient and her husband, I therefore had no hesitancy in adopting such measures as would relieve the woman. She was put on quarter-grain doses of oxalic acid in solution every three hours. After three days she miscarried, without any ill-effects.

I have now used oxalic acid in some forty odd cases of amenorrhea, depending upon all the different causes, other than physiologic, which are likely to enter into the suppression of the menstrual function. Its reliability as an emmenagogue may be judged from the fact that it proved successful in three-fourths of the cases. As an oxytocic it proved its power in the four cases herein mentioned.

1427 Walnut Street.

ORIGINAL ADDRESS.

MEMORIAL OF PROFESSOR JEAN-MARIE CHARCOT.[1]

By PROFESSOR M. ALLEN STARR, M.D., Ph.D.,
PRESIDENT OF THE NEW YORK NEUROLOGICAL SOCIETY, ETC.

Gentlemen: It is my painful duty, at this the first meeting of the New York Neurological Society after the summer recess, to announce to you the death of our distinguished Honorary Member, Prof. Jean-Marie Charcot.

It is fitting that on this occasion we should turn from our ordinary proceedings and offer a tribute of respect to the memory of one whom we unite in considering the greatest leader in that department of medicine in which we have a common interest.

Charcot was born in Paris on the 29th of November, 1825. He was the son of a wagon-maker, a man of such limited means that he was not able to give all of his children an education. Jean-Marie, however, showed so much ability in school that he was selected from among his brothers as the most promising member of the family, and while one brother was enlisted as a soldier and another put to work in the father's shop, he was allowed to enter the Lycée St. Louis, at that time the best academy in Paris. After his preliminary education was completed there, the choice of the medical profession was made after some hesitation, for the inclination of the young man was for the life of an artist, and it was possibly the lack of means that finally determined him to take up medicine. After passing through the medical school and serving as an interne in La Salpêtrière—an almshouse for old women, then almost unknown, but later to become famous as the theater of his wonderful activity—he took his doctorate degree in 1853.

For the next three years he served as chief of the medical clinic in the medical school, supporting himself meantime by giving private tuition. He was then appointed physician to the Central Bureau of Paris, with a moderate salary, his duties being to examine applicants for the hospitals and assign them to the proper services. While filling these positions and slowly making his way, he was not idle, but was preparing for that competitive examination to which ambition for success leads every young physician in Paris.

It is to be remembered that hospital appointments in France are under Governmental control, and that as fast as vacancies upon the attending staff of hospitals occur they are filled by the appointment of men who have qualified themselves for these positions by passing a very rigid examination, by presenting theses, and on occasion defending in public debate the position taken in the thesis. Charcot succeeded in passing this examination in 1860, at his second trial, and it is said that he always supposed that he owed his success to his ability in defending the points made in his thesis upon chronic ulcerative pneumonia, which were ruthlessly questioned and criticised by his examiners. Later the discussion of theses was abandoned by the official examiners, much in opposition to Charcot's views, as he never forgot his own experience.

Having qualified for a position as attending physician to a hospital, Charcot was able to select in 1862 the service at his old hospital, La Salpêtrière. He found a large number of old people collected together in this poorhouse, and among them many with chronic incurable diseases. He had opportunities to watch the progress of disease, both acute and chronic, in old age, and, most important of all, he had unlimited pathologic material to supplement his clinical observations. It is to this latter fact that he owed the beginning of his reputation. For at that time pathology was just beginning to reveal the true reasons for diseases. It was an epoch of rapid progress in medicine. The nature of disease, the changes in tissues which caused the manifestation of symptoms, were just beginning to be recognized. Symptoms were no longer being regarded as diseases, but were being

[1] Read before the New York Neurological Society, October 3, 1893.

grouped together in classes and assigned to the actual pathologic process that lay at their base. If you will glance over any general treatise upon medicine written in 1862 and select the chapters that deal with nervous diseases, or rather with symptoms that we now know to be of nervous origin, you will be amazed at the degree of ignorance, in comparison with our present knowledge. It required a man of Charcot's ability in clinical observation, power of continued, earnest endeavor, talent for classification and broad generalization, diligence in pathologic study—a branch of medicine that requires unending patience, hard work, delicate manipulation, and constructive genius of the highest kind—to bring order out of the chaos of ignorance. By the careful study of his cases, by his power to seize upon salient features that present points for differentiation, by his persistent following of cases from the clinical ward to the autopsy-room, and by the exhaustive study of the material collected there, he began to reach conclusions, to arrive at facts which were veritable discoveries in the medical world. Study the files of the *Gazette hebdomadaire* from 1860 to 1870 and you will find a series of articles from his pen, each of which adds a distinct fact, observation, or conclusion to the sum of medical science.

These articles soon began to attract attention, and the young hospital physician found his rounds beginning to be attended by students who liked to watch his careful study of cases, or see him demonstrate the lesions that he found. In 1866 a small room in the hospital was set aside for the purpose of instruction and he began to hold clinics and to lecture. The lectures were soon crowded by graduates in medicine, and the next year he was invited to give an open course of lectures at the Ecole pratique of the medical school. Here he had an opportunity to cultivate the power of teaching and soon showed that wonderful facility of clear, direct statement and power of graphic illustration that later made his lectures the most attractive in the world. His first open course had for its subject cerebral hemorrhage and softening—an early indication both of his preference for neurology and of his firm belief in the need of pathologic study. In the following year he demonstrated for the first time the clinical and pathologic differences between paralysis agitans and multiple sclerosis, up to that time confounded under the title of "tremblement choreiform." There is little to-day for the writer on this subject to do but to present in inferior form the facts contained in those lectures. In his succeeding course he described the arthropathies appearing in the course of locomotor ataxia, which have ever since been known as Charcot's joint-disease. The next year the course was upon trophic disturbances following cerebral and spinal disease, and this course, given in 1870, necessitated the opening of a larger hall, as the number of students had already outgrown the small one. Thus, within four years, he had risen from the position of an unknown teacher to that of one of the best lecturers in the Paris school.

The year 1870, so full of sad events for France, brought a change in the service of La Salpêtrière. Under the exigencies of the war many buildings near Paris were destroyed and hospitals were in demand, and a new classification of their inmates necessitated the removal to La Salpêtrière of all female epileptics and hysterics that were not insane. This afforded Charcot new material for study, and from 1872 the study of hysteria in its multiform manifestations became one of his pursuits. This fact does not at once appear either in his writings or in his lectures. In fact, it was not until six years later that his work indicated any special interest in this new class of patients. But that the presence of this class at La Salpêtrière had its influence no one who has watched the recent investigations made within its walls will deny.

In 1872 Charcot was made Professor of Pathologic Anatomy in the Faculty of Medicine in Paris, the highest prize in the French medical world. For the ten following years he held this position, contributing in that time many facts upon diseases of the lungs, liver, and kidneys, and other organs, meanwhile, however, not neglecting his other lectures at the Salpêtrière upon diseases of the nervous system. It was these latter that were his favorite studies, and it was in this department that his work brought renown to himself and to France.

In 1882 this fact was officially recognized by the French Government, under the leadership of Gambetta—a personal friend of Charcot—by the foundation in the Medical School of a Professorship of Nervous Diseases, and Charcot's appointment to it, with the establishment of a public clinique at La Salpêtrière. From that time to the present year his annual courses of lectures have been attended by students of medicine from every land, and it may be truly said that there are few men of eminence at present living and working in neurology who have not drawn inspiration from his model clinics.

It was in the spring of 1883 that I had the good fortune to be numbered among his students, and it may be of interest if I relate some details of his work. On three mornings of the week, at nine o'clock promptly, he would come to the dispensary of the hospital and seat himself behind a little railing, which separated him on one side from the patients and on the other from the crowd of students, many of them foreigners, and all graduates in medicine. His assistants would then bring the patients, one by one, from the adjoining waiting-room. A concise history would be given of the case. Then Charcot would ask some searching questions, would elicit some unexpected symptom, would discover some physical appearance that others had not noticed; would examine the patient himself if there was any special point of interest, and then would quickly state his diagnosis, supporting the position taken, or discuss the probabilities or difficulties of diagnosis, often with interesting comments, and finishing occasionally with some therapeutic suggestion. Some patients were admitted directly to the hospital; others were referred to the assistants for treatment, but were not lost sight of, for it was not an infrequent occurrence for him to inquire, from time to time, about old patients, to have them brought in from the other rooms in order to note their progress or to compare them with some new patient, often with an appearance of personal interest that it was a pleasure to observe. After two hours of this work he would enter the hospital to make the rounds in the various wards. Here he would often stay till one o'clock, examining patients in bed or having them brought to one of the many rooms devoted to special investigations—to the eye-room, where careful tests of the visual fields for form and color were at that time engaging his attention;

to the photographers, to secure just the picture that he wanted of their deformity; or to the electric room, for tests or for therapeutic applications. He would often go to the bath-house, where he had had constructed all the various forms of douches and showers to which he attached much therapeutic value. He would also go to the laboratory and show us specimens, even slides under the microscope, of lesions, which had relation to the cases that we had seen in the wards. Lastly, we would gather in his own study—a room whose walls were covered with photographs illustrating disease in art, copies of celebrated paintings whose subjects were the healing of disease by miracle, a subject of which he always delighted to speak; for in the attempt of the painter to show the poor sufferer for whom the miracle was performed, he would detect a model suffering from hysterical contractures, or from hysterical convulsions, or some victim of a real paralysis. Many of these pictures have recently been published, with his comments, in the *Nouvelle Iconographie de la Salpêtrière*.

I remember that at that time there was a remarkable case of aphasia of the variety known as word-blindness in the hospital—a man who could talk and write, but could not read what he had just written—and Charcot would have him brought to his study day after day and put him through numberless tests, and then draw out some diagrams to illustrate aphasia, one of which he subsequently published in recording the case. This was the routine work of three days in the week, the best hours of the day being given up to his hospital service.

On Tuesdays the public clinic of the week was held in a large building just within the hospital gate. The room was arranged with a stage and footlights, and tiers of seats arose from the front level to quite a height at the rear of the room. As many as 600 students could be seated, and the place was always full. After the audience had gathered, dark shutters were closed at the windows, the footlights were turned up, and the clinic began. Charcot, attended by a number of his assistants, entered and seated himself on one side of the stage, at a little table, looking not at his audience, but across the stage. Then the patient or patients, for he usually showed a number at once, either to display variations of one disease, or to draw contrasts with other diseases, were placed before the footlights, and sometimes when a particular feature had to be demonstrated, a calcium light was turned on the patient, whose figure, the chief point of light in the darkness, could always be perfectly seen by all. In a clear but not loud voice, with a slowness of speech that led to a clear understanding—especially to the foreign element in his audience—Charcot would describe the case, call attention to special symptoms, show the peculiarities of spasm or deformity or tremor or gait, compare them with other similar forms for the purpose of differentiation, and sum up the diagnosis. Then, dismissing the patient, he would begin to describe the lesion, and at once on the screen at the opposite side of the stage the magic lantern would flash out the picture he was trying to draw, either in the form of a sketch made from Nature or an actual slide of a section of the spinal cord, or a part of the brain magnified by the microscope. Thus, symptomatology, diagnosis, and pathology were presented in orderly succession in a manner most clear and forcible, and with an effect that was most instructive and impressive. It has been said that the whole clinic was arranged for theatric effect. I believe that it was the only manner in which it was possible to demonstrate in a clear light to the large audience all the features, clinical and pathologic, of the subject. But grant that it was theatric; it left on the mind of the student a series of mental pictures of patients and of lesions which no amount of private study could possibly produce. It taught men so that they could not fail to remember, and what higher result can a teacher wish. And the students appreciated it. They gathered enthusiasm from Charcot's evident earnestness. No teacher has ever had such a constant company of devoted young men about him, eager to share in his studies, to be directed in their investigations, to be considered a part of his working force. He had the faculty of engaging their interest, of stimulating their investigations, of directing their work. He supplied them with material and showed them how to use it. As a result, there have appeared in France during the past fifteen years an enormous number of clinical and pathologic researches in the department of neurology, all of them inspired by Charcot, though carried out by some one of his pupils. He built up the school of the Salpêtrière. One can hardly name a young man of eminence in medicine in France to-day who has not at some time been glad to call himself a pupil of Charcot. And when, in addition to the long list of his own articles—his collected works will fill fifteen large volumes—the articles are collected on which his name appears as collaborator, there is presented a mass of medical literature far surpassing that of any other medical school in the world.

Bourneville has said that Charcot was not fond of writing or of publication, that it required two years of constant urging to induce him to publish the first two volumes of his lectures, and that he never would have given to the world many of his articles had some one of his assistants not attended to the details of publication. Fortunate then for the medical world, that he had these devoted assistants, by whom some of the drudgery of work could be carried, and through whom his marvellous knowledge could be spread abroad for the benefit of science.

It would take too much time to allude to his various books, lectures, and articles published between 1865 and 1892. I cannot, however, omit to mention his collection of cases of local lesions in the brain and spinal cord, which did much to establish on a firm basis the doctrine of the localization of cerebral and spinal functions, and which appeared in the *Revue de Médecine* in 1879, and his numerous valuable papers on the pathology of spinal lesions. It should also be known that, with Vulpian and Brown-Séquard, he founded the *Archives de Physiologie* in 1869; the *Progrès Médical* in 1873; the *Revue mensuelle de Médecine et Chirurgie* in 1877, now known as the *Revue de Médecine*, which still bears his name; the *Archives de Neurologie* in 1880; and the *Nouvelle Iconographie de la Salpêtrière* in 1888. To all these he continued to contribute from time to time until his death. It is said that no other medical work has ever approached the sale that his three volumes of lectures published from 1872 to 1880 have had. These lectures have been translated into German, English, Spanish, Italian, Hungarian, and Russian, and new editions are called for every year.

Public recognition of his abilities and eminence was not wanting. He had been president of all the chief medical societies in Paris, was a corresponding member of numerous societies abroad, of our own Society and of the Academy of Medicine in this city, and was made a member of the Institute of France in 1883 and Commander of the Legion of Honor in 1892. It may be justly said that France honored herself by conferring honors upon him, for there are few Frenchmen who, during the past quarter-century, have done as much to support the waning French authority in matters of science or to preserve the fading reputation of the French school of medicine. Not medicine alone, but French prestige as well, has reason to regret his untimely demise.

It has been made a matter of criticism that during the past few years Charcot's attention had been very largely directed to the study of hysteria and to the investigation of hypnotism and allied subjects. As we have already seen, it was force of circumstance that brought to his immediate notice this branch of nervous affections—a very large number of hysterical patients having been transferred to La Salpêtrière at the time of the war. When he turned from the study of organic diseases to that of functional affections he found the knowledge of hysteria in a chaotic state. Isolated observations had been recorded, but no definite classifications had been made. Theories abounded, but no real explanation or working-hypothesis on which to approach the subject was established. He began by grouping certain types together and clearly distinguishing them from others. He described in detail the more pronounced manifestations of hysterical convulsions, the epidemic forms of hysteria which had appeared all over Europe, in the past and even recently. He brought out clearly the sensory disturbances, the anesthesiæ, and visual defects of the hysterical sufferer. He called attention to the vasomotor and trophic symptoms of this affection. And thus, as one reads even the titles of his various articles, one begins to get an orderly view of the various types of the disease. With the facts of the affection before one, it is easy to follow Charcot into the more obscure ranges of speculation regarding its nature. Two conclusions largely established by his reasoning must now be admitted: *First*, that there is usually a basis for hysteria in a hereditarily degenerate nervous system; that its existence almost always implies some inherited weakness of brain-structure. *Secondly*, that, however various its manifestations, however distant from the central organs its point of appearance, hysteria is a disease of mind and brain alone, is central in its location. It is to prove this that all Charcot's researches into hypnotism tend. It was his great discovery that any hysterical symptom can be exactly reproduced in a healthy person by hypnotic suggestion—in other words, that the basis of hysterical manifestations is an abnormal mental state. The abnormal mental state being established, causes powerless to affect such results in health are potent to produce the peculiar manifestations known as hysterical. If these basal facts were the only outcome of Charcot's investigations upon this obscure subject, they would have been an ample return for the labor expended.

Charcot's investigations in hypnotism have attracted much attention both from the profession and from the laity. It is difficult for anyone to enter upon the study of this subject, or to pursue it with any degree of thoroughness, without subjecting oneself to adverse criticism and remark. One might have supposed that the reputation of Charcot would have protected him from such criticism, for never was one imbued more deeply with a desire to learn the truth, never was one more averse to that spirit of charlatanism which seeks notoriety or personal emolument. Charcot did not, however, escape the envious criticism of would-be rivals, or the ignorant comments so largely traceable to the public press. Even since his death one has read with regret the wholly erroneous estimates of his character which have been made in the daily papers by men of no knowledge, who allude to his recent work on hypnotism as if his reputation rested on that alone. It it difficult to estimate the true value of this department of his labor, but it cannot be denied that all through the years that he devoted to this study his mind has been imbued with the purest scientific motives; that facts and not theories were his aim. We may not accept his interpretation of the facts; we may even doubt some of his conclusions, but we must admit that the work has been done on a very different plane from that on which similar investigations had previously been conducted, and that, throughout, personal considerations were entirely in abeyance.

Another criticism that has been offered is that in his scientific zeal he neglected therapeutics, that his interest in patients ceased with the diagnosis. But those who make these statements must surely forget that our best methods of treating functional and hysterical nervous diseases, viz., the electric methods and the hydrotherapeutic methods, were successively developed and most successfully employed by Charcot. The use of baths and douches was introduced by him in La Salpêtrière many years ago; and to-day all over Europe, and I am glad to say at last in this country, the great remedial value of water-treatment is being acknowledged, largely through his influence. And even in the treatment of organic nervous diseases, where every scientific man feels that his object is at best merely to palliate suffering, as he cannot alter tissues, we owe some fairly useful methods to his experience and investigations. The use of the Paquelin cautery, of the ethyl chlorid spray, of the suspension apparatus, of vibratory therapeutics, may be cited.

It remains to allude to his personal characteristics. Charcot was a man of great dignity, of calm repose, of even temper, of slow thought and utterance, but of much reserve power. In appearance like Napoleon, and in manner reserved and observant, he was not the type of man to be popular. Yet his dignity was one that was felt to be appropriate to a man of great power and was never assumed. With patients suffering from trifling affections he showed no sympathy, possibly no interest. With patients whose diseases were grave, or obscure, or of rare type, he was kind, attentive, interested, and was ready to spend valuable time in most careful investigation. Of this I am assured by patients who had been under his care, and who would never have come away with such kindly feeling had they not experienced his thoughtful attention. His relation to his pupils was also one of mutual interest and affection. He was never familiar with them, yet he always respected and sought their opinions, was never autocratic in the

direction of their work, and was always the subject of their devoted admiration and respect. No man could have kept about him such a number of able medical workers, all loyal to him in the midst of their labors, without characteristics of many kinds of the noblest type.

His domestic life was a delightful one. He was married early in life to a lady of considerable wealth, who was enthusiastic in his work, and by whose aid many scientific undertakings otherwise impossible were carried out. He had two children, one a boy, whom it was his fond desire to see succeeding as a physician, and who gives promise of being worthy of the name. Their homes—he had a large country place at Neuilly as well as a fine mansion on the Boulevard St. Germain—were superb in every appointment and contained many treasures of art, for the artistic sense was one which he delighted to indulge. He was a designer, a painter on porcelain and in oils. The tiles in his study mantel and the ceiling of one of his salons were painted by his own hand. Many of the drawings displayed at his lectures and published in his books were drawn by himself. And he delighted in gathering about him curios of every kind. He cared less for music than for painting, and always preferred the classic and Italian schools to Wagner, showing himself thoroughly French in this respect.

Like every man of eminence he had his enemies, critics in science, rivals in medicine. Yet after all their criticism is exhausted, we must admit that Charcot remains the greatest French physician since Trousseau, the greatest ornament of the medical profession of the present age. We admire his genius; we esteem his scientific work; we respect him as the greatest of medical teachers; we honor him as a noble, unselfish, and truly great man.

CLINICAL MEMORANDA.

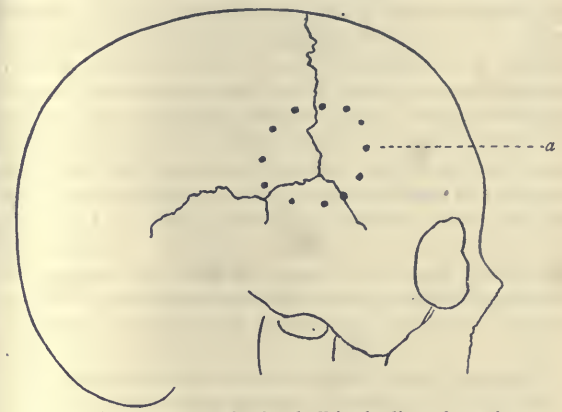
TRAUMATIC HEMORRHAGE IN THE RIGHT CEREBRAL HEMISPHERE; RECOVERY.

By R. EMMETT GIFFEN, M.D.,
of Lincoln, Neb.,
Surgeon-General National Guard of Nebraska; Surgeon-in-Chief St. Elizabeth Hospital, Lincoln, Neb.

D. Y., twenty-three years of age, a Russian, living in the squatter portion of the city, on December 8, 1892, while quarrelling with a companion, was struck on the head with a hatchet, the pole of the hatchet striking him on the right side above the ear and to the front, about the junction of the temporal, parietal, and frontal bones, and producing a lacerated wound.

He was seen by Dr. Britt soon after the accident, who found him in a dazed condition, with the scalp wounded as described, but with no depression of the skull. I saw him on the following morning, sixteen hours after the accident, and found him presenting all the evidences of compression of the brain; the right pupil was dilated and irresponsive to light; the left normal and responsive to light The skin was hot and covered with a profuse perspiration; the pulse slow, forty per minute and irregular; the respiration stertorous. During the night, the man's sister told me that he had had spasms of the left arm and leg, but that now these limbs were completely paralyzed, and the right was gradually becoming so. This, to my mind, was important, as it showed that compression was gradually taking place, involving one structure after another; and if something was not done immediately, death would result soon, or if not death, a permanent disorganization of brain-tissue with its results, which are worse than death.

My diagnosis was hemorrhagic clot pressing on the arm and leg center on the right side of the brain, possibly caused by fracture of the inner table of the skull, cutting the meningeal artery; and, as the man was sinking gradually, I advised opening the skull—not trephining, but raising a piece of the skull, after the manner of Wolfe, Horsley, and others. It took very little chloroform to affect the patient. I cut through the scalp down to the skull; then with a brad-awl, such as is used by carpenters, I cut holes in the skull over the line in which I intended using my chisel, in this manner:



a. Perforations made in the skull in the line of opening.

It is surprising how rapidly one can use the awl and make the openings, which weakens the line of incision so much that the chiselling is not difficult, as the bone readily gives way between the points of opening. Having raised the skull I found a large blood-clot, and the middle meningeal artery bleeding profusely. After turning out the clot, I tied the artery; then, upon examining the inner table of the skull, I found it fractured, and that a spicule of bone had been the cause of the trouble by cutting the artery. I removed some, and replaced other pieces, for the fracture was a stellate one, and was ready to replace the bone that had been raised up, but, in examining the broken, or under part of the hinge of bone, which is always broken by raising the piece of skull, and in passing my finger along the break, I found that a spicule of bone had been broken off by raising the piece, and had cut through and was pressing on the brain-tissue. I removed this, for there was ample room, and there would have been no excuse for leaving anything unfinished, and stopped the bleeding with styptic cotton. Then washing the wound thoroughly with hot water, I permanently closed it. Twenty-four hours afterward the man was sitting on the side of the bed with his trousers on, and he said that with the exception of the headache he felt well and did not see any use in staying in bed. I advised him to stay in bed for a few days, which he did. At no time after the operation did he have a temperature of over 100° F., and two weeks later he was on the

streets and able to attend the trial of the man who struck him. He is now working on the railroad, perfectly well. In this case, it was utterly impossible to use any antiseptic precautions, as the man lived in a hut surrounded by the filthiest of people—four of them living in the same room, all cooking, eating, and sleeping, in one apartment. The bed he was lying on was a feather-tick that had been brought from Russia with him; and for dirt, I never saw anything to equal it. They would not allow us to remove him to the hospital, so I was forced to do the best possible. I used plenty of hot water, but no other aseptic. Yet, as stated, this man's temperature never went over 100° F.

ACETANILID AS A DRESSING FOR WOUNDS.

BY FRANCIS W. HARRELL, M.D.,
OF GILMAN, WASH.

As surgeon-in-charge of the Seattle Coal and Iron Company's mines at this place, and having to treat a great number of burns, scalds, contused and lacerated wounds into which coal-dust, ashes, iron-filings, grease, and dirt of every kind have been thoroughly ground, and finding none of our present dressings equal to preventing suppuration in these cases, I have naturally been searching for some means of making these wounds aseptic and keeping them so—some dressing that would prevent sepsis, and kill germs by contact. I think I have found what I wanted in acetanilid in the form of a powder. Reasoning in my own mind that many of the coal-tar derivatives have germicidal properties, and being struck by the non-hygroscopic properties of acetanilid, I began experimenting with it as a dressing for wounds.

The first case in which I tried it was an extensive laceration of the skin and muscles of the lower arm and forearm in a boy of nineteen. There were two wounds, one on the upper surface of the lower arm, an inch by two inches in extent, and one on the under surface of the forearm, an inch by two and one-half inches in extent. After carefully washing these surfaces with warm water, I applied pulverized acetanilid; the next morning I examined the wounds and found no pus, and then applied more acetanilid. The same result was observed each time I examined the wounds, and I also noted that they were growing perceptibly smaller. After a week the boy went off on a fishing excursion and I did not see him for a week. The dressings had not been changed during this time, but the wound on the forearm had healed, while the one on the arm was not larger than a dime. I applied a fresh dressing, and healing was complete in about a week. At no time was there any show of pus in these wounds. The young man called my attention to the fact that the dressing when first applied "was a little peppery," as he expressed it, but that in ten minutes all pain had disappeared.

The same effect has been noted in every case in which acetanilid has been used, clearly showing that it has local anesthetic powers. I have treated similar injuries with iodoform, boric acid, carbolic acid solutions, and with bichlorid solutions and gauze, but I have never succeeded in curing them without the formation of pus. Since then I have used acetanilid in the treatment of every case I have had in which there was extensive loss of tissue, and in every case it has acted well, the usual result being no pus and rapid recovery. I have not been able to use it in any major operations, as, fortunately, we have had no very severe accidents here for the last two months. My method of treatment has been cleanliness, with the application of finely powdered acetanilid to the wound. Apply plenty of it; in fact, for a crushed finger I make a bed of acetanilid.

Not being a practical chemist myself, and not having a hospital at hand where I can carry on extensive investigation, never having seen anything written on this subject, and being impressed with the cheapness of this substance, its lightness, its bland, non-irritating qualities when applied to abraded and wounded surfaces, I make this communication to call the attention of the profession to the value of acetanilid and to get someone who has more opportunities than I have to investigate it. I have found acetanilid a dry dressing that does not scald the skin, as does boric acid; does not have an offensive odor, as does iodoform; will never poison by absorption, as does sometimes carbolic acid or mercuric chlorid solution, or gauze.

MEDICAL PROGRESS.

Secondary Post-partum Hemorrhage.—At the last meeting of the Colorado State Medical Society, DR. JOHN T. DAVISON reported the case of a primipara, twenty-nine years old, who was delivered of twins at about the eighth month of pregnancy, being attended by a midwife. The children were syphilitic in appearance; one died twenty-eight hours, the other nineteen days after birth. The mother was up, engaged in her by no means light household duties, five days after the labor. She attended the funeral of the second child, riding some miles in an open wagon. Three weeks after delivery the woman was seized with profuse uterine hemorrhage. She was found lying upon the bed, quite pale and anxious. Her clothing and the bedding beneath her were saturated with blood. There was not even hot water in the house, and no attendant save a neighbor who had chanced in.

Bimanual examination showed the uterus well contracted, of the usual size for the period elapsing after delivery, and occupying the natural position. Upon introducing a duck-bill speculum, blood was seen issuing freely from the os. At this juncture the patient became quite blanched, sweat appearing on the forehead, and the pupils dilating. The emergency being pressing, the vagina was tamponed with the first accessible substance—a new, clean sheep's-wool sponge of about two ounces in weight. This was torn into shreds, soaked in a one to six solution of ferric chlorid, and introduced until the introitus was reached. In spite of this, considerable oozing from the orifice continued. This was subsequently thought to be due to the patient's previously anemic condition, or possibly to a hemophilic tendency. The oozing continued for about an hour, finally ceasing. Fluid extract of ergot was given in dram-doses every four hours for a few days, quinin, iron, and a liberal diet prescribed, caution enjoined as to the use of hot liquids, and small quantities of stimulants allowed. The tampon was removed thirty-six hours after its introduction; vaginal irrigations of mercuric chlorid, 1 : 3000, and carbolic acid, 1 : 50 (to destroy fetor), were employed. The tam-

poning with absorbent cotton and the irrigations were repeated daily for about one week; then discontinued. Nine days after the first profuse hemorrhage the woman concluded to sit up in a chair, when a second, but a lighter hemorrhage took place. Tamponing was again resorted to with success, as far as immediate control of the hemorrhage was concerned, but any attempt to discontinue the use of the tampons was followed, on slight exertion, by hemorrhage, so that their use was continued daily for some weeks. An inspection of the os, made previously to the introduction of the tampons, disclosed the existence of a bad laceration, but any attempt to ascertain the precise location of the torn artery resulted in the loss of a large amount of biood. In view of this, and of the patient's weakened condition, tamponing alone was relied upon to control the hemorrhages, and, as the sequel shows, with success.

Perhaps four weeks after the first hemorrhage, a semiglobular body was observed protruding at the os externum. This suggested partial inversion of the uterus, or a polypus. Its spontaneous disappearance after some weeks supported the former assumption. Under roborant treatment, with rest in bed and a liberal diet, the patient's general health and strength gradually improved, and she was soon allowed to get up, finally recovering fully and gaining many pounds in weight. About sixteen months after her first confinement the woman was delivered of a large male child, when the cervical scar could be easily felt by the examining finger, incidentally verifying the previous diagnosis of hemorrhage due to laceration of the cervical artery.

Sigmoiditis.—Mayor (*La Semaine Médicale*, 1893, No. 46) has observed a condition of inflammation of the sigmoid flexure of the colon giving rise to symptoms analogous to those of typhlitis and perityphlitis. Constipation appears to play the principal rôle in the etiology of the affection, either mechanically or as a result of the absorption of toxic matters. The inflammatory process may be limited to the walls of the intestine proper, constituting sigmoiditis; or it may extend to adjacent structures, giving rise to a local peritonitis, and constituting perisigmoiditis. The principal and most characteristic symptom consists in the presence of a painful movable tumor in the left iliac fossa. In cases in which the inflammatory process is limited to the coats of the bowel the tumor is cylindric in shape and of considerable size, being lost below in the pelvic cavity and being continuous above with the descending colon. This swelling may be mistaken for the cord described as present in cases of enteroptosis; for an iliac phlegmon or adenitis; for simple gastro-colic dilatation; and for muco-membranous colitis. The sigmoid cord of enteroptosis is of smaller volume and more perfectly cylindric; it is also characterized by hardness and retraction. Inflammation of the iliac glands is attended with dulness upon percussion, while a certain degree of resonance usually persists in case of sigmoiditis. An iliac phlegmon is to be differentiated from an iliac peritonitis by the fact that the swelling of the latter is bosselated, not flat on percussion, and does not extend to the abdominal walls or to the pubic arch. In case of simultaneous dilatation of the stomach and sigmoid flexure, inflammatory symptoms are absent. Cases of muco-membranous colitis are usually associated with hysteria or neurasthenia and present pain and induration in the left iliac fossa; the mass present is band-like, and there is an absence of inflammatory symptoms, while the stools are characteristic. Patients affected with iliac enteritis sometimes, but not always, present fever. They are often emaciated, with coated tongue and anorexia. The stools are irregular and scybalous. The condition is curable, although sometimes obstinate. Should pus form it will require evacuation. Under all circumstances the patient should be put to bed and restricted to a liquid or semiliquid diet; occasional doses of castor-oil may be given; a copious enema is to be administered on alternate days; cataplasms may be applied over the painful region, and possibly mercurial ointment; tincture of iodin and a flannel bandage may also be applied.

"The Metapore (Foramen of Magendie) in Man and an Orang" is the title of a paper presented to the American Neurological Association, July, 1893, by Professor Burt G. Wilder, M.D., which was designed:

First. To call attention to the existence of at least two varieties of the metapore, viz., one in which the metaplexuses barely project at the margin, the other in which they extend for some distance upon the cerebellum.

Second. To record the discovery by the author of the metapore in an adult orang and in three Old World monkeys. In the former there are several orifices in the metatela.

Third. To admit the unsatisfactory state of our knowledge as to the structure and relations of the parts and cavities involved, and as to the functions of the arrangement.

Of the ten special questions asked in the paper, nine are discussed more or less fully in the *Reference Handbook of the Medical Sciences*, Supplement, 1893, pp. 615, 616, the tenth is as follows:

10. *Does the metapore represent an evagination of the metacelian endyma?* This is suggested as an alternative to the usual view of perforation, by Professor C. S. Minot (in a manuscript communication to Professor Wilder, dated July 17, 1893), who says: "The passage from my *Human Embryology*, quoted by Dr. Wilder in the *Reference Handbook of the Medical Sciences*, Supplement, p. 613, is not intended to throw any doubt on the existence of the foramen of Magendie or metapore. . . . It is an opening through the roof of the fourth ventricle. There are two possibilities: Either it is a break in the epithelium, or it is the orifice of an evagination." Dr. Minot does not state at what period the evagination hypothesis occurred to him; it is not even hinted at in his *Embryology*, in which, indeed, on page 676, the very existence of the metapore seems to be ignored. Hence, Dr. Wilder holds that any misapprehension on his part as to the actual nature of Professor Minot's views is due to the summary and inadequate treatment of the roof of the fourth ventricle, already commented upon in Dr. Wilder's review of the book in *The Nation*, May 11, 1893.

A Case of Leprosy resembling Morvan's Disease.—At a recent meeting of the Société Médicale des Hôpitaux, Debove (*La Médecine Moderne*, 1893, No. 60, p. 758) presented a man, fifty-one years old, who fourteen years

previously had a whitlow upon the palmar aspect of the right thumb, incision of which was unattended with pain. For a number of years successive whitlows recurred in the same situation, which, though painful at first, subsequently became insensitive. There was, however, no necrosis of bone. In the course of time the right hand became contracted, claw-like, with a deviation to the ulnar aspect, and atrophy of the muscles of the thenar eminence. Common sensibility was preserved, but thermal and painful sensibility were lost on the right forearm up to the elbow. Morvan's disease was at first thought of, but subsequently a diagnosis of leprosy was made. It was learned that the man had lived in Mexico, and on investigation neuromata were found in various parts of the body. From the data obtained, the disease must have had a period of incubation of fifteen years.

Acute Parenchymatous Nephritis following Varicella.—CASSEL (*Deutsche medicin. Wochenschr.*, 1893, No. 32, p. 769) has reported the case of a girl, four years old, who had previously never suffered with any infectious disease, but who upon the sixth day of a febrile illness presented a typical varicellous eruption. The urine at this time contained no albumin, but nine days later, when she was brought on account of a swelling of the face and diminished renal secretion, the urine contained blood, albumin, and granular and epithelial tube-casts. In the following days the condition of affairs progressively improved and so continued to do until the child was lost from view.

THERAPEUTIC NOTES.

Theobromin for Cardiac Dropsy.—At a recent meeting of the Paris Academy of Medicine, GERMAIN SÉE (*Allg. med. Centralzeit.*; *Wiener med. Pr.*, 1893, No. 34, p. 441) reported excellent results from the employment of theobromin in the treatment of grave cases of cardiac dropsy. Theobromin, like caffein, belongs to the group of xanthins, which are closely related to uric acid. Theobromin is dimethyl-xanthin, while caffein is trimethyl-xanthin. Theobromin was administered in daily doses of from 45 to 75 grains for three days successively, with excellent results. The amount of urine was increased at once and the diuresis subsequently became still greater. The drug was employed in cases of cardiac dropsy, valvular or myocardial in origin, independently of whether ascites coëxisted or not. It proved inefficacious in cases of ascites dependent upon nephritis. Theobromin has the advantages over other diuretics, such as digitalin, caffein, calomel, milk, and milk-sugar, that its use is unattended with unpleasant result of any kind, that its action is more certain, and further, that the ordinary diet is not interfered with. The use of so-called theobromin sodio-salicylate is cautioned against, which is said to be only a mixture of theobromin and sodium salicylate.

A Remedy for Dysentery.—MIXON (*Texas Sanitarian*, vol. ii, No. 10, p. 414) recommends choparro amargoso, a small thorny bush that grows in Southwest Texas, in the treatment of dysentery. The bush belongs to the natural order Simarubaceæ, which also includes quassia and simaruba. All parts of the bush possess medicinal virtue, except old stock. The bark, leaves, thorns, flowers, and fruit, all have an intensely bitter and characteristic taste. The tendrils contain the active principle in greatest proportion and are generally selected for pharmaceutic purposes. The plant yields its virtues to boiling water, in the proportion of from two to four ounces to the gallon. The dose of the fluid extract is from ten minims to half an ounce as a tonic, from three drams to an ounce as a stimulant. Large doses cause flushing of the face and fulness of the head. The odor of the drug can be detected in the urine, although no appreciable effect upon the renal secretion has been observed. The drug has some antiperiodic properties, which might make it a desirable remedy in the treatment of malarial dysentery. The active principle upon which the properties of the drug are supposed to depend has not yet been isolated.

Aconitin Nitrate in the Treatment of Erysipelas.—At the recent Congress of the French Society for the Advancement of Science, TISON (*La Médecine Moderne*, 1893, No. 65, p. 822) reported the employment of aconitin nitrate in the treatment of some twenty cases of erysipelas, with the result in every instance of diminishing the pain and shortening the duration of the attack. Complications developed in but two cases, inflammation of the knee-joint developing in one, and an abscess of the temple in the other. The alkaloid was dissolved in a mixture of water, glycerin, and alcohol, having the density of distilled water, in such proportion that each fifteen minims contained one-seventh of a grain. The dose ordinarily employed was one-three-hundredth of a grain.

For Dysentery.—

℞.—Salol. . . . . gr. xxiv.
Sodii bicarbonat. . . . . ʒss.
Essentiæ canellæ . . . . gtt. v.
Mucilaginis acaciæ . . . ʒjss.
Ol. ricini . . . . . ʒiv.
Aquæ chloroformi . . . . ʒvj.—M.

S.—Two teaspoonfuls every three hours.

Rif. Med.; *Münch. med. Wochenschr.*, No. 33.

For Alopecia.—

℞.—Ol. cinnamomi . . . . mxx.
Ætheris . . . . . fʒj.—M.

S.—Paint once daily. The hair should be cut short and washing the head should be abstained from. From three to four weeks on an average are required to accomplish good results.

Centralbl. f. d. ges. Ther., No. 7; *Corr.-bl. f. Schw. Aerzte*, No. 16.

For Acute Articular Rheumatism.—

℞.—Acid. salicylic. . . . . ʒjss.
Alcohol. absolut. . . . fʒj.
Olei ricini . . . . . fʒij.—M.

S.—Apply topically morning and evening by means of saturated compresses, covered by an impermeable dressing and held in place by a flannel bandage.

RUEL, *Rev. Méd. de la Suisse Rom.*, 1893, No. 8, p. 484.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage in North America.

Per Annum, in Advance . . . . . $4.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, OCTOBER 14, 1893.

ABOUT CORONERS.

The office of Coroner is of great antiquity, and exhibits in common with other judicial offices the complex and unnecessary forms of procedure that characterized the jurisprudence of the middle ages. No doubt, in days when pathology was non-existent, violence common, and the practice of medicine carried on without organization or ethical control, it was imperatively necessary that some constituted authority, possessing compulsory process for witnesses and broad jurisdiction, should pass judgment on any cases of suspicious or obscure death. In the present state of medical science, however, the office is an anachronism, and in the corrupt politics of our larger cities is in constant danger of either abuse or neglect. It is true that since the revenues, regular or extortionate, are not usually large, and the functions of the office concern directly but a limited portion of the community, there is rarely any public discussion on the matter, but the opportunity for reform exists none the less.

At the present time considerable attention is being attracted to New York City, where, largely through efforts of the *New York Herald*, an extended exposure of Coroners' methods is being made. The agitation has resulted in a formal presentment by the Grand Jury, charging the Coroners with dereliction of duty, and advising that at the formal revision of the State Constitution, to be made shortly, the office of Coroner be abolished.

Some years ago an analogous newspaper exposure was made in Philadelphia, though the maladministration related almost entirely to questions of finance, and did not lead to suggestions of radical reform. Some years subsequently The Medical News had occasion to severely animadvert upon methods prevailing in the same office in regard to the distribution of unclaimed dead, but this was remedied by the passage of the Anatomical Act.

The abuses in the New York offices (for the city has several Coroners) have been of long standing, and involve not only the despatch of business, instances of flagrant delay having occurred, but irregularities in the summoning of witnesses and in making returns to the police authorities. In Philadelphia the office has of late years been administered satisfactorily, although occasionally individual members of the medical profession have been not very kindly treated. The truth must be confessed, however, that more errors have been committed in Philadelphia by medical than by lay incumbents.

The office of Coroner is one of much greater local power than is generally supposed. It has not much patronage or social weight, but the transportation companies are usually careful to maintain friendly relations with it. A Coroner has much control over his own juries; the character of a verdict in a case of railroad accident may be of much importance in subsequent legal proceedings. Then, investigations into suspicious deaths may be pushed with vigor or be allowed to fail.

Agitation which results only in securing more efficient and honest management of the office fails to do its best. The whole system should be remodelled. The finding of a Coroner's jury is an entirely unnecessary preliminary. It is not regarded in the subsequent judicial proceedings, and many grave criminal cases are tried without any such verdict. By far the larger proportion of inquests passed upon are matters of simple routine, the cause of death being patent, while in the obscure cases the jury and even the Coroner are compelled to rely upon the testimony of experts. These experts would be equally competent to pass judgment in the simpler cases.

The Massachusetts law exemplifies the direction that reform should take. The antiquated methods of inquest and verdict are done away with; com-

petent local officials, termed medical examiners, who must be graduates in medicine, view the bodies, and, in the event of inability to determine the cause of death or of suspicion as to criminal acts, refer the inquiry to experts or to the prosecuting authorities.

The organization of local and State boards of health and the appointment of health-officers, with powers to supervise interment and to require competent certificates of death, are also conditions which render the Coroner's inquest unnecessary. It matters but little as to the title given the official who is charged with the duty of ascertaining the cause of any sudden or violent death. In Massachusetts he is called a medical examiner; he might be called a registrar or a coroner; the important point is to shake off from our procedure the absurdity of the inquest by a jury made up often of the political idlers who may be about the office and representing no social, medical, or legal constituency, dependent for their appointment on the head of the office, and in most cases forming their judgment solely on the suggestion of the experts. Questions of responsibility for murder by deliberation or neglect can be fully settled by the public prosecutor.

One point in which there is great need of increased efficiency in Coroners' inquiries is in reference to death from poison. There is little doubt that both criminal and accidental poisoning is more common than is apprehended by the public at large. Not only are many cases of this kind so obscure or so simulative of disease that no suspicion is aroused, but the methods of procedure often involve such expense that the officials are unable or unwilling to undertake investigation. Expert witnesses receive so little consideration from the courts, are put to such unnecessary inconvenience by delays in trials, that it becomes necessary for them to ask fees sufficiently large to protect themselves from absolute loss. County authorities are often unwilling to pay such fees unless it is very apparent that a successful prosecution will justify the outlay. It would be a great advantage if some systematic method of inquiry could be devised by which more frequent preliminary examinations could be made. In the sparsely settled counties it is often very difficult to get the county commissioners to authorize any unusual expenditure for analytic work, and it sometimes happens that to secure such investigations private parties, relatives of the deceased, are obliged to guarantee payment.

It is to be hoped that some day a collegiate course leading to a thorough knowledge of sanitary science and State medicine, not as a mere accessory of medicine, but as an independent degree, will be inaugurated in one of our large cities, and that the valuable material for practical instruction which the Coroner's office in such a city furnishes will be utilized in the teaching.

HIGHER MEDICAL EDUCATION.

PROFESSOR DA COSTA'S timely, earnest, and eloquent address before the Harvard Medical Alumni Association, published in THE MEDICAL NEWS of September 23d, challenges comment on several important points. We shall speak of but three of these: 1st. Preliminary training; 2d. Examinations; 3d. The university idea.

As to preliminary training, DR. DA COSTA is at one with PROVOST PEPPER and PRESIDENT ELIOT in advocating a shortening of the collegiate course in arts, if it is desired that medical students should have the training and the degree of such a course.

The University of Pennsylvania has made such a concession; and we trust that all other American universities will soon do the same.

DR. DA COSTA recognizes, however, that under existing conditions in America many men who have never entered college may be properly qualified to study medicine, and, while approving of the four years' course, he insists upon the importance of reforming medical education, not so much in the direction of lengthening the course as in securing a proper foundation, whether in or out of a college or academy. This is the position THE NEWS has steadily maintained. A man properly qualified in biology, in chemistry, and in physics can learn more in three years at a good medical school than the average student of the day, even at Harvard, can learn in five years. Begin at the beginning, then the rest will come. It is not in practical skill in medicine or surgery that American physicians are deficient, but in exact scientific knowledge. It is for this reason that, despite our LEIDYS and our DRAPERS, we have proportionately fewer great names in the sciences than in the arts of medicine, and that most of our ambitious graduates are compelled to go abroad for technical training. Increasing the number of medical students with degrees in arts will not of itself remedy this defect. We need scientific preparation. The kindergarten chemistry now taught to senior stu-

dents in many medical colleges is far less than the student ought to know before he is admitted. There is no preliminary training in biology now demanded —nor is general biology taught, except incidentally and accidentally. Yet how can human anatomy or human physiology be understood without it? As to physics, let anyone attempt to get an explanation of such simple matters as the siphon or the cupping-glass from some of the men and women to whom learned discourses on blood-pressure are to be delivered, and he will hear theories that would have amazed, rather than delighted, Pascal or Toricelli.

Dr. Da Costa does not approve of multitudinous and incessant examinations. "Why must you always pull up the student by the roots to see whether he is growing?" "We do not want to turn out medical prize oxen, stuffed and fattened for examination, but medical men, with thought, with power, with intelligence, with love of work, and of orginal investigation." There is nothing to be added to this. But it takes good teaching to turn out thinking men, while any dunderhead, with the aid of a quiz-compend, can stuff medical oxen, geese, or dummies for examination. We are afraid the examination-system will continue until we get gardeners who have sufficient confidence in themselves and in their methods to let their plants grow undisturbed.

In his remarks upon the useless multiplicity of colleges, the Harvard orator went to the root of the whole matter. So long as medical education is a business, carried on by private individuals for personal gain, whether gain in money, gain in notoriety, or gain in consultation-practice, so long will there be an insufficient preliminary standard, with its inevitable sequelæ of kindergarten lectures, cram-books, and examinations. There should be ample endowment for every medical chair, with its necessary adjuncts of laboratories and hospital beds, and the work should be done not by one lecturer, but by a large staff of able teachers with comparatively small classes. There should be no insane jealousies and envious repression of rising men, but everybody with the ability and the desire to teach should be given the opportunity, and from among those who do the best work should the promotions be made. This, as a rule, means no medical school apart from a great university, because, generally speaking, only such a university can obtain the necessary endowment; and because, moreover, several adequate and rival endowments of indispensable laboratories cannot be obtained in the same city, hardly in the same State. The time is not yet ripe, however, for so radical a measure. A gradual approach to it can be made by consolidation, as has been done in Chicago and New York within recent years.

Where consolidation is impracticable—where for instance a great school not connected with a university has glorious memories and traditions, as, for example, the Jefferson Medical College of Philadelphia—coöperation is not impossible, on some such plan as was suggested by Provost Pepper at a dinner of the Jefferson alumni. Let medical students who come to Philadelphia, said Dr. Pepper in effect, attend lectures where they will—at the University, at the Jefferson, at the Medico-Chirurgical College, or the Woman's Medical College. Let all the laboratory and hospital facilities be open to them. Let them be students of the medical faculties of Philadelphia, and let them, by having choice of teachers, stimulate the teachers to generous rivalry. Something like this seems to be the thought, too, of Dr. Da Costa, when he says: "The future of medicine lies in the universities and in such great schools as can vie with them in clinical and other facilities."

If the undergraduate and post-graduate schools of cities like Philadelphia choose to overlook mere personal interests, they have it in their power to give, by their coöperation, the greatest impulse of the century to Higher Medical Education in America.

EDITORIAL COMMENTS.

Powers of Boards of Health to Deal with Nuisances.—Several important questions have been decided by the General Term of the Supreme Court of New York in the case of the Board of Health of the City of Yonkers *v.* Copcutt (24 N. Y. Supp. 625). The testimony in this action disclosed the existence of an intolerable nuisance in the heart of that city of 30,000 inhabitants. Environed by dwellings in close proximity to its shore, there has been for many years maintained a mill-pond whose bed is covered to the depth of seven feet with foul sediment, impregnated with offscourings and putrid substances, covered at times with polluted water, and at times bare, giving off noxious, offensive, and sickening odors, which endangered the lives and health of the people. It also showed that the only effective way to abate the nuisance was to destroy the dam and enjoin the rebuilding of any obstruction to the running current of the water. The remedy of the Board of Health was, therefore, said the Court, to abate and remove the nuisance, if one existed, and charge the expense upon the owner of the land—not to order him to do it and impose a penalty for failure

to do so. However, under a statute authorizing the Board of Health to establish such regulations as might be necessary to carry into effect the powers of said Board, and to enforce observance of its sanitary code by imposing penalties, the Board could maintain an action for a penalty and injunction against the person who maintained the dam, it being declared by one section of the Board's code that anything dangerous to public health was a nuisance, and that one who supported it was guilty of violating the section, and a penalty being prescribed by another section for any violation of the code or any ordinance or resolution of the Board. But when the Board, without notice to the person to be affected, passed a resolution requiring the removal of the dam, the penalty for disobedience of the resolution could not be enforced. The fact that others beside the owner contributed to it, and even the city of Yonkers itself, by discharging sewer matter into it, did not relieve the owner of the dam from responsibility for its condition, for it was his act in maintaining the dam that kept the foul substances confined in the pond. It was also objected on the part of the owner that the Board had no power to prohibit the rebuilding of the dam and thereby prevent a nuisance, but that the Board must wait until it was rebuilt and then adjudge it a nuisance. It might as well be said that the Board could not prohibit a load of cholera-infected clothing from coming into the city, but must wait its arrival before taking measures to abate the nuisance. It was simply a means taken to prevent the increase or renewal of what had already been adjudged a nuisance dangerous to life and health. Besides, the penalty could be collected by it for violation of the resolution of the Board prohibiting the rebuilding of the dam.

Abstracting from the French as She are Done.—To make a useful and trustworthy abstract of a medical article requires a high degree of intelligence, both literary and medical, and also a great conscientiousness. One who is conversant with the originals and who is experienced in such work is frequently disgusted or amused by the slipshod quality of a large part of the "abstracting" served up by medical journals for the delight and profit of their readers. As an illustrative instance there recently appeared in a monthly medical magazine of great dignity, and with claims to *international* recognition, an abstract of an article on "Syphilis of the Liver," epitomized from the *Revue mensuelle des Maladies de l'Enfance* for January, 1893. The final sentence of the original reads:

"Dans la suite, le foie diminua considérablement de volume, au point que deux mois plus tard, il fallait le chercher sous les fausses côtes. Mais en Novembre, 1891, apparurent des gommes frontales qui vinrent prouver la nature syphilitique de la lésion."

The translator thus renders the last sentence: "About four months after operation syphilis was suggested *by the appearance of the gums!*" We are sincerely grateful for the medical abstractor's ignorance that the French word *gommes* also means *gummata*. Why did he not say. *frontal gums?* Where, also, was Mr. Editor, and what was he about?

Yellow Discoloration of Hands and Feet in Enteric Fever.—Filipovich, of Odessa, notes as diagnostic of enteric fever a peculiar yellow or orange discoloration of the prominent portions of the palmar and plantar surfaces which in health usually display a pink tint. He attributes this discoloration to the enfeebled action of the heart, the incomplete filling of the capillaries, and the dryness of the skin. Filipovich found the sign constant and marked. In Philadelphia this sign has long been known to many physicians, whose attention was called to it by the late Dr. Ellwood Wilson. A valued collaborator informs us that at the Philadelphia Hospital, some two years ago, he examined the hands and feet of every fever patient in the house during a number of weeks, and found the sign present in every case of enteric fever, and, with the exception of one case of acute tuberculosis and one of acute pneumonia, absent from other cases of febrile diseases. In neither of these exceptional instances was the discoloration so marked as in the enteric cases. It is not, however, invariably well marked, even in enteric fever. The actual state of the case seems to be that the sign, while not pathognomonic, is interesting, and should count with others in making a diagnosis.

Declarations of Wounded Persons.—The declarations of a person who has been wounded, respecting the circumstances under which the wound was inflicted, are admissible in prosecutions for the killing of such person, if made at a time when he did not expect to survive the injury and all hope of recovery had been supplanted by the conviction that he would certainly die. The time when made need not be when the declarant apprehended immediate dissolution; but the declarations are admissible if made at any time when he believed that death was impending and certain. So holds the Supreme Court of Arkansas in the case of Evans *v.* State (22 S. W. Rep. 1026). It is within the province of the court to hear the circumstances under which the declarations were made and to determine whether or not they are admissible; but after they are admitted it is within the province of the jury to weigh them and the circumstances under which they were made, and give to them only such credit, upon the whole evidence, as they may think they deserve.

The Abuse of Medical Charities.—The British Medical Association has inaugurated a determined fight against the abuse of medical charities in Great Britain, and as a means to that end its committee recommends (1) that a wage-limit be established above which income persons applying for treatment will be required to pay fees; and (2) that the hospitals and dispensaries hereafter have displayed in a conspicuous place within their precincts a placard bearing the following inscription: "This institution being established to relieve only those persons who are too poor to pay for suitable medical aid, notice is hereby given that on and after this date patients will be required to give information as to their means and circumstances, with a view to prevent the abuse of this charity by persons who are well able to pay." Cannot American hospital authorities be moved to "go and do likewise?"

Admissible Expert Evidence as to Death and Nature of Blood-spots.—It is not error, holds the Supreme Court of Pennsylvania, in the case of Commonwealth *v.* Cross-

mire (27 At. Rep. 41), to permit a physician, after describing on a murder trial the injuries found on the body of the deceased, to state what, in his opinion, caused death, and how the injuries upon the person were inflicted. Nor is it error to admit in evidence his testimony to the effect that certain spots on the clothing of the person accused of the murder are blood-spots.

Honor to American Medical Investigation.—We are glad to learn that the excellent and valuable article of Professor Vaughan on "The Principles of Immunity and Cure in the Infectious Diseases," concluded in this number of The Medical News, has, in advance of its complete publication, attracted some of the recognition it so well deserves, both in our own country and abroad. Dr. S. Pozzi, of Paris, has obtained the privilege of translating the address into French. We congratulate Dr. Vaughan and American medicine.

SELECTION.

STANLEY'S TRIBUTE TO SURGEON-MAJOR PARKE.

"Himself depleted in body from excessive perspiration after a march through hot, moist jungles, starving on one green banana a day, half-naked from loss of clothing and the constant wear and tear of bush-life, half fainting from the pernicious ague, which could only be suppressed by heroic doses of quinin, and yet presenting to each and all of us a face whereon one read naught but pleasantness and benevolence. Pursuing steadily, day by day, throughout a period which has no equal in my life for downright utter and extreme misery, an even temper so admirable and beautiful for its sweetness and devotion, that I can think no human being, male or female, could excel it. It is here, in the possession of these natural gifts, this charming benignity, that I think Parke is great. Oh! at such a time had the ordinary human creature stood up and freed the pent-up feelings with a shout of blasphemy and explosive fury, we could not have remembered it as a sin against poor, weak, overpressed human nature; but never within my hearing or knowledge did I hear a murmur or a mean expression. That singular sweetness and tender anxiousness, having been noted by me so often when he sat in the midst of his patients unsuspecting, remain stamped on my mental image of Parke, and calling him now up to my mind I can see nothing else but that. The 'Doctori,' as the Zanzibaris called him, was to them a friend to whom they might expose their constant and ever-recurring ailments, for no one but one who was sincerely friendly could look as he did, or speak so soothingly and comfortingly.

"After his short rest he would be seen striding across the camp, always erect, vigorous, and soldierly, going from hut to hut, apparently thinking of nothing in the world but the condition of a patient he had just seen, and presently he would be bending down over another bad case with a new face and eyes which glowed with glad promise of recovery to him. The chronometer was not so faithful to Greenwich time as our doctor to his duties. No person reminded him of them; the warm interest he took in his noble profession and his own faithful, humble, and upright heart were quite sufficient. The fate of the expedition—the prospects of getting food the next day, the whereabouts of Emin or anybody else—did not appear to have that importance for him as to how Juma or Ali or Sungoro was doing. The thoughts of impending starvation and calamitous forebodings had to yield to those which included his own immediate responsibilities."—Henry M. Stanley, in the *Lancet*, September 23, 1893.

REVIEWS.

A Dictionary of Medical Science: containing a full explanation of the various subjects and terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, Pharmacology, Therapeutics, Medicine, Hygiene, Dietetics, Pathology, Bacteriology, Surgery, Ophthalmology, Otology, Laryngology, Dermatology, Gynecology, Obstetrics, Pediatrics, Medical Jurisprudence, Dentistry, etc. By Robley Dunglison, M.D., LL.D. Twenty-first edition, thoroughly revised and greatly enlarged, with the Pronunciation, Accentuation, and Derivation of the terms, by Richard J. Dunglison, A.M., M.D. Philadelphia: Lea Brothers & Co., 1893.

If hereafter physicians err in matters pertaining to medical lexicography it will certainly be their own fault. From the press of the present and of late years has been poured a steady stream of excellent books, from the splendid works of Foster and the Sydenham Society to those of Billings, Keating, Thomas, and others. Throughout all these years the fine old volume of Dunglison has kept its place, despite needed revision long delayed, as a classic and reliable helper of the practical and literary physician in his struggles with the thorny subject of medical nomenclature. At last the scholarly son of the great lexicographer has felt the challenges of many rivals and has put his own hand to a revision of the father's handiwork, seeking to bring to it the almost riotous wealth in the fields of new word-coinages and medical progress that has accumulated in the years since the last edition.

Few know or can even faintly realize the labor that such a resolution necessitates upon the part of the conscientious man. . The verification of the mere form of a word, a date, an etymology, or a definition may mean an hour or hours of search, letters to half a dozen scientists, and perhaps at last doubt and disappointment. The delver in these dark fields surely deserves a far greater reward, both in gratitude and in hard cash, than he will ever receive. He must be content to go on his toilsome way, cheered only by the thought that conscientious work somehow brings its own reward, and that thousands of minds will be a little clearer and better as a result, direct or indirect, of his years of patient and fatiguing work. For there is a deep and widespread educational value attached to this dictionary work that few recognize. The medical profession owes Robley Dunglison a great debt for clarifying and definitizing the minds and concepts of many thousands of its younger men, for sparing young and old much intellectual vagueness, much misuse of its greatest profes-

sional tool or instrument, and much loss of labor and of time. In the face of such labor, criticism must be motived by the best kindness; it is impossible to carry out such a huge undertaking without numerous omissions and the creeping in of errors, and all reviews should be written with the idea of leading to the correction and improvement of future editions, or of warning the public against mistakes so long as they must remain uncorrected. Moreover, in the mind of the critic there must rise the thought of the interminable and exasperating differences of opinion among the best philologists pertaining to almost every word that one has to decide about.

Although thus minded, we must nevertheless remember the sharp limits of our space which prevent even mention of the many and most excellent things that might and should be enumerated. These must "go without saying," and only a few minor points noted wherein we differ from Dr. Dunglison.

The most astonishing mistake made is not printing Greek etymologic terms in the Greek characters. Epsilon can thus not be distinguished from Eta, nor Omega from Omikron. Every consideration, scholarly, literary, or scientific rebels against the plan pursued. But when decided upon, a definite rule should have been followed; the Greek letter Upsilon, for example, should have been uniformly represented either by the English *u* or by *y*, and not haphazard by either, as, *e. g.*, *pharynx* or *pharunx*. Moreover, the plan makes it impossible to say from what language the word is derived, whether from the Latin or the Greek. Then it lands our author in another difficulty, illustrated for example by the derivation of words meaning pus by four different somewhats on the same page: "*pyo*," "*pyon*," "*puon*," and "*puros*."

In pronunciation, of course, the rule, *de gustibus*, holds, but here, too, we should have adherence to *some* rule. We cannot understand why *psych-* is first *sik-*, then *si-*; *hyper-*, first *hi-per-* and then *hip-er-*; *micro-*, first *mik-ro-* and then *mi-kro-*; *gyne-*, first *gi-* and then *gin-* (both, too, wrong, as the proper pronunciation is *jin-*), *phyto-*, first *fi-to-*, then *fit-o-*, *bio*, first *be-o-*, then *bi-o-*, *dia*, first *de-ah-*, then *di-ah-*, etc., alternately and haphazard until one is sadly confused. We sincerely regret to say that the pronunciation throughout is unsatisfactory. It will be long before Dr. Dunglison gets either good or bad speakers to pronounce as he advises, *e. g.*, *pe-a'-me-ah* (pyemia) (why not *sep-te-sa'-me-ah* also?), *kar-e-o-kin-a'-sis* (karyokinesis) *pe'-ah mat'-er* (pia-mater—also strangely translated, "delicate mother"), *em-is-sah'-re-um* (emissarium), etc. A large number of words are not pronounced at all, and the one possible wrong pronunciation is too often chosen. Thus, there are several pages of *hæmas* and *hæmos* all pronounced *he-*. Suddenly we come upon our old friend (or enemy) *hæmorrhage*, and the pronunciation is as suddenly omitted; we are strangely referred to *hemorrhage*, where we get *hem*, and haul up with AHEM! There is a similar history with *hæmorrhoid*, (*he-*), *hæmorrhoids*, (*hem*), *hemorrhoids*, etc. We do not understand the significance of *h* in the phonetic pronunciation of all words with the Greek aspirate, *ῥ*—as, *e. g.*, in all the *-rhages* and *-rheas*.

We think the editor, if adhering to the old spelling, should have been consistent. If *fæces*, why then *defecation?* If all *hæma-*, *hæmo-*, etc., why an exception of *hemorrhage* and *hemorrhoids?* Why, oh! why does the author on the title-page spell *gynecology* and *pediatrics* as here written and stultify himself in the body of the book by spelling these words in the medieval way. It is trifling and absurd to thus "blow hot and cold" at the same time and in the same book. We also think the new spelling of words in chemistry, etc., recommended by so many learned societies, used by so many scientific writers, adopted by so many great lexicons, should at least have been mentioned.

We have noticed a number of minor slips, to which we will not here refer. But we must protest against the identification of *albumen* and *albumin*; even the lay Webster does not make this error. A number of eponymic diseases, such as Darier's, Morand's, Quincke's, Rivolta's, etc., are not to be found; a great many *images* are omitted; erythromelalgia is not a synonym of "*Reynaud's*" disease, nor of *Raynaud's*; Reichmann's disease is not necessarily followed by ulcer; several elements recently discovered are omitted from the table; several knots, all tests of birth and of death; several anesthetics and anesthetic methods (inhalers, Hyderabad, etc.); all of Weissmann's terms as to heredity (id, idant, biophore, determinants, etc.), and a number of hernias are absent. The table of bacteria is very incomplete. Hermaphroditism and an hermaphrodite are not identical. We are also sorry not to find such words as gastrodiaphany and gastrodiaphanoscope, obligate (applied to parasites), control-animal (or experiment), Laveran, cross-circulation experiment, etc.

Such things as these, however, may be expected in the best of books, but in spite of them the learned editor is to be congratulated upon the excellence of his book and upon the satisfactory completion of his arduous labors.

A HANDBOOK OF LOCAL THERAPEUTICS. By ALLEN, HARTE, HARLAN, AND VAN HARLINGEN. Edited by HARRISON ALLEN, M.D. 8vo, pp. 500. Philadelphia: P. Blakiston, Son & Co., 1893.

THIS book, under the efficient editorship of Professor Harrison Allen, is amply fitted to fill the place in therapeutics for which it was prepared. In looking over its pages one cannot fail to be impressed with the great number of drugs that have found a place as remedial agents in local affections, and the grouping together of such agents must necessarily be of value to the specialist in medicine in the saving of time and in a concentration of knowledge of the therapeutic measures at his disposal. The surgeon, the dermatologist, the otologist, the laryngologist, the oculist, and the gynecologist can each here revel in a mine of information without being compelled to wade through a mass of absolutely irrelevant material. An index of remedies is supplemented by one of diseases, both of which conduce to ready reference. A few relatively unimportant errors and omissions have necessarily crept in. Thus, in treating of the management of acute gonorrheal vaginitis no mention is made of the truly valuable results that have followed the application to the entire vagina of strong solutions of silver nitrate, and while bran as a surgical dressing has received notice, the value of the

bran-bath as an emollient in ulcerated and irritable conditions of the skin is not set down. The editor and his collaborators have completed their work in an excellent manner.

The Diseases of the Nervous System: A Textbook for Physicians and Students. By Dr. Ludwig Hirt, Professor at the University of Breslau. Translated, with permission of the author, by August Hoch, M.D., assisted by Frank R. Smith, A.M. (Cantab.), M.D., Assistant Physician in the Johns Hopkins Hospital. With an Introduction by William Osler, M.D., F.R.C.P., Professor of Medicine in the Johns Hopkins University, etc. With 178 illustrations. 8vo, pp. xv, 683. New York: D. Appleton & Co., 1893.

In less than two years several neurologic text-books have been presented to the profession by American publishers; but we cannot have too many, if they are good, and each presents some special feature. Hirt's treatise, known to the German profession since a few years, is now presented to English-reading physicians in an admirable translation. It is a work of great merit and contains some strikingly original features, as in its manner of classification. Tabes dorsalis and dementia paralytica are placed under diseases of the general nervous system, instead of under spinal affections and mental diseases, a natural and philosophic method of classifying and one that could be extended much further than it has been by Hirt. In the discussion of special subjects, and in remarks on treatment, the book in many places presents a freshness and vigor that are often wanting in compendious text-books. Certain subjects, as myxedema, have been omitted, although akromegaly and other recently described affections are considered.

Part II, which is concerned with diseases of the cranial nerves, is especially full. Under diseases of the vagus, Hirt treats of numerous nervous affections of the air-passages, angina pectoris, nervous palpitation of the heart, tachycardia, cardialgia, nervous dyspepsia, esophagismus, exophthalmic goiter—a somewhat unusual but scientific collocation.

Particular attention is given to therapeutics. The illustrations are excellent and many of them are new. The book is produced in admirable style.

The Throat and Nose and their Diseases. With one hundred and twenty Illustrations in Color, and two hundred and thirty-five Engravings, designed and executed by the Author, Lennox Browne, F.R.C.S.E., Senior Surgeon to the Central London Throat and Ear Hospital, etc. Fourth edition. Philadelphia: Lea Brothers & Co. London: Baillière, Tindall & Cox, 1893.

The special features of this work have been described and commented upon in noticing previous editions. This edition has been revised and brought up to date; but, possibly, in order to save alterations of stereotype plates, the additions are in some instances awkwardly joined. We notice in passing, a misquotation on p. 514, whereby the substitution of "and" for "or," in the citation of Cohen's opinion on the subject of laryngeal neuroses, entirely changes the meaning of the authority quoted, who certainly did not say that *he* could not recognize any difference between the cadaveric and the extremely abducted position of the vocal bands. As a matter of fact the difference is easily recognized and is important in diagnosis. In the copy of Mr. Browne's book before us the tinting of the colored plates is not so good as in previous editions. The pinks are too brownish.

Judging the book as a whole, it is an admirable presentation of its subject in the light of the large clinical experience of a careful observer. It is a book that no specialist can afford not to have, and that the general physician can rely upon as a safe guide and practical adviser.

CORRESPONDENCE.

HAIG'S URIC-ACID THEORY.

To the Editor of The Medical News,

Sir: In the article entitled "Haig's Uric-Acid Theory" in The Medical News of September 16, 1893, p. 310, appears the following: "Already his work has had considerable influence among physicians, and everyone who reads his fascinating pages must feel a strong inclination to acccpt his sweeping generalizations, which ascribe to uric acid human disorders of every complexion." I shall endeavor to show that an excess of uric acid in the blood is the cause of many and diverse human disorders. If Alexander Haig had done nothing more than to direct the attention of the medical world to the dire effect of an excess of uric acid in the blood, great would have been his work.

Just one hundred years ago, in 1793, Forbes Murray affirmed the starting point of gouty symptoms to be the presence of uric acid in the humors of the economy. In 1874 Murchison announced that the excess of uric acid was due to functional derangement of the liver. In these later days Haig writes, elucidating the action of uric acid in the causation of disease.

What disease is more common among adults in America than lithemia, presenting itself under so many various disguises. If it be true that Americans are a nation of "nervous prostrates" (and so it appears), then common indeed is lithemia. Take for example insomnia, a condition far from rare in city life, so frequently *made worse by hypnotics*, so quickly relieved when once the true cause is recognized—a sleeplessness due to derangement of the liver, producing lithemia. In such a case sodium salicylate in combination with caffein citrate yields excellent results.

Then, again, megrim, so very common, is quickly relieved by the same agents as were so useful in insomnia, when the cause is rightly understood as simply a lithemic crisis. The neurologist, Sachs, says that the same form of treatment that had been successful in a number of cases of insomnia proved successful in most of the cases of megrim with which he had to cope.

In acute tonsillitis, always found in subjects whose urine contains an excess of uric acid, I know of no treatment offering better results than sodium salicylate. The same treatment is likewise beneficial in both acute gout and acute articular rheumatism, both of which are due to the same cause—an excess of uric acid in the blood.

At the first annual meeting of the Association of American Physicians, held in 1886, Dr. H. C. Wood (THE MEDICAL NEWS, June 26, 1886, p. 716) said that it was his experience that rheumatism and gout are the same disease.

At the same meeting Dr. Draper, an authority on gout in America, said he thought Dr. Wood was correct in regard to the difficulty of diagnosis between gout and rheumatism. He would be glad to hear from any physician present who was always able to diagnosticate between the two.

Neuralgic pains, so annoying when due to an excess of uric acid; muscular rheumatism, a manifestation of lithemia; gravel, and the painful urethritis so often an accompaniment; and general pruritus, so often due to an excess of uric acid, are all relieved by the administration of sodium salicylate.

Oftentimes palpitation and irregularity of rhythm of the heart are produced by the state of the blood (Garrod); also the minor symptoms of disturbed action of the heart, such as giddiness and dimness of vision (Duckworth); the most prominent symptoms are the nervous, especially those referred to the head, in those cases in which uric acid is present in excess in the blood.

The mal-products of digestion are positive depressant poisons (Brunton); hence lithemic patients present themselves as woful objects; they are in dread of apoplexy or are sure that they are developing paresis, or they are insufferable cranks.

The functions of the liver and the kidneys are very closely related (Delafield); so that what starts as a mere functional disorder of the liver will in time, if not checked, end in organic disease of the kidneys. "Renal degeneration is a consequence of the long-continued elimination of products of faulty digestion through the kidneys"; so that what originates as lithemia often terminates as uremia. It is well to remember that uric acid is a "kidney irritant"; also that uric acid "teases the whole urinary tract from the tubules of the kidney to the meatus"; also that an excess of uric acid is a frequent cause of various ailments. The whole medical world is greatly indebted to Murray, Murchison, and Haig.

Respectfully,

H. A. SHELLEY.

319 EAST 120TH STREET, NEW YORK.

NEWS ITEMS.

Dr. D. W. Montgomery has been elected Professor of Diseases of the Skin in the University of California.

W. Moldenhauer has been made Professor Extraordinary of Laryngology and Rhinology at the University of Leipzig.

A Municipal Hygienic Institute has been established at Hamburg and placed under the charge of Dr. Dunbar, a former assistant of Prof. Gaffky, at Giessen.

Charles Clay, known as the father of ovariotomy, died recently at Poulton-le-Fylde, near Blackpool, England, at the ripe age of ninety-two years. He performed his first ovariotomy in 1842, with success. In 1845 he extirpated a uterine fibroid through an abdominal incision. He was a prolific contributor to medical literature.

Dr. William B. Towles, Professor of Anatomy and Materia Medica in the University of Virginia, died September 15, 1893, at the age of forty-six years.

Cholera at New York Harbor.—Bacteriologic examination has disclosed the presence of comma bacilli in the dejections of a case of fatal illness on board the steamer Russia from Hamburg, detained in quarantine at New York Harbor. There were several deaths during the journey, but the disease was not believed to be cholera.

The American Electro-therapeutic Association at its third annual meeting, recently held at Chicago, elected the following officers: President, Dr. W. J. Herdman, of Ann Arbor; Secretary, Dr. Margaret Cleaves, of New York; Vice-Presidents, Dr. Franklin H. Martin, of Chicago, and Dr. A. Lapthorn Smith, of Montreal; Treasurer, Dr. R. J. Nunn, of Savannah, Ga. It was decided to hold the next meeting in New York City, on the last Tuesday in September, 1894.

A Week on Cataract.—The Philadelphia Polyclinic will devote a special week, beginning October 30th, to the consideration of cataract. Cataract-operations will be performed by the different methods preferred by Professors Harlan, Jackson, Risley, and de Schweinitz, including operations with iridectomy and simple extraction. The whole subject of etiology, diagnosis, and the dressing and after-treatment will be considered.

In addition to the clinics, demonstrations, and practice of operations on the eyes of lower animals, there will be a series of clinical "conferences," participated in by the professors and the members of the class.

Opening of the Johns Hopkins Medical School.—The regular courses leading to an M.D. degree at the Medical School of Johns Hopkins University opened on October 5th with a class of sixteen, of whom three are women. The high standard set by Johns Hopkins for admission to this school has, for the first time in the United States, secured a band of medical students each with a bachelor's degree from some reputable college. Of the thirteen men, Johns Hopkins supplies four, Yale three, Harvard two, and Amherst, Swarthmore, Virginia Agricultural College, and the University of Wisconsin each one. The women are graduates respectively from Smith, Vassar, and Wellesley.

PRACTICAL MEASURES FOR THE PREVENTION OF TUBERCULOSIS.[1]

BY LAWRENCE F. FLICK, M.D.,
OF PHILADELPHIA.

THE history of tuberculosis in all times and in all countries in which any history of it is recorded is a broad demonstration of its contagiousness and, by inference, of its preventability.[2] So insidious, however, is its contagiousness that, although this has been recognized by the greatest minds of every age, and has at times taken strong enough hold of the lay as well as of the medical mind to beget successful measures of prevention, at no time in the history of medicine prior to the present age had it been recognized and understood by the medical profession as a body. The contagious theory of tuberculosis is now so far accepted by the profession that it is being taught in our medical schools; so that the medical profession is committed to it, at least through its teaching faculty. The prevention of the disease has, moreover, had sufficient practical testing to remove it from the category of experiments and place it upon the list of sanitary expedients deserving of the most earnest attention of sanitarians. Spain, by teaching her people the contagious nature of the disease in question and by practising crude and unscientific but, nevertheless, successful methods of prevention, avoided carrying the disease into its new colonies in America;[3] Italy, by similar methods, in less than a century, reduced the mortality-rate from the disease in her midst from that of a most virulent epidemic to a comparatively rare disease;[4] England, by establishing special hospitals for the treatment of pulmonary tuberculosis and the consequent isolation of its tuberculous poor, reduced its mortality 50 per cent. in forty years;[5] and Philadelphia, by preaching the doctrine of contagion and teaching its people methods of avoidance and prevention, has reduced the mortality-rate from the disease about 20 per cent. in eight years.[1] With these facts before us and with our profession committed to the theory of contagion, we cannot, without failing in our duty, remain inactive while this disease carries off hundreds of thousands of human beings to a premature grave and inflicts indescribable suffering and loss upon hundreds of thousands of others.

A comprehensive scheme for the prevention of tuberculosis implies: 1. Registration of all cases of the disease which have arrived at the breaking-down or infectious stage. 2. The education of the public at large and of the people immediately concerned as to the contagious nature of the disease and how to avoid contracting it and how to avoid transmitting it to others. 3. The careful and thorough disinfection of all infected houses, penal and reformatory institutions, conveyances and public places. 4. The establishment of special hospitals for the treatment of the poor suffering from the disease. 5. Government inspection and regulation of dairies and slaughter-houses. 6. The enactment of laws and ordinances forbidding practices as a result of which others are liable to be infected. 7. The restriction and regulation of interstate and international emigration of persons suffering from the disease. 8. The retirement of all tuberculous patients in the infectious stage from occupations in which they can infect others and the pensioning of those who cannot be maintained in hospitals.

The enforcement of such a scheme in every particular would completely wipe out tuberculosis in a very few years. Of this there can be no doubt, whether our conclusions be evolved from our present knowledge of the etiology of the disease or from what history records of the past attempts at prevention.

As regards the merits of the respective measures named there will probably be differences of opinion. I have enumerated them partly in the order of their importance, as I rate them, and partly in their natural order of sequence. The feasibility of their enforcement will necessarily vary, and ought to determine which should be adopted when all cannot be adopted. At the present stage of sanitary science and as governments are now

equipped for the prevention of disease, there is probably no country in which the entire scheme could be put into operation; nor is it likely that any government is at present in a position to thoroughly enforce any of the measures. The prevention of tuberculosis is, however, so easily accomplished that even the incomplete enforcement of some of the measures would bring about a marked reduction in the mortality from the disease.

1. *Registration of all cases which have arrived at the breaking-down or infectious stage.* Registration is necessarily the foundation-stone of all orderly systematic effort at prevention. To be able to fight an enemy one must first know where he is. Even individual effort at self-protection is futile without this knowledge. Registration should not only include the residence, but also the movements of infectious persons, such as removals from one house to another or from one city to another—for a temporary residence in a house or even a transitory occupancy of a conveyance may infect it sufficiently to convey the disease to others. One tuberculous patient, by frequent change of residence, may infect many houses during the continuance of the disease.

Registration will be objected to on the ground that it will impose additional suffering upon those who are already sorely afflicted. In a matter of such great importance to the well-being of the majority of those now living and of all of those yet to be born, the greatest good to the largest number ought to be our motto. Moreover, the registration of infectious cases of tuberculosis need inflict no suffering on anyone that would not be fully compensated for by a knowledge that near and dear ones can thereby be protected against the disease.

Objections based upon commercial grounds have no foundation in fact. People are too familiar with tuberculosis to take fright at it, even when they believe it to be contagious. The registration of cases would have no depressing effect upon the community as a body, and whatever care-inspiring influence it might have upon individuals would be a benefit. Private business might in certain cases be injured because people would not buy at a place conducted by a tuberculous person; but this would be a benefit to the community, and the individual concerned could easily rid himself of the injury by removing the attendant from a position in which he jeopardizes the health of others. Interference with the value of real estate could be prevented by government disinfection of infected houses.

As most countries are now equipped for carrying out sanitary measures, registration would have to be accomplished through Boards of Health, with the aid of practising physicians. This is already being done with such diseases as smallpox, scarlet fever, typhoid fever, diphtheria, and some other contagious diseases. Many physicians object to being burdened with the labor of making out reports and to being placed in the embarrassing position of having to make public the ailments of their patients. But, with properly prepared blanks, the making out of reports can be termed neither a labor nor a burden, and could easily be attended to by the busiest practitioner. As regards the making public of the ailments of patients, it is, under the circumstances, not only a privileged communication, but one which the public has a right to insist upon being made. The physician has no reason to complain of such duties, because they belong to the profession which he has espoused.

There can be no practical difficulty in the way of registering tuberculosis because of the obscurity of the disease or inability on the part of the physician to make a diagnosis. Tuberculosis is never contagious until broken-down tissue is given off, and when this occurs a diagnosis can always be positively made. There is no occasion for making a report until this stage has been reached.

2. *The education of the public at large and of the people immediately concerned as to the contagious nature of the disease and how to avoid contracting it and how to avoid giving it to others.* Of all of the contagious diseases the most easily prevented is tuberculosis. Its contagion is strictly confined to broken-down tissue, and this broken-down tissue, when given off, is readily recognizable—is indeed likely to attract attention. Efficient sterilization of all broken-down tissue must absolutely prevent the spread of the disease, and as this tissue is always within reach when it is a source of danger to others, and is never a source of danger to others unless it is within reach, sterilization is always feasible and is within the power of every one. The proper education, upon this subject, of the public and the people who either have tuberculosis or who are exposed to it would go a long way toward preventing the disease.

The public at large ought to be educated upon the question of contagion. This can best be done through the Public Press, which has already accomplished a great deal in this direction. Those who have tuberculosis ought to be taught how to avoid giving it to others, and those who nurse tuberculous patients or whose duties require them to be about those who have the disease should be taught how to avoid contracting it. Special literature ought to be prepared for such persons and placed within their reach. This can be accomplished through Boards of Health, and better still through the organized efforts of humane persons who have given the subject special thought. Societies for the prevention of tuberculosis will find in this work not only a legitimate cause for springing into existence,

but a field of labor worthy of their most earnest efforts. Such societies ought to be organized everywhere, and a concerted effort should be made, the world over, to educate the people upon methods of avoidance and prevention. The Pennsylvania Society for the Prevention of Tuberculosis was organized in Philadephia about two years ago, and during its brief existence has printed and distributed about thirty thousand tracts on "How to avoid tuberculosis" and "How persons suffering from tuberculosis can avoid giving the disease to others." There is reason to believe that its efforts are already bearing good fruit in an increased reduction of the mortality-rate from the disease in Philadelphia. The greatest obstacle in the way of performing its work has been non-registration of the disease. Were every case of tuberculosis registered it would be an easy matter to place literature where it would do the most good.

3. *The careful and thorough disinfection of all infected houses, penal and reformatory institutions, conveyances and public places.* Were it possible to induce every person suffering from tuberculosis to sterilize every particle of broken-down tuberculous tissue, immediately upon its being given off, it would not be necessary to institute any other measures for the prevention of the disease. Unfortunately this is not possible. The majority of tuberculous patients, even when they have been informed of the infectious character of the sputa, will spit where it is most convenient, and thus contaminate everything about them.

Infected houses play a most important rôle in the spread of the disease. In my topographic study of tuberculosis in the Fifth Ward of the City of Philadelphia I found that at least 50 per cent of all cases were contracted in such houses.[1] Drs. Chapin, of Springfield, Mass.,[2] and Louis S. DeForrest, of New Haven, Conn.,[3] have since made similar studies in their respective towns, with identically the same results. Dr. Cornet, of Berlin, has produced tuberculosis in animals by inoculating them with the scrapings from the walls of rooms which had been occupied by tuberculous patients.[4]

Penal and reformatory institutions have been so scourged by tuberculosis that commitment to them is frequently paramount to a death-sentence. In Germany, Baer and Cornet have made statistical studies upon this subject and have found that from 45 to 70 per cent. of all deaths in penal institutions were due to tuberculosis.[1]

Conveyances, such as steamboats, railway-cars, street-cars, carriages, etc., and public places, such as churches, public halls, public squares and streets, are constantly being contaminated with the expectoration of tuberculous patients. Fortunately however, these are not prolific sources of infection, because most people require prolonged and continuous exposure to contract tuberculosis. But persons who are greatly predisposed to the disease or who are in a weakened, depressed condition will contract the disease upon slight exposure, and infected conveyances and public places are to these a real source of danger.

With the clear knowledge that we have upon these various methods of spreading the disease it is incumbent on the government to see that every place which has become contaminated with broken-down tuberculous tissue be carefully disinfected. When a death from tuberculosis has occurred in a house the Board of Health should see that the rooms occupied by the deceased, and the furniture and clothing, that could in any way have been contaminated, are properly disinfected. When a house has been disinfected the fact should be recorded in an open record, of easy access to the public, so that persons seeking residences can first inform themselves as to whether or not a house is free from contagion. In penal and reformatory institutions every cell or room which has been occupied by a tuberculous person should be thoroughly disinfected before being assigned to a new occupant. Here the authorities have absolute power and there ought to be no difficulty about enforcing the most rigid rules in regard to prevention and securing the most thorough disinfection after contamination. The disinfection of conveyances and public places will have to be left largely to the sense of justice and propriety of those who have charge of them, as it is practically impossible to make and enforce rules covering such cases. Much can no doubt be accomplished by education. Most people are well disposed to do what they can to prevent the spread of disease, provided they have the proper knowledge and the necessary means. The demands of an enlightened public will probably be the most powerful lever that can be brought to play upon both individuals and corporations who have charge of any and all kinds of conveyances and places of public resort, to induce them to keep these free from contagion.

4. *The establishment of special hospitals for the treatment of those suffering from the disease.* Among the very poor, preventive measures in their homes are so difficult of execution that they are practically

impossible. Families who can barely make a living during health and of which every member has to contribute toward a common fund for sustenance are so badly upset by a prolonged illness, such as tuberculosis, that they are not capable of either understanding or putting into operation any systematic sanitary measure. Everything is made subservient to the happiness, comfort, and freedom from worriment of the sick one. The room that serves as the family kitchen and dining-room is turned into a sick-room, and spitting all over it, into the coal-scuttle or into the front of the cooking-stove, anywhere indeed that is convenient, is a privilege that is freely accorded. Such habits in such places mean extension of the disease to the weakest member of the family, until in turn every one has assumed the rôle of victim and propagator of the disease. Among this class of people the most efficient measure for the prevention of the disease is the establishment of special hospitals for the treatment of those who are stricken down. Removal of the patient to a hospital removes the source of infection and at the same time relieves the pressure of worry, want, and care, which so strongly predispose the remaining members of the family to the disease.

Special hospitals for the treatment of tuberculosis have existed in Europe, and especially in England, for many years. In England the motive for their establishment was not prevention, but extending charity to the deserving poor. Now that it has been demonstrated that segregation will prevent the spread of the disease and we still have the inspiring motive that England had, we ought to move more rapidly in the matter than is possible on the slow wheels of charity. Whilst every effort to establish special hospitals on the basis of charitable support should be encouraged by general aid, the government should promptly establish such hospitals on its own account. The only legitimate ground upon which the government can appropriate money for the support of hospitals is that of protecting the public against disease and death. Inasmuch as tuberculosis has been demonstrated to be a preventable disease, and as it has been proved by experience that segregation will prevent its spread, the establishment of hospitals for tuberculous patients becomes as much a function of the government as the maintenance of a police force. The truth of this proposition must sooner or later present itself to every enlightened government.

In considering the matter of special hospitals for the treatment of tuberculosis as a preventive measure, the question of forcible segregation, with its horrible features, need have no deterring influence. In the first place there is no necessity for such segregation. Were hospital-doors throw open for such cases there would be more applicants for admission than could be accommodated. With all its present capacity, which is very large indeed, England cannot accommodate all of the poor tuberculous patients that appeal for admission into its special hospitals. In the next place an alternative can always be given without jeopardizing public health. In a given case of tuberculosis in which the question of forcible segregation might arise, the sick person and the family could be given a choice to either have the patient go to a hospital or practise certain preventive measures at home. Such measures could then be enforced by the Board of Health, as there would be a penalty at hand to support the order.

In our American system of government the taxation for the support of such hospitals ought to be as direct as possible, and for this reason they ought to be established and maintained largely by cities and States. Every large city should have such hospitals under the supervision and support of the city government, and every State should have at least one such hospital under its supervision and support.

It would be a step in the right direction of judicious bestowal of charity if some of the general hospitals of our large cities would take up this subject and devote themselves entirely to the care of the tuberculous poor. It is a well-known fact that the unfortunate victims of tuberculosis are turned away from general hospitals because of the disease from which they suffer. As general hospitals have grown so numerous of late that there is at times a lively competition for patients, it would no doubt prove a wise deviation from the beaten path for some of them to take up this specialty.

5. *Government inspection and regulation of dairies and slaughter-houses.* Ever since it became known that tuberculosis affects animals as well as man and that it is identically the same disease in both, there has been much speculation as to which was attacked first and what part each respectively plays in infecting the other. Some who have given the subject much thought and study, and notably among them Dr. E. F. Brush, of Mount Vernon, N. Y., claim that the disease is primarily a bovine disease and that human beings and animals other than the cow are infected from this source. I have myself never been able to accept this theory, but whether we accept it or not, so much is certain, that human beings and domestic animals can and constantly are infecting each other.

The mediums through which the cow infects human beings are milk and meat. Much study has been given to this subject both in this country and in Europe, and we now have a pretty clear idea as to what constitutes infectious milk and meat. The milk of a tuberculous cow is not likely to be infectious unless the udders are diseased, so that the secretion becomes mixed with broken-down tuberculous tissue. At all events it is necessary that the bacilli gain

entrance into the milk in order to make it capable of conveying the disease. The meat of a tuberculous animal is only infectious when the deposit exists in the parts that are consumed or when those parts have become contaminated in slaughtering and preparing for the market. It is important that these facts be kept clearly in mind, because of the important positions which meat and milk occupy as foodstuffs and the great injury that can be done by exaggerating the danger of using them. Clinically we have very little evidence of the conveyance of the disease through these mediums. I have never seen an authenticated case recorded in literature, and personally I have never seen a case which I could trace to the use of meat, and have seen but few cases in which there was satisfactory evidence that they were contracted from the use of milk.

But while scientific investigations and clinical observations both point to the conclusion that in practical life the use of milk and meat is not a prolific source of tuberculous infection, it nevertheless cannot be denied that it is a source of sufficient importance to demand the most earnest attention of the government. An effort should be made to stamp out tuberculosis among cattle. To accomplish this the coöperation of Federal, State, and city governments will be needed. The Federal Government should prohibit and prevent the importation of tuberculous cattle. State governments should carefully examine every herd within their borders and condemn every head that is in the slightest affected by the disease. Cities should condemn and forbid the sale of every carcass that shows the slightest evidence of taint in the slaughter-house, and permit no one to sell milk within its limits except such as draw their supplies from dairies of which the herds have been officially examined. Such concerted effort would soon stamp out the disease among cattle, for it would no longer be commercially profitable to keep anything but healthy herds. Actual loss to individuals ought of course to be made good by the government.

6. *The enactment of laws and ordinances against practices which are liable to infect others.* Civilized man, in spite of his civilization, retains many of his primitive habits. Among these is the horrible custom of spitting anywhere and everywhere that is convenient. There are a great many diseases of which the contagion resides in the expectoration, and all of which put people to a great deal of inconvenience, but none of which is so serious in its results as tuberculosis. How much would be added to the comfort and happiness of the human family were it possible to put a stop to the filthy habit of indiscriminate spitting.

The promulgation of knowledge about the danger of promiscuous spitting would no doubt contribute something toward breaking up the custom. It is, however, so much easier and more convenient to spit out than into a cuspidor or handkerchief, that with the majority of people it will require more than education to induce them to change their habits. The necessity of washing handkerchiefs no doubt contributes something toward the custom, and its continuance after people know the danger. The introduction of cheap paper handkerchiefs, which could be burned after using, would do away with this excuse for the habit. The enactment of State laws and city and borough ordinances against spitting into public conveyances, into public places or upon the streets would, however, be the most powerful lever that could be brought to bear upon the custom with the masses. It would be difficult to enforce such laws and ordinances, and they probably could not be enforced to the letter. Their existence and attempted enforcement would, however, do much good, if only even as a means of education. Many street-car companies now have notices up in the cars warning passengers not to spit upon the floor, but they do not attempt to enforce the order, probably because they have no warrant of law to support them should the matter be brought to an issue.

The disposal of clothing and furniture, either by gift or sale, without previous disinfection, is another practice fraught with danger. The Spaniards and the Italians recognized this source of infection a century ago and took the most careful precautions against it.[1] Their method was cumbersome and would not do as a model, but it was effective, and serves to illustrate what can be accomplished by a determined effort. The simplest way of stopping this mode of spreading the disease would be to make it a misdemeanor to dispose of anything, whether by sale or gift, that had been used by a tuberculous patient or had been in his room during his occupancy, without first thoroughly disinfecting it. Here again would, of course, come up the difficulty of enforcing the law, but the existence of such a law would at least enable individuals to protect themselves.

7. *The restriction and regulation of interstate and international immigration of persons suffering from the disease.* History teaches that one of the most potent factors in the spread of tuberculosis has been the migrations of tuberculous persons.[2] The will-o'-the-wisp of a climate that would cure tuberculosis has been indirectly the means of infecting the world. There is scarcely a country which has not at one time been free from the disease, and which for that reason became a resort for those suffering from it. In turn, the place became a place of exodus and a source of infection to some newer country. All of America was a virgin soil for the disease when Europeans first came. New York, Pennsylvania—in

[1] Flick: Prevention of Tuberculosis, supra cito.
[2] Flick: Contagiousness of Phthisis, supra cito.

fact every State and Territory—has in turn been a resort for the tuberculous, and has at some time been believed to possess a curative climate.[1]

Unfortunately, this seductive method of spreading the disease is still in active operation, and with our modern facilities for travel has become more prolific than ever. It probably furnishes the most frequent source of infection for the wealthier class—those who can change their place of abode with every change of season. It infects our hotels, our sleeping-cars, and our state-rooms. It has made tuberculosis as rampant under the sunny sky of California as in the changeable climate of the Atlantic slope.[2]

What is the remedy? International immigration of persons suffering from tuberculosis should be entirely stopped. This is a matter for the Federal Government, and in the United States is, I believe, through the efforts of Surgeon-General Wyman, already receiving attention. Foreign travel of persons in the early stage of the disease, before there is any breaking down, need not be interfered with. Interstate emigration should be restricted and regulated. This would, of course, be a matter for the States, and in certain cases for cities to take charge of. Persons in the infectious stage of the disease should be discouraged as much as possible from changing their places of residence, and when they do make changes it should be with the consent and under the supervision of the health-officer. Some of the Territories and newer States, which are as yet comparatively free from tuberculosis, would probably find it to their advantage to shut out from their borders all tuberculous persons in the infectious stage who seek admission for climatic reasons. Such an embargo need, of course, not be applied to those in whom the disease has not yet reached the breaking-down stage, and to those that have it would be more of a benefit than an injury, as they can no longer be saved by a change of climate, and are frequently injured by it.

8. *The retirement of all tuberculous patients in the infectious stage from occupations in which they can infect others, and the pensioning of those who are dependent on their own labor for a living and who cannot be maintained in hospitals.* Because of the prolonged duration of tuberculosis it is necessary for the poor to follow their callings in life during the infectious period of the disease. We consequently have tuberculous patients as cooks, waiters, barbers, fruiterers, grocers, butchers, dairymen, nurses—in short, we have them in every walk of life. To have these people give up their positions would be a great hardship, unless some provision were made for their support and that of the destitute families depending upon them. As the giving up of their positions would be in the interest of the public good they ought to be retired at the public expense. Every case of tuberculosis which has arrived at the infectious stage ought to be retired from any position carrying with it the danger of infecting others, and either be admitted into a hospital or paid a pension sufficient for maintenance. For the destitute family depending upon the labor of the person affected there would be ample provision in the eleemosynary institutions already in existence.

Retiring and pensioning persons suffering from a disease which is a menace to others will no doubt be considered too advanced ground in preventive medicine to be considered seriously at present. It will, however, force itself upon our attention in the near future. The justness of the principle involved has already been admitted in the compensation allowed for diseased cattle slaughtered by direction of the government.

By the establishment of special hospitals for the treatment of persons suffering from tuberculosis the tuberculous poor of the country could be maintained at a quite reasonable expense. The taxation which would have to be imposed upon the individual to enable the government to carry out such a plan would be returned a hundred-fold in the protection afforded against the disease. Tuberculosis carries off at least one hundred thousand people annually in the United States. It has been estimated that this entails a loss in public wealth of about five hundred millions of dollars a year.[1] A small fraction of this great loss well expended would go a long way toward wiping out the disease.

TESTS FOR HETEROPHORIA, AND THEIR COMPARATIVE VALUE.[2]

BY EDWARD JACKSON, A.M., M.D.,
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC; SURGEON TO WILLS EYE HOSPITAL.

WE discover a latent squint, a tendency of the visual axes to turn, not both toward the point fixed, but in different directions, by preventing binocular vision, in the interest of which the tendency is habitually overcome and the squint rendered latent. By preventing binocular vision the latent squint becomes manifest, and can be measured. The different methods of accomplishing this might be considered as constituting three classes of tests for heterophoria.

First, the *objective method.* By covering one eye

[2] Read before the Section on Ophthalmology of the College of Physicians of Philadelphia.

with an opaque screen, as the hand, and so preventing binocular vision, the covered eye is allowed to deviate. The extent of the deviation is commonly estimated by shifting the cover from one eye to the other, causing the eyes alternately to fix and deviate, and observing the amount of motion required to carry each eye from the one position to the other.

The *separation of images.* In the second class of tests binocular vision is rendered impossible by the removal of the image formed in one eye from the region of the fovea by a prism, the removal being in a certain definite direction, and of such extent that the physiologic power of adjustment is unable to overcome it. This is the ordinary diplopia-test with prisms, the production of vertical diplopia to test lateral deviations, or of lateral diplopia to test vertical deviations.

Dissimilarity of images. In the third class of tests binocular vision is prevented not by the removal of one image, but by the alteration in character of the image, so that if both images should fall on the fovea they will be so entirely different that no attempt at fusing them will be made. Of the latter class the production of diplopia by placing a red glass before one eye, and the Maddox rod or the cylinder-test are the familiar examples.

In estimating the relative values of these different classes of tests, the first has the advantage of being entirely objective. If the patient obeys instructions and conforms to the conditions of the test (and it is usually easy to judge as to the accuracy of conformity) we are in no way dependent on his honesty or powers of observation. The accuracy of result depends on the training and care of the observer, and in no way on the mental attitude or mental development of the patient.

Another advantage which it seems to me gives the test greater practical value and makes it impossible to dispense with it is the fact that for one of the eyes all vision is prevented. If the screen be properly held the useful field of one eye becomes a complete blank, and the movements of that eye have absolutely no significance as regards the objects to which attention is directed. Under these conditions the tendency to habitual innervation of the muscles, the innervation habitually required for binocular vision must be reduced to the minimum, and the results obtained will be free from an influence that enters more or less in the application of the other tests. For instance, in a certain class of cases, generally highly neurasthenic, even possibly hysteric, tests of the other kind may show a high degree of heterophoria; and this will, by the wearing of correct prisms, run up to almost any extent. Yet the tests are evidently a cause of effort on the part of the patient. The results of repeated trials, or of the continuance of a single trial, are extremely variable and the objective test may show but little or no heterophoria.

In these cases, it has seemed to me that the results of the objective test were the ones upon which to base our practice, that with the other tests, the effort of looking, combined with excitement produced by the distorted appearance of the observed object, excited an unusual and abnormal condition of innervation of the muscles, and yielded results often far removed from those to be obtained in a condition of real relaxation. On this account I would not in any case in which I purposed direct treatment of the heterophoria, omit the repeated application of the objective test.

The second class of tests, which have practically been developed from the Graefe dot and line, seem to me rather the least valuable of the three, although their value depends much on details of application. The condition of binocular diplopia produced by prisms makes the impression on the sensorium of diplopia produced by faulty innervation of the muscles, or of pressure altering the direction of one of the eyeballs. Such diplopia we expect to correct by an effort directed to the ocular muscles, an effort that in childhood may be voluntary and conscious, but that after the establishment of binocular vision is maintained as a reflex. If the images are separated widely enough this effort may after some little time be given up. But that there is a tendency to make it I think can be readily demonstrated, both by the sensation of confusion or of strain produced by the application of the prism-test, or by such phenomena as the change of position, the middle light, when a Maddox double prism is used but little stronger than the ocular muscles are capable of overcoming. With such a prism it will almost always be found that the middle light, instead of remaining half way between the others, approaches either the upper or the lower light (if the prism be held with its base horizontal), even though the vertical balance be really quite perfect.

If the two images of the test-object are sufficiently separated to prevent any effort at fusing them or bringing them closer together, and in the field of vision lie other objects, which, from their large size or the direction in which they are placed, furnish lines that can be fused either with or without effort of the ocular muscles, such effort will be persisted in. For instance, the images of the dot or point of light may be quite removed from one another, but images of doors, windows, or pieces of furniture, will partially overlap and so furnish inducement for continued muscular effort to maintain fusion. Such tests are improved by furnishing a uniform background, as by thoroughly darkening

the room when the point of a flame is employed, and by using a dot on a large sheet of plain paper. And if this test be mainly relied on these precautions are essential.

Other sources of variation and inaccuracy lie in imperfect placing of the prisms, rendering necessary the use of some such instrument as the Stevens phorometer. And a source of possible inaccuracy, which I have not seen mentioned, is the image produced in a weak prism by double reflection from its surfaces, having a displacement in the direction of the displacement of the refraction-image of the prism, but much greater in degree. This is most noticeable when the point of light is employed in the thoroughly darkened room. In fact, under these conditions, otherwise the best conditions for such a prism-test, this reflected image can scarcely be ignored.

The third class of tests present certain distinct advantages, in that fusion being prevented by the difference in appearance of the images, the images can be exactly superimposed, requiring no estimation as to their relative position or distance apart. The simple test of covering one eye with a red glass is valuable in all cases in which it gives diplopia. The placing of glass of one color before one eye and of another color before the other so increases the difference between the two images that it may increase the range of application of the test, but I have not employed the test in this form. For its best application the condition of the uniform background, obtained by thoroughly darkening the room, is also essential, as the difference obtained in the images of miscellaneous objects by alteration of color would be quite insufficient to suspend the tendency to binocular fusion.

With the Maddox rod-test or cylinder-test care as to the background for the test-object is unnecessary, because the alteration of image produced by the rod placed before one eye is so great that nothing but the test-object, the point of light, gives rise to any recognizable impression, can be identified at all.

For the recognition of heterophoria at a distance this has proved with me the most satisfactory test. Its simplicity makes the application easy with even the least intelligent patient. While it does depend on the patient's observation, the simplicity of the observation required and the low grade of the intelligence necessary to make it render the result uniform and satisfactory for all sorts of patients. This simplicity of requirement constitutes its superiority over the test proposed by Stevens, in which a strong spherical lens was substituted for the cylinder, and which allowed the estimation of all sorts of heterophoria at once, instead of selecting out a defect in a single direction.

As a collateral test the measurement of the power of abduction, adduction and sursumduction is of some value, although the variability of different results obtained with different patients, or with the same patient at different trials, makes these tests alone of very little value. In the estimation of these powers the variable rotary prism is of especial value, as greatly saving in time; but I have not found that with it the results obtained were essentially different from those with tests made by placing before the eyes the prism from the trial-case.

In using the rotary prism it has been suggested to record both the strength of prism with which diplopia appears and the strength that permits binocular re-fusion. It seems to me, however, when repeated trials are made, that, except for adduction, the difference between these is not very great, being principally due to the time lost partly by the patient and partly by the surgeon in registering the fact of separation or re-fusion.

The tests so far discussed are intended for application at a distance of four meters or more. For use at the ordinary distance for near work, I formerly found the objective test and the diplopia, by vertical removal of one image, the only ones of general practical utility.

Recently, however, I have found the rod-test or cylinder-test capable of an important application in this direction, by merely diminishing the lens-strength of the cylinder sufficiently to allow the recognition through it of the elongated image of a black dot on white paper, held at ordinary reading-distance. A 12 D. cylinder, or the two 6 D. cylinders from the trial-case held together, answer the purpose admirably.

DEVIATION OF THE SEPTUM NASI.

BY WILLIAM MARTIN, M.D.,
OF BRISTOL, PA.

DEVIATION of the nasal septum is a subect of considerable interest, and one that has received a good deal of attention from rhinologists, but the profession in general has not as yet recognized the value of inspecting the nasal cavities, by which they might frequently be able to find a *causus morbi*, which otherwise would be hidden. During recent years there has been considerable literature from specialists upon this and kindred subjects, and stress is laid upon the advisability of inspecting the nasal cavities in each case in which there is the slightest suspicion of irritation there. This has been my practice, and I feel well assured that it has proved a most useful aid in diagnosis and treatment. One can readily see that the terminal nerve-irritation here may be the cause of trouble in other parts of the organism, as well as when situated in other cavities of the body.

With true deflection of the nasal septum there are usually associated such other abnormalities as spurs, ledges, and thickenings, that tend to produce the same result, viz., narrowing or occlusion of the spaces. The point of curvature of the cartilage, in my experience, and I think this is the experience of most, has been principally in the anterior portion of the nasal cavity.

The frequency of septal deviation varies with the race and country, according to the observations of some authorities. Civilization appears to be a factor also, for Americans and Europeans seem more prone to them, whilst Collier estimates that about 80 per cent. of savages are exempt. This may account for the different figures given by different authorities. In 1888 Delavan found deviations in 50 per cent. of his cases, Mackenzie (1884) in 76.9 Jarvis (1888) in 81, Löwenberg in 86, and Heymann (1886) in 96.4 per cent., showing quite decided differences, and these only to be accounted for by the difference in place and time of observation. The classification of these abnormalities by Stocker is about the simplest, and therefore the best. It is as follows: 1. Angular, or when there is a decided angular prominence in one cavity, with a corresponding widening of the other. 2. Curved, or an arch-like condition. 3. Sigmoid or double-curved, which may be either from above downward, or from before backward.

The causes of deviation are more or less obscure, but may be stated to be as follows: traumatism; such diseases as syphilis and rickets; growths, such as polypi and hypertrophies of turbinated tissues; and such possible factors as forcibly wiping the nose in children, which tends to displace the yielding and, as yet, unossified plates of bone, as well as the less resistant cartilage. The theories in reference to the cause are numerous and interesting, but so far as I have seen, I think Seiler's the most practical. He maintains that the beginning is a long-standing inflammatory process during childhood. The thin cartilaginous plate, being over-nourished by the continually congested perichondrium, has deposited within its substance more new cells than are required to replace the defunct ones, which are being carried off, and the tissues consequently increase in bulk; the bony framework into which this plate is fixed preventing this extension, bulging to one side or the other naturally follows. This explanation seems quite logical, but it is only one of many theories advanced, and while all are interesting, too much space would be required for their presentation here.

The symptoms connected with septal deflection are quite numerous and vary with the degree of the deformity. They may be divided into two classes, the mechanical and the reflex.

The first set of symptoms are probably those which attract attention to the nasal cavities, as frequently they are of the most decided character, resulting from partial or total occlusion. Mouth-breathing may be mentioned as one easily recognized. The one almost constant condition is chronic catarrhal inflammation of the mucous membrane; this is held by some to be the cause rather than the result of deviation of the septum, but I think that the weight of opinion is in favor of the latter view. At all events, chronic catarrhal inflammation is usually found accompanying this septal deformity. It is probably caused by the unevenly distributed air-pressure, which is followed by congestion, and this in time develops into an inflammation, going through its various phases until the chronic type is reached. The symptoms of this condition are too well-known for me to enter into details here. I may mention that the hypertrophic form is that most often met. In my practice I have found this affection and septal deformity to go hand-in-hand. Some months ago, in a paper upon this subject read before the Burlington County (N. J.) Medical Society, I spoke of finding in my first one hundred cases of chronic catarrhal rhinitis, this deformity of the septum in various degrees, and, in my mind, dependent upon the latter condition; and since then I have had no reason to change my opinion, for it has been found to be the same in subsequent cases. It is a noticeable fact that the greater the deformity the more difficult the cure, and some cases, in fact, are incurable, unless operated upon. This has been my experience in a fairly large number of cases.

Another condition that may follow nasal occlusion is partial or total deafness. One other result that often proves intractable is the annoying pharyngitis sicca, which is due to the supply of the natural moisture of the breath being cut off, because of mouth-breathing, the air not entering, as it should, and being moistened and warmed in the nasal cavities; this in time is followed by atrophic changes in the mucous membrane and its glands. Together with these preceding conditions may be mentioned such minor symptoms as a feeling of fulness in the head, frontal headache, epistaxis, etc., which are more or less dependent upon the inflammation of the pituitary membrane.

Now as to the reflex symptoms. Here we have those that often puzzle the physician, in search for the cause of the affection he may be treating. It has not been many years since the nose has been recognized as a factor in disease, and for this reason I think the true cause of some affections has been overlooked and some other organ has been accordingly badly dealt with. It is natural to think that it is possible for the nose to be the seat of trouble, considering the amount of irritation to which it is

constantly exposed, and of course it is connected with other organs sympathetically, and it seems to me strange that it is not more frequently looked after.

To enumerate some of these symptoms, we have more commonly persistent headache; violent sneezing, often difficult to control; a sense of suffocation; frontal neuralgic pains, spoken of as being deep in the bone; constant lacrymation, and many other minor ones. The one condition made prominent in recent years is hay-fever, while it has been proved pretty conclusively that asthma may at times be dependent upon this nasal condition. Some of the more rare results are supra-orbital neuralgia, rarely trigeminal, and insomnia. Heymann mentions a case of paresthesia as a result of this irritation.

The diagnosis of deviation is very easily made, being apparent upon inspection of the nasal cavities.

The treatment depends upon the amount of the deflection. When slight, strong astringents will probably remove the irritability and inflammation of the tissues, and thus relieve; but when the deformity is sufficient to obstruct the canals, operative procedure is called for. In the average case of excess of cartilage projecting outward in the canal, the knife or saw will quickly remove it, but more is required when the deviation is greater, and, as it often does, meets the turbinated tissue of the same side, and to which it becomes united by cartilage This must be removed and the septum straightened; this may be done by cutting out a piece at the point of greatest curvature, and forcibly straightening with a pair of strong, smooth-bladed forceps. The septum should then be held in place firmly until healed. I omit the minor details purposely, as the operation is one well known. I generally use a 10 per cent. solution of cocain for the local anesthesia.

In conclusion, I may say that I have had a number of cases of the conditions mentioned, in which both sets of symptoms were very evident, and, after the cause was removed by operation, I had the satisfaction to find the symptoms disappear.

335 RADCLIFFE STREET.

CLINICAL MEMORANDA.

ABORTIVE TREATMENT OF GONORRHEA WITH OIL OF CINNAMON.

BY J. CHALMERS DACOSTA, M.D.,
DEMONSTRATOR OF SURGERY IN JEFFERSON MEDICAL COLLEGE.

THE treatment of gonorrhea is as yet purely empiric. Countless remedies and innumerable methods have been employed, but as yet no specific has been discovered, and no entirely satisfactory plan has been devised. The discovery of the gonococcus, and the fact that it dwells under the epithelial layer as well as upon it, points the way toward a scientific method of cure. We can affirm that remedies that act merely upon the surface by application through the medium of the urine cannot effect a cure. The balsams, taken internally, modify the symptoms, but that their use shortens the case is much to be doubted. The astringents, it is quite true, will improve an ordinary non-suppurative inflammation of any structure by causing constriction of the vessels, increasing the rapidity of circulation, washing adherent corpuscles from the vessel-walls, and promoting absorption; but astringents do not do good in acute suppurations. My experience with astringents as remedies in the acute stage of gonorrhea has not been favorable.

The proper method of treatment of gonorrhea, when the case is seen early, would be to use an antiseptic agent. The use of hot retro-injections of corrosive sublimate does unquestionably do good, but the corrosive has to be used in great dilution (1:20,000), as strong solutions are irritating. In order to most certainly cut short a beginning gonorrhea:

1. The mucous membrane should be cleansed as a preliminary to every antiseptic injection. The stream of urine, so often relied upon, does not satisfactorily accomplish this. The mucous membrane is thickened and thrown into folds; small drops of urine lodge in the crypts and hollows, to decompose and irritate, if not washed away; and the urine, so far from cleansing, is an offending substance which it is desirable to remove. Hence, before injecting an antiseptic, the bladder should be emptied, and the urethra washed out with hot water or, better, with a solution of hydrogen dioxid. Dr. J. William White has for some time recommended the use of hydrogen dioxid in gonorrhea. The fifteen-volume solution is diluted with an equal bulk of water and injected with an ordinary syringe, or, as I prefer, sprayed in with a metal-nozzled atomizer. The spraying enables us to reach all parts of the urethra. It causes considerable distention, which must not be permitted to produce much pain. In letting it out care should be taken that flakes of froth do not fly into the eyes. The spray should be continued for a moment or two, the meatus being opened repeatedly to allow the froth to escape.

2. After cleansing the urethra an antiseptic agent should be injected. This agent should be non-irritant, or but slightly irritant. It should be certainly germicidal; it should be capable of permeating the connective tissue beneath the epithelial cells; and it should have a tendency to remain in contact with the surface-tissue, and not at once to flow away. For many months past Dr. D. Braden Kyle has been engaged in our private laboratory in a series of experiments in regard to the properties of the oil of cinnamon. He found this substance to possess the most remarkable antiseptic powers (the report will soon be published), and used it in the treatment of infective and non-infective inflammatory conditions of the nasal and aural passages, with most gratifying results. His success induced me to employ the agent in the treatment of gonorrhea. The oil can be applied once daily by means of the atomizer (and this plan is most efficient, if the physician applies it himself, or the patient is sufficiently intelligent to do so.) The oil is mixed with benzoinol in three degrees of strength, 1 drop, 2 drops, and 3 drops of the oil, respec-

tively, to the ounce of benzoinol. On the first day solution No. 1 is used (one drop to the ounce); on the second day solution No. 2, and after this solution No. 3. The benzoinol serves the useful purpose of causing the thorough diffusion of the oil, and also causes it to adhere with considerable tenacity to the mucous membrane. Dr. Horwitz prefers to use the oil by injection, employing a solution of the same strength in albolene or benzoinol. This plan I have tried, and believe it to be the best when the patient lacks intelligence, and is obliged to largely carry out his own treatment.

It is in beginning gonorrhea that oil of cinnamon finds its most useful field. In acute, thoroughly developed cases, its employment induces considerable pain; but, though it does not check the disease, it causes abatement of the *ardor urinæ*. In chronic cases it also seems of considerable use. I am far from claiming to have found a specific, but I am quite sure that cinnamon is a valuable remedy in certain cases of gonorrhea. In forty cases of beginning acute urethritis, clinically recognized as gonorrhea, of from three to five days' duration, the following results were obtained:

In 6 cases the discharge ceased in two days and did not return; in 12 cases the discharge ceased in five days; in 6 cases the discharge ceased in from eight to ten days; in 10 cases the discharge ceased in from ten to fifteen days; in 2 cases the treatment failed entirely, and was abandoned after two weeks; 4 cases did not return after the first visit.

No other treatment was used, although ordinary hygienic and dietetic precautions were taken. Dr. Horwitz informs me that 15 beginning acute cases under his observation were cured within ten days. In 10 cases of chronic gonorrhea, without apparent stricture or granular patches, the treatment proved successful: 4 cases were cured in two weeks; 3 cases in three weeks; while 3 cases were benefited but not cured. In no case was a complication observed.

These observations, chiefly made in the Jefferson College Hospital, would seem to justify the conclusion that oil of cinnamon is of value in the treatment of beginning gonorrhea and of chronic gonorrhea. Whether or not the drug will prove of benefit when given internally, future experiments will show.

The injections should be made three or four times a day, immediately preceded by micturition and cleansing of the urethra with hydrogen dioxid. In cases in which considerable pain is caused by the injection, the weaker solutions should be used, and retained for but a short time.

The irritant injections, if strong solutions are used, seem to favor the development of stricture, an objection from which oil of cinnamon appears to be free.

CHRONIC ENDOMETRITIS: TREATMENT BY DRAINAGE.

By JACOB C. RUTHERFORD, M.D.,
of Providence, R. I.;
Adjunct Professor of Obstetrics and Diseases of Women in the Medical Department of the University of Vermont.

The conditions present in a case of chronic catarrhal inflammation of the endometrium are enlargement, softening, and congestion of the uterus, increased succulence of, and the growth of moss-like vegetations on, the uterine mucous membrane, thickening and congestion of the cervical mucous membrane, and not infrequently enlargement, thickening, congestion, and dropsy of the tubes. The uterus is usually dislocated posteriorly, there is a congestion of all the pelvic organs, and a thick tenacious muco-purulent discharge from the uterine and cervical mucous membrane.

The general symptoms are lassitude, sleeplessness, loss of appetite, constipation, pain in the sacral region, which is increased by walking or driving, dragging pain in the abdomen, profuse painful menstruation (usually; although the flow may be scanty), and mental disturbance.

Examination through the speculum reveals a relaxation of the vagina, an ill-smelling leukorrheal discharge, erosion and eversion of the cervix, and retroversion of the uterus. With the sound we find the uterus enlarged and sensitive, and that the mucous membrane bleeds very easily. Occasionally digital examination reveals enlargement of one or both tubes, and tendernesss of the ovaries.

The treatment usually adopted in such cases includes rest, tonics, laxatives, hot douches, thorough curetting, tampons bearing either glycerin, boroglycerid, glycerole of tannin, glycerin and iodin, or tincture of iodin, and in some cases it is deemed necessary to employ severer methods, such as cauterizing the uterine cavity with nitric acid or caustic potash. I have followed this plan of treatment for years, with varying success, but usually the treatment had to be continued for a long time, the improvement was slow, discouraging alike to patient and physician, and I finally discarded it altogether and adopted a plan the basis of which is drainage. To illustrate, allow me to present one of a number of cases:

Mrs. X., twenty-six years of age, has been married nine years, and has borne one child now seven years old; she has had no miscarriages; she came to me complaining that for four years she had suffered with pain in her back and abdomen, leukorrhea, loss of appetite and strength, irritability of temper, and sleeplessness. Upon questioning her I learned that her bowels were constipated, moving once in three or four days; that she suffered so greatly at her menstrual periods that she was obliged to keep her bed three or four days; that the flow was profuse, lasting from seven to ten days, and that she frequently vomited her food. She was anemic and greatly emaciated. Examination showed the uterus enlarged (depth 3¼ inches); the cervix slightly lacerated, eroded, and everted; the left tube was somewhat enlarged, the uterus and both ovaries extremely tender. The uterine mucous membrane bled freely, although I used great care in introducing the sound. There was also a profuse muco-purulent discharge from the uterus.

My treatment was as follows: The patient was ordered to bed and given a saline laxative. The next day she was etherized, the vagina thoroughly washed out with hot water, the cervix mopped out with a hot 5 per cent. sodium bicarbonate solution and carefully dilated to the extent of an inch. The uterine cavity was then carefully washed with the hot soda solution, and gently curetted with a blunt curet. A large amount of fungus growth was removed, which caused considerable bleeding. The uterus was then filled with a strip of iodoform-gauze (cut ½ x 1 inch wide); a quantity of gauze was also left in the vagina around the cervix. The gauze was held in place

by a dry cotton tampon. There was little pain following the operation, but slight uterine contractions caused some uneasiness, which was relieved by a mild anodyne. Forty-eight hours afterward the tampon and gauze were removed, the uterus and vagina washed with the soda solution and again packed as before. From the third day the patient was up and about her room and suffered no pain whatever. The tampon and gauze were renewed every forty-eight hours during the first week and every seventy-two hours during the second week, when treatment was interrupted by menstruation. To the patient's surprise she suffered very little during the menstrual period; the flow was greatly lessened in amount and lasted but four days. Three days after menstruation I found the cervix contracted to nearly its former size, and I again dilated it. The dilatation was rendered almost painless by first applying the Faradic current—one pole in the cervix, the other on the abdomen—for about ten minutes, which softened the cervix and made it much more easily dilatable. The gauze was again introduced and allowed to remain forty-eight hours, when the patient removed it, gave herself a hot vaginal douche, and came again for treatment. From that time until she was discharged the gauze was introduced twice each week and allowed to remain forty-eight hours each time. At the end of five weeks of treatment I found the uterus normal in size, free from tenderness, no leukorrhea, and the enlargement in the left tube had disappeared.

She tells me now (four months afterward) that she feels in every way better, that she is relieved of her constipation, that menstruation is normal, that appetite has returned, and that she sleeps as well as ever. She has also put on considerable flesh and her general appearance is greatly improved.

The advantages of this plan of treatment are, first, that it removes the danger of puncturing the uterine walls, always present when the sharp curet is used; second, it shortens the time the patient is under treatment; third, the gauze by its presence excites uterine contractions, which lessen the congestion, thereby assisting in reducing the enlarged uterus to the normal size; fourth, the gauze again, by its presence, brings about a thinning of the uterine discharge; and this, fifth, allows it to be drained off as fast as it is thrown out; sixth, as the muscular fibers of the uterus are continuous with those of the oviducts, contractions of the former must necessarily be accompanied by contractions of the latter, and hence any accumulation of mucus in the tube would be carried by that contraction to the uterus and drained off by the gauze; seventh, the cervix remains permanently dilated, which facilitates the flow of menstrual blood; eighth, by draining off the contents of an enlarged tube, we do away, in many cases, with the necessity of celiotomy.

Many cases require curetting with a sharp instrument, owing to the presence in the uterus of fungous growths that cannot be otherwise removed, but the majority of cases will yield to drainage. Again, thorough curetting should not be undertaken by one inexperienced in the operation, as there is danger that he may scrape away not only the mucous membrane and a part of the muscular wall, but that he may unconsciously perforate the wall and set up a fatal peritonitis.

When the cervical laceration is so extensive as to demand an operation for its repair, the treatment I have suggested will prepare the parts for the operation in less time and much more satisfactorily than the treatment by douches and medicated tampons.

STRANGULATED LITTRÉ'S HERNIA AT THE FEMORAL RING, FOLLOWED BY SLOUGHING OF THE INTESTINE, WITH EXTRUSION OF A SCYBALOUS MASS WHICH BECAME ENCAPSULATED.

BY JOHN B. ROBERTS, A.M., M.D.,
OF PHILADELPHIA,
PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

A WOMAN, aged twenty-eight, native of Poland, noticed during the fifth month of her second pregnancy, which was about a year before she came under my observation, that a swelling the size of a thimble appeared in her left groin. This varied in size at different times, and disappeared when the patient assumed the recumbent position. The enlargement persisted after the birth of her child, and remained in its previous condition until two weeks before I saw her. Then her bowels became very much constipated, and she suffered from violent attacks of nausea and vomiting. From that time she had had no natural movement of the bowels, which had been moved only by the aid of rectal injections which were ordered, by a physician, to be taken daily. For a week previously to the time this history was taken there was no movement of the bowels whatever, notwithstanding the rectal enemata spoken of, and for some time before that date only a very small amount of feces had been passed. She had taken no solid food for two weeks, had little appetite, and slept very little. The tumor grew steadily larger and more painful, but there was no vomiting after the first attack. She says that a physician who saw her two weeks ago told her that she had rupture.

On the night of her admission to the Woman's Hospital, which was January 26, 1893, repeated rectal enemata produced a free evacuation. When the patient was brought to the institution her sufferings were extreme. An oblong swelling was observed in the groin, in the region of Poupart's ligament. This was red and tender, and looked very much like a suppurating bubo. No vulvar lesion of a venereal character was discovered, and no history of any such condition was obtained. The lungs and heart were normal. The urine had a specific gravity of 1030, was acid, and contained no albumin and no sugar; microscopic examination showed some pus-cells, epithelial masses, uric-acid crystals, and blood-cells. The left labium was swollen and inflamed, and was continuous with the inflamed mass in the left groin. There was found a small laceration of the cervix uteri, but the uterus was normal in size, and movable. Percussion over the swelling in the groin gave a tympanitic note, but as the tumor was painful to the touch, this was only noticed after etherization. At no time was there any connection found between the intestine and the swelling in the groin.

The site of the tumor was rendered aseptic by thorough cleansing and sponging with a solution of mer-

curic chlorid, and a careful incision, about one inch in length, was made into the tumor over its most prominent point. An abscess-cavity was entered, and fetid gas and a large quantity of thin and extremely fetid pus escaped from the wound, together with broken-down tissue and old clots of blood. Upon irrigation of the cavity with a solution of mercuric chlorid (1:5000), a large quantity of such material was washed out, together with what appeared to be a portion of intestinal wall or the collapsed walls of a cyst. A rounded mass about the size of a small walnut was also washed from the wound. Its external surface consisted of a grayish tissue, which, when incised, showed the contents to be a dark, tarry, granular substance of fecal odor. The finger of the operator was carried into the cavity, and it was found that the abscess extended downward through the femoral canal into the pelvis. No bowel or opening into the bowel could be detected. It was decided, after thoroughly cleansing the cavity, to pack it loosely with iodoform-gauze. Antiseptic dressings were applied and the patient was placed in bed in good condition.

Directions were given for cleansing the cavity twice daily with a solution of corrosive sublimate (1:10,000) and re-dressing with iodoform-gauze.

At the time of the operation, I thought that an abscess had been formed by inflammatory involvement of the tissues surrounding a strangulated Littré's hernia, which had become gangrenous, or that the tumor resulted from a pelvic abscess which had communicated with the bowel and permitted the entrance of fecal matter into the sac. The former supposition was proved by the pathologist's report to be the correct one.

Examination of the specimens was made by Drs. Formad and Van Gasken. The rounded mass proved to be inspissated fecal matter, and contained particles resembling tomato-seeds, pepper, and other articles of food. The sac or membranous mass was found on section to be a portion of intestine.

The patient made a prompt recovery, and is now (March 3d) up and about. She seems perfectly well. The temperature seldom went above normal after the operation; and on February 24th the wound was, according to the notes, healed. After the operation, some other masses of feces were washed from the wound during the irrigation practised twice daily.

It is evident that the section of the circumference of the intestinal wall, which was strangulated, sloughed away, permitting masses of hardened feces to escape into the hernial sac, and that the intestinal opening became closed. Finally the scybalous feces became surrounded in one instance with a sort of capsule; and then an abscess occurred around the fecal masses and the portion of the bowel which had been detached at the point of constriction when strangulation happened.

POST-DIPHTHERIC PARALYSIS OF BOTH EXTERNAL RECTI MUSCLES.

By HARRY FRIEDENWALD, A.B., M.D.,
LECTURER ON OPHTHALMOLOGY AND OTOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

The occurrence of eye-symptoms during convalescence from diphtheria has long been known. It was formerly placed in the great category of amblyopia. But Donders showed that the visual disturbance was usually remedial by convex glasses, and that it depended on paresis of the accommodation. This form of post-diphtheric paralysis is quite often met with, though not as frequently as paralysis of the pharyngeal muscles. It is characterized by being bilateral, and unaccompanied by mydriasis (*i. e.*, due to paralysis of the sphincter iridis).

There are other forms of post-diphtheric ocular paralysis beside the one just mentioned. The extrinsic muscles may become affected, but this occurs much more rarely than the form first named. Cases of paralysis of the abducens, of the oculo-motor, and even complete paralysis of all of the ocular muscles, have been described; still there are not many on record.

The case to be related belongs to the class of paralyses of both external recti muscles, which may be monocular or binocular.

R. G., a female, five and a half years of age, came for treatment March 12, 1893. She had had a sore throat six weeks before, which had lasted three weeks. The throat-trouble had not been severe, but she had been very weak after the attack. Three days before coming, diplopia had set in. There was paresis of both external recti muscles, especially of the left, and as a result convergent strabismus of about 25°. Neither eye could be brought far enough to the temporal side to hide the sclerotic on the outer side of the cornea. The mother was very anxious and feared that an operation was necessary. A very favorable prognosis was given, for the trouble was evidently post-diphtheric paralysis. Dr. Clagett, who had treated the child during its illness, has kindly informed me that, at the time, he considered the attack one of mild tonsillitis and pharyngitis, and that he was not able to find any diphtheric membrane. The child was treated with syr. ferri iodid., and rest, and was seen at short intervals. On March 27th, her mother brought her, and stated that she had gotten perfectly well as suddenly as the affection had made its appearance. Three days before, she still had had diplopia, but now there was none. The lateral movements of both eyes were perfect —the cornea reached the outer canthus on both sides. The duration of this affection was sixteen days, the onset three weeks after the primary disease had left her. This is in accord with the few cases described by others.

Special attention is to be called to the fact that the patient had had a very mild attack of diphtheria, so mild as not to have been recognized as such by one of the most competent and experienced physicians of our city. But post-diptheric ocular paralyses result from slight as well as severe attacks. A case of post-diphtheric paralysis of the accommodation, which recently came under my observation, had followed what was considered a "slight sore-throat." Our literature abounds in such cases.

The prognosis of this affection is extremely favorable. Cure usually results in a few weeks, or in one or two months. The treatment consists in tonics. Some give great praise to electricity.

Ernst Jendrassik has been made professor of neurology at the University of Budapest.

THE TREATMENT OF LUMBAR CARIES.

BY BENJAMIN T. SHIMWELL, M.D.,
ASSISTANT PROFESSOR OF SURGERY, MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA.

THE great difficulty in the treatment of caries of the spine lies as much in the inability to secure perfect drainage as in the fact that the disease is due to constitutional taint. Tuberculous bone-disease is always amenable to treatment, if so located as to allow of perfect care—that is, removal of offending material and the maintenance of the part in a perfectly or nearly perfectly aseptic condition.

The anatomic situation of the vetebræ to a certain extent precludes surgical interference. The treatment has been to keep up the general condition by appropriate remedies, opening of the psoas-abscess, and attempting to maintain an aseptic state.

There presented in my service, within a week, two cases of psoas fistulæ, both having a pronounced discharge. In the first case I made an opening below Poupart's ligament, with the fistula as the center of the incision. After passing through the superficial tissues down to the iliac fascia, I began to separate this from the muscles below, and working carefully inward, raising it upward as I proceeded. While the denuded bone could be felt with a long probe, I found I could not reach it with the fingers. I then made an incision to the outer side of the erector spinæ muscles down to the posterior leaflet of the transversalis fascia, through this and the quadratus lumborum, and worked to the vertebræ; making a free communication with the lower opening and establishing drainage. Having failed to do any good, except the provision of more perfect drainage, I proposed to change the location of the incision in the second case. In this one it was commenced above Poupart's ligament, at about its middle, then curved upward to near the ribs, with the convexity outward. When the transversalis fascia was reached it was separated, as in the other case, without any difficulty, until the promontory of the sacrum was reached. I then made an opening posteriorly as in the previous patient, only larger. I was now able to pass one hand from below, the other through the lumbar opening, and make a complete inspection of the lumbar vertebræ.

The incision made in this manner, with complete separation of the fascia, allows any interference without risk of tearing through into the peritoneal cavity or the wounding of any neighboring structures. The bone can be curetted, and the parts thoroughly washed and drained. In both of these cases the wounds were packed with gauze. Although in the second case the openings were of considerable extent no sutures were used, the object being to allow of after-packing and the filling up of the denuded surface by granulation.

Approximation of the edges would have interfered with the after-treatment by causing retention and increasing the difficulty of packing.

Both cases did well. The operation commends itself by its advantages and the ease with which it is performed. It is also applicable to cases of retro-peritoneal abscess and to growths that arise in this region.

1253 SOUTH SEVENTEENTH STREET.

MEDICAL PROGRESS.

Unilateral Paralysis of the Recurrent Laryngeal Nerve from Implication in Tuberculous Glands.—FINLAYSON (*Archives of Pediatrics*, vol. x, No. 9, p. 759) has reported the case of a girl, four and a half years old, who presented a peculiar cough, resembling the most extreme form of hoarse cough met with in aneurismal disease complicated with laryngeal paralysis. Examination of the larynx disclosed an absence of swelling, ulceration, or other morbid condition of the laryngeal mucous membrane. There was, however, abductor paralysis of the left vocal band, which remained fixed in the middle line, while the right band moved freely. The symptoms and physical signs pointed to consolidation and softening from tuberculous disease, the left lung being particularly involved. In the absence of tuberculous disease of the larynx, the conclusion was arrived at that the case must be one in which the recurrent laryngeal nerve had become pressed upon by enlarged bronchial glands or involved in pleural adhesions. The child was extremely rhachitic and the family history was strongly tuberculous. The peculiar cough continued, utterance being given to curious hoarse, whining cries when anything was wanted. The child spoke little, but the voice was not specially hoarse. The temperature was at times high, but extremely low temperatures were also frequently found. On one occasion fluids were returned through the nostrils. No tests for anesthesia were employed, but it was noticed that the irritation caused by the laryngeal mirror was remarkably well borne. After an illness lasting about five months, as far as cough was concerned, death took place. Upon post-mortem examination both lungs were found to be tuberculous. The left pneumograstic nerve was adherent to a much enlarged and caseating gland, but could be traced down to the level of the root of the lung without much apparent alteration of structure. The recurrent laryngeal nerve was intimately connected with and involved among some caseating lympathic glands almost from its origin, so that it could only with difficulty be traced around the aorta. It appeared to be spread out and its substance involved in the infiltration. The larynx presented no noteworthy abnormality. The pericardium was completely adherent, and the visceral layer was almost completely beset with yellow tubercles. There had been a partial organization of tissue between the visceral and parietal layers. The parietal layer presented small, white tubercles, scarcely at all caseous. There were also extensive adhesions between the peritoneum and the omentum.

Epilepsy due to Porencephalus.—KOCHER (*Corr.-bl. für Schweizer Aerzte*, 1893, No. 15, p. 527) has reported the case of a girl, nineteen years old, who presented a deep depression in the right frontal region, resulting from the application of the forceps at birth. From the age of two years there had been a left lateral curvature of the spine, as well as some distortion of the left hand and some weakness in the lower extremity. At the age of twelve years epileptiform convulsions began to occur, setting in with a cry, followed by a fall and loss of consciousness, but without motor manifestations. The first and second occurred on the same day; the subsequent

ones at intervals of considerable length. After a year convulsive movements, involving the left side of the face, the left arm, and the left leg, were noticed during the attacks. At the age of seventeen years trephining was performed in the situation of the indentation in the skull, and a cavity containing almost seven ounces of clear fluid and communicating with the lateral ventricle was found. Drainage by means of a glass tube was maintained for three months. Only two paroxysms occurred during the time of drainage, the tube being removed because there was no further flow. But one attack occurred in the following two months. Then there were no attacks for nearly a year. At this time menstruation failed to take place, and the attacks recurred. At the same time the loss of power upon the left side progressively increased and contractures formed. Treatment with sodium bromid had but a transient effect. The scalp over the site of the previous operation was incised and a drainage-tube introduced, giving exit to clear fluid. An intercurrent attack of pneumonia was attended with a severe epileptiform convulsion, followed by an increase in the palsy. The mental condition now displayed signs of deterioration. Upon recovering from the attack of pneumonia the flow of serum from the drainage-tube, which had been diminished during the attack, increased. The girl was soon restored to her previous condition. The drainage-tube was permanently removed after the expiration of six weeks. In the subsequent four months no attack occurred. The cessation of the attacks is ascribed to the occurrence of permanent changes in the left cerebral hemisphere, in conjunction with the drainage employed, and under the influence of an acute infectious disease.

The Pathogenesis of Hepatic Abscess.—In the course of experimental observations, Zancarol (*Revue de Chirurgie*, 1893, No. 8, p. 671) found that the injection of dysenteric stools of a cat, containing amebæ, into the intestine of twelve other cats, was followed in six cases by the development of hepatic abscess dependent upon the presence of streptococci; in 11 of the cats dysentery developed, in 7 with amebæ in the evacuations and in 4 without amebæ. In the intestines of these animals was found the ulceration characteristic of dysentery. In none of the animals were amebæ found in sections of the bowel, while in 11 of the 12 streptococci were found in the depths of the intestinal mucous membrane. The injection of hepatic pus, sterile by culture, into the rectum in 7 cats was followed by the development of abscess of the liver in 2, purulent infiltration in 3, and dysentery in 4. The injection of pure cultures of streptococci from these inoculated animals into the intestine in two cats caused dysentery in one, with recovery after the lapse of forty-four days, and dysentery in the other, with death after the lapse of sixty-seven days. Upon post-mortem examination ulceration of the large intestine was found, together with cicatrices and streptococci in lungs and liver. Injection of a pure culture of streptococci into the ischio-rectal fossa of a cat was followed by the development of dysentery. Upon post-mortem examination a peritoneal effusion was found, with ulceration and edema of the walls of the small intestine. A pure culture of streptococci was obtained from the blood of the liver, as well as from the blood of the heart, the pericardium, the gall-bladder, and the peritoneum. Injection into the intestine of dysenteric stools from man, containing amebæ, was followed by the presence of amebæ in the intestine, but after death by the presence of streptococci in the spleen. The large intestine was in a state of exfoliation and congestion.

Successful Operation upon a Splenic Abscess in a Child.—Sendler (*Deutsche Zeitschrift für Chirurgie*, Bd. xxvxi, Heft 5, p. 536) has reported the case of a girl, four years old, of good family history and previously never ill, who, without known cause, began to fail in health. The child was languid, without appetite, vomited occasionally, and from time to time suffered with diarrhea. A fall down steep stairs was immediately followed by pain in the left hypochondrium and repeated vomiting. The pain became progressively more severe and a swelling formed in this region. At the same time, the general condition suffered correspondingly. It could not be learned whether or not there had been fever, but there was no knowledge of chills. The skin covering the swelling was smooth and unchanged in color. The mass was immobile and yielded deep fluctuation. There was no evidence of involvement of lungs, pleura, or heart. It was recognized that an abscess existed, but its origin was not clear, although implication of the spleen received consideration. At all events, operation was believed to be indicated, and was accordingly undertaken. A free incision was made below and parallel with the left costal arch, revealing an abscess-cavity, with thickened walls adherent to the abdominal parietes, and containing inspissated pus of cheesy consistence. The abscess was about as large as a small hen's egg and occupied the body of the spleen. After the sac was evacuated a rubber drainage-tube was introduced into the cavity, the overlying tissues were sutured, and an antiseptic dressing was placed over all. Recovery ensued without complication. The etiology of the abscess could not be determined, although it is believed that it existed at the time of the fall, which resulted in its rupture, with the formation of inflammatory adhesions.

Hypodermatic Alimentation.—Caird (*Edinburgh Medical Journal*, No. cdlix, p. 205) has reported the case of a man who for three years had suffered from gastric catarrh and had received great relief from washing out his stomach. For five months there had been increasing difficulty in taking solid food and in passing the stomach-tube. Finally, only fluids could be taken; and on examination a stricture was found at the cardiac extremity of the esophagus. Gastrostomy was proposed, but declined on account of the great weakness and emaciation. Nearly twenty-five pounds had been lost in weight in two months. The temperature was rather subnormal. But little of the fluid taken by the mouth was retained, the greater part being rejected. Some nourishment was administered by the rectum. In the hope of increasing the strength and securing sufficient improvement to warrant the performance of gastrostomy, the subcutaneous administration of sterilized olive-oil was begun. Intra-muscular injections in the gluteal region caused no discomfort, and for a week the patient received three or four ounces in this manner, experiencing appreciable benefit; so that gastrostomy was undertaken under the

local anesthetic influence of cocain. The operation was unattended with shock or pain. The stomach was opened with a tenotome, and a catheter was introduced for feeding purposes. The patient's temperature rose a couple of degrees after the operation, but he did not improve as had been anticipated, and in six days he suddenly collapsed and died. Upon post-mortem examination an annular epitheliomatous stricture at the cardiac extremity of the esophagus was found. There was also some thickening and ulceration about the pylorus, one of the ulcers having given way into the peritoneum.

Bilateral Empyema in an Infant Thirteen Weeks Old.—CASSEL (*Deutsche medicin. Wochenschr.*, 1893, No. 32, p. 768) has reported the case of an infant, thirteen weeks old, that for ten weeks had presented symptoms of broncho-pneumonia consequent upon an attack of influenza. The child was pale and emaciated, its respirations short, shallow, and accelerated to fifty-six in the minute; the pulse regular, but frequent. Physical examination disclosed signs of an encapsulated pleurisy upon either side, posteriorly and inferiorly, which upon puncture was shown to be purulent in character. Neither pneumonia-cocci nor tubercle-bacilli could be found in the pus, although streptococci were present. A few days later an incision was made on either side in the sixth interspace in the axillary line, and twenty-four ounces of pus were evacuated from the left pleural cavity and eleven ounces from the right. The child withstood the operation well and was better for a short time, but the suppuration persisted, with hectic fever and loss of flesh. After the lapse of more than a month a small portion of the sixth and seventh ribs on either side was resected, but the child only survived ten days longer. At the post-mortem examination the left pleural cavity was found obliterated, except in the area of the empyema, which communicated with a cavity as large as an apple in the lower lobe of the left lung. The remainder of the lobe contained many caseous masses. The right pleural cavity was also completely obliterated, while the lower lobe of the right lung contained a large cavity, and the remainder of the lung numerous caseous masses. Tubercle-bacilli were demonstrable in the contents of the cavities. The bronchial glands were enlarged, and on section displayed caseation.

THERAPEUTIC NOTES.

The Action of Scopolamin Hydrobromate.—From a comparative study of scopolamin hydrobromate, ILLIG (*Münchener medicin. Wochenschr.*, 1893, No. 33, p. 617) concludes that this drug, even in weak solution, is more prompt in action than atropin; in strong solution it may at times surpass atropin in mydriatic action; but the continuance of the action, as well as the ultimate activity, of the strongest solutions of scopolamin allowable is considerably less than that of atropin. Scopolamin is, therefore, not to be considered upon a therapeutic equality with atropin, and certainly not upon a higher plane, in cases in which atropin is well borne. In case of idiosyncrasy to atropin, however, scopolamin is to be considered as the best substitute, as even after long-continued use no unpleasant secondary phenomena are observed. Scopolamin is also a useful substitute in cases in which a mydriatic is required, but in which at the same time an increase in the ocular tension is contraindicated. Cocain must continue to be the preferable mydriatic for diagnostic purposes, as the action of scopolamin persists for too long a time.

Physical Rest in the Treatment of Chlorotic Anemia.—As the result of clinical experience, TAYLOR (*Practitioner*, September, 1893, p. 161) recommends the employment of physical rest in the treatment of chlorosis. The rationale of the procedure depends upon the fact that there is a diminution in the number of red corpuscles, which, besides, individually contain a deficient amount of hemoglobin. By thus sparing the blood a certain amount of functional activity restoration to the normal is facilitated. It is further suggested that chlorosis is, as a rule, the result of exceptional demands upon the system at the time of puberty, and that rest at this time affords the organism a means of meeting these unusual conditions. Other measures usually employed, such as purgatives, iron, and nutritious food, are not to be ignored. The same plan of treatment is likewise well adapted to other forms of anemia, and particularly when there is a tendency to dilatation of the heart, with dyspnea and edema.

The Treatment of Erysipelas.—KÖSTER (*Centralblatt für klinische Medicin*, 1893, No. 38, p. 793) has treated upward of fifty cases of erysipelas by covering the affected parts and the adjacent skin for a short distance by means of a brush with a moderately thick layer of white vaselin. Over this is placed an ordinary piece of linen (if upon the face, suitable openings being made for the eyes and nose) and finally a gauze bandage is applied with moderate firmness. The vaselin is renewed twice a day. The results obtained have been entirely satisfactory, comparing favorably with those obtained from other means of treatment. In most cases critical defervescence took place on the second or third day, and the pain and tension soon subsided. Relapses were not more common than after other methods of treatment.

For Coryza.—

℞.—Acid. carbolic. pur. } . . āā ℥ijss.
Aquæ ammoniæ }
Alcoholis . . . . . ℥v.
Aquæ destill. . . . . ℥j.—M.

S.—Inhale several drops for a few seconds from a piece of bibulous paper.

HAYEM, *Rev. de Lar., d'Otol. et de Rhin.*, No. 18.

For the Diarrhea of Tuberculosis.—

℞.—Acid. tannic. . . . . gr. vj–xij.
Calcii phosphat. . . . . ℥j.—M.
Ft. chart. no. xx.
S.—Take four or six daily.

Centralbl. f. d. ges. Ther., No. 7; *Corr.-bl. f. Schw. Aerzte*, No. 16.

Delirium Tremens due to Chloral.—BALLET (*Le Mercredi Méd.*, No. 31) has reported a case presenting all of the manifestations of delirium tremens as ordinarily seen in the course of alcoholism, but dependent upon the excessive use of chloral.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 21, 1893.

SUNLIGHT AND SANITATION.

IT is not a mere effort at alliteration that leads to the association of these terms. In the earlier ages of human history the sun was worshipped as the source of all earthly existence and action, and modern science has proved that from a merely material point of view this is true, and probably we do not yet fully appreciate the influence that the light, heat, and electricity emitted by the sun exercise upon the earth.

A belief in the sanitary and therapeutic effects of sunlight has long been held. The general experience of mankind has demonstrated the beneficial effects of light and air. The contrary effects of deprivation of these are among our commonest observations. Ingenious suggestions of sun-baths and roof-hospitals have been proposed in medical journals from time to time, and the organizations for securing brief outings for the children of our large cities are among the most substantial and practical charities of the present time.

The methods at present available for studying sanitation are in many respects exact. Especially do we find that all questions relating to the destruction of infection are capable of determination with a positiveness that was entirely unattainable some years ago. While much uncertainty may still exist as to the identity and relationship of some specific microbes, we can no longer doubt the extended part that microbic life plays, and that conditions which are inimical to it are practically conditions of disinfection. We must, therefore, regard with much interest the results of recent investigations by different observers, tending to show the marked action which direct sunlight exercises on bacteria. A short time ago, in noticing some publications by Pettenkofer's pupils, attention was called to a paper on the self-purification of streams, in which it was shown that running water, under the influence of diffused daylight, is materially purified. It is not unlikely that a portion of this action is due not to a direct interference of sunlight, for such an effect seems paradoxic, but to the decidedly stimulating action, which causes the microbes to develop more actively and thus run their life-course more speedily. It is certain that a knowledge of such action must be not only reassuring but it also affords indications for sanitary engineering. Pollution of running streams in densely populated districts is almost certain to occur, and the knowledge that a protected flow through a limited course will result in self-purification will serve to allay some fears. The dogmatic statement occasionally uttered by sanitarians, that a river once polluted will not again become clean, never had any satisfactory foundation in observation, and may now be considered as much too sweeping. Engineers will also recognize the advantage of open channels over closed ones in the transportation of water.

Another very interesting and important feature of this question is that relating to solid materials carrying infection. Several observers have noted that infected articles of merchandise are often rendered harmless by simple exposure to light and air. Among the most recent data in this respect are those furnished by STERNBERG, who has shown how quickly the cholera-microbe is killed by exposure to these influences. On ordinary textiles it lives for but a short time. From these observations we learn to modify our fears of infection through the mails or by such merchandise as old rags. We recognize also that in combating such a disease as cholera a great amount of good may be accomplished by simply hanging infected articles where free airing and sunning are attainable.

Indirectly, sunlight has an important bearing on sanitation, and that is as an aid to cleanliness. Obscurity covers a multitude of sins. Cleanliness ought to be pursued for its own sake; but, unfor-

tunately, this is not always the case, especially when circumstances are such as to enable the uncleanliness to be concealed or overlooked. In the construction and arrangement of our houses, whether on a large or a small scale, every effort should be made to place those parts which are necessarily associated with uncleanliness under the best light. It is curious to note how long the custom has been just the opposite. Sinks, dust-bins, water-closets, etc., are usually placed in dark corners. Sinks and washstands are generally enclosed so as to furnish a closet in which rubbish is certain to be kept. A due regard for sanitation as well as for decency indicates that these arrangements should be placed at the most favorable point for securing light and air. It will then be far less easy to neglect them and to permit them to become unclean. We may hope that the time is past when a water-closet will be placed in a cellar or at the end of a long dark alley-way, or boxed in with fine wood-work that becomes a nest for vermin and a harbor for filth. The cellar should be on top of the house!

A further thought that grows out of these considerations is in regard to the disadvantage of shade around houses. Intelligent farmers have occasionally inveighed against the practice of surrounding country houses by a dense clump of trees, but we still see this error frequently committed. In our cities, except at special places set apart as parks and as a boulevard ornamentation in very wide streets, trees are often out of place and serve both to disfigure the view and to shut out needed light and even air from offices and residences.

CARBOLIC ACID AND PAPAYOTIN IN THE TREATMENT OF DIPHTHERIA.

WITH the knowledge of the etiology of diphtheria that we possess it will be readily understood that any mode of treatment, in order to be successful, must be directed first against the dislodgment of the causative microörganisms from their local nidus, or at least the inhibition of their activity; secondly, to the elimination of the poisons generated or to their neutralization; and, finally, to the restoration of the organism to its original condition. In cases in which complications of a purely mechanical nature arise, such as laryngeal obstruction, surgical measures will yet, as heretofore, be required. It is hoped to attain the first of these desiderata by the local application of antiseptic agents, such as methylene-blue, carbolic acid, hydrogen dioxid, and various inhalations. It has also been found that good results are secured from the topical application of digestants, such as pepsin, trypsin, pancreatin, and papayotin, the mechanism of the efficacy of which, however, further than their digestive action upon the membrane, has not been made entirely clear. Recent observations by LEVY and KNOPF (*Berliner klinische Wochenschrift*, 1893, No. 32, p. 771) would, however, make it appear that, of these agents, papayotin at least subserves a more important purpose, in that it displays the property of neutralizing the activity of the toxic matters generated by the diphtheria-bacillus. The same property, no doubt, belongs to the other ferments named. In order to secure the best results from this use of papayotin, however, it was found necessary to first make topical applications of a germicide. With this end in view, a mixture containing five parts of pure liquefied carbolic acid and ten parts of papayotin in one hundred parts of water was employed. With this solution an application was made by means of a brush every ten minutes during the first two hours, and subsequently at intervals of two hours, by night as well as by day. The applications were made gently, without any attempt to bring away the membrane. The results are said to have been most gratifying, much more so than the figures would indicate. With the topical treatment was conjoined the use of an ice-collar, generous inhalations of steam, and the administration of stimulant in the form of wine. The cases, being seen in hospital, were of grave type. Fifty-three cases were treated in the manner outlined. In thirty-six of these (71 per cent.) recovery took place; in fifteen (29 per cent.) death ensued. Among the complications present in the fatal cases were croupous pneumonia, pulmonary and pleural tuberculosis, repeated hemorrhage after tracheotomy, and broncho-pneumonia; while in the cases in which recovery took place there was observed involvement of the nares, laryngeal stenosis, albuminuria, measles, croupous pneumonia, and abscess of the naso-pharyngeal cavity. Comparative observations showed that not only was the death-rate lower than common and the proportion of cases in which tracheotomy was necessary smaller, but the membrane also disappeared more rapidly, and a larger number of cases appeared to be saved from the necessity of tracheotomy, while some patients were saved that, in the absence of the treatment, must have perished.

JOHN HUNTER.

To honor and cherish the memory of its great men adds strength and dignity to a profession. One hundred years ago, on the 16th of October, in John Hunter there died the greatest anatomist and pathologist the world has seen, the man in whose faculties reason and observation were blended as they had not been since Aristotle. The creator of the science of comparative anatomy, the founder of scientific surgery, a physiologist of such wide observation that his researches covered the whole range of animal and vegetable life, the originator of the modern science of pathology, he stands in the history of our profession with a genius *nihil simile aut secundum*.

Hunter not only remodelled the very fabric of our knowledge of the structure and functions of living beings in health and disease, but some of his brilliant conceptions in geology and embryology foreshadowed, indeed actually express, ideas that we regard as very modern. Von Baer's law that the embryo in development passes "through life of lower phase," he expressed in so many words. A broad, comprehensive survey of nature, in which, though "the beauty of the plan and the necessity of the sequence are not always perceptible," all things in order move, led him to study aberrant forms and deviations from normal structure. Buckle has so clearly drawn Hunter's position in this relation that we give his words: "To generalize such irregularities, or, in other words, to show that they are not irregularities at all, was the main object of Hunter's life, and was the noblest part of his mission. Hence, notwithstanding his vast achievements in physiology, his favorite pursuit was pathology, where, the phenomena being more complex, the intellect has more play. In this great field he studied the aberrations of structure and of function in the vegetable as well as in the animal world. . . . . By sweeping through this immense range of thought his mind attained to such commanding views of the philosophy of disease that in that department he is certainly without a rival. As a physiologist he was equalled, or perhaps excelled, by Aristotle; but as a pathologist he stands alone, if we consider what pathology was when he found it, and what it was when he left it."

In an age of differentiation we miss these broad-minded men, who could both see and think. The hedge-rows between which we walk permit of progress and of vision in one direction only. Beyond lie pleasant fields, into which the enormous extensions of modern science make it increasingly difficult for us to wander; but the study of the works of a great master like Hunter will not only lead us (whether anatomist, surgeon, physiologist or pathologist) into pleasant ways of thought, but will even add a cubit to our professional stature in the very remembrance that such a man practised the same art as ourselves.

EDITORIAL COMMENTS.

Tobacco Mania.—It is scarcely an exaggeration to estimate that the American people spend about five hundred millions of dollars for tobacco each year. Every man who can afford it feels it incumbent upon himself to buy only the most expensive cigars; those who can ill afford it, take pride in being lavish with "a good brand"; the poorest can find money for tobacco, even though they have to ask charity for such things as medical attendance and "Sunday breakfasts," whilst the gamins hunt the gutters for "stubs." And not only the ragamuffins, alas! but well-dressed school-boys have learned the nasty habit. The writer has observed hundreds of Philadelphia boys on their way to school, and has been shocked to see a large proportion scrutinizing all the gutters and side-walks, and pouncing with avidity upon every bit of cigaret or cigar-stub to be found. No boy really likes to smoke, but does it because he desires to be as big-appearing as the men. And now the women are to ape the fashion! In Russia the railways have to supply special smoking-cars for women, and in England it is held stylish and aristocratic for ladies to smoke. The reason for all this is beyond scientific explanation, but the financial objection is evident to everyone, while the esthetic objection is no less apparent; but it is the physician who sees the physiologic objection, the vicious crop of future diseases that is being planted and watered with reckless improvidence. Why could the smokers not have machines, smoke-cylinders with an exhaust-fan, to do the smoking for them, something after the manner of Oriental prayer-mills, thus saving much trouble and health-injury, while at the same time wasting the money? But let the machine consume all its own stubs, so as to check the formation of nauseous and dangerous habits in the young.

Dr. Reeves and the "Amick Cure."—The United States Grand Jury at Chattanooga, Tennessee, has ignored the bill in the criminal suit for libel instituted against Dr. James E. Reeves for his denunciation of the so-called "Amick Cure for Consumption" as quackery and fraud. There is still a civil suit pending, but Dr. Reeves is afraid that it will not be pressed, as the rules of civil suits will permit him to introduce testimony in support of his statements which in criminal proceedings might have been fought out. He says that he welcomes the opportunity "to expose the vile thing," and that if he once gets before a court with his testimony there will be nothing left of the fraud.

Dr. Reeves is to be congratulated for a display of

courage in standing up for the right, which is unfortunately rare among medical men to-day. The very mention of the words "libel suit" causes many to close their mouths tight lest they be suspected of taking part in the reprobation and exposure of the nostrum-traffic and other forms of quackery and imposture. The number of so-called medical journals that have given advertising and reading columns to the exploitation of this "Amick" nostrum is a humiliating spectacle. The continued violation of the rule forbidding advertising of nostrums by the trustees of the *Journal of the American Medical Association* is another sight that should bring the blush of shame to the cheeks of every member of the great association defiantly misrepresented by its elected officers. To think that the absence of one man from the Milwaukee meeting caused the matter to be passed over in silence is an evidence of general pusillanimity that makes courage like that of Dr. Reeves stand out in bold relief.

Effect of After-Pregnancy on Damages Recoverable for Personal Injury.—When a married woman sustains a personal injury, and her physician does not caution her to avoid pregnancy, and there is no evidence that her injury was such that it was not prudent for him to do so, her pregnancy occurring several weeks after the accident, is not necessarily, and as a matter of law, sufficient to justify a reduction of damages. So holds the Supreme Court of Wisconsin in the case of Sallady *v.* town of Dodgeville (55 N. W. Reporter, 696). If the after-pregnancy may have prolonged the injury or delayed her recovery, the damages which she would otherwise be entitled to recover should not be reduced because of such pregnancy. Her duty after the accident would be to take reasonable care of herself, and to avoid, so far as reasonably possible, doing anything which would tend to increase, prolong, or render permanent her injuries, sufferings, or disability. The mere doing of an act which would prevent or retard her recovery would not of itself be a ground for reduction of damages. To have that effect it must be a negligent act, and whether an act is or is not negligent is a question for the jury, and not of law for the court. So, in the case under consideration, the measure of duty, the court said, was ordinary care and diligence in the adoption of such measures of care or prevention as the case required and were within her knowledge or power.

Voice Without a Larynx.—At a meeting of the College of Physicians, on the 4th inst., Dr. J. Solis-Cohen exhibited a patient who speaks without a larynx; and the College desired the President to appoint a committee to investigate the manner in which the voice is produced.

The larynx and the uppermost tracheal ring of this patient was removed by Dr. Cohen some eighteen months ago for an intraneous and extraneous laryngeal adenocarcinoma. The upper end of the trachea was drawn forward and then stitched to the skin, so that there has been no communication since the operation between the lungs and the mouth. Yet the man speaks with a fairly well modulated voice, sufficiently audible for all practical purposes.

He breathes without a tracheal canula, through the upper orifice of the trachea, which presents externally. When he is about to speak the skin above the trachea becomes distended into a small vesicle of air, the contents of which are propelled in a stacatto-like manner against some structures just at or above the orifice of esophagus, and which Dr. Cohen takes to be the horizontal fibers of the inferior constrictor muscles of the pharynx.

Elevation in the Treatment of Leg-ulcers.—If there is one condition in surgery that is more obstinate than another in yielding to treatment it is a chronic leg-ulcer. Means and measures without end have been employed, but none has proved infallible. There is one form of procedure, however, whose efficacy makes it deserving of more common employ than it has hitherto received, and that is elevation. The subject receives consideration in an editorial in the *Canada Medical Record*, August, 1893. The affected member is not merely to be placed upon a level with the rest of the body, but must be elevated and the head depressed. This is best accomplished by raising the foot of the bed and also placing the ulcerated extremity upon an inclined plane or splint. The usual dressings may also be employed in accordance with special indications. The method is exceedingly trying to the endurance of the patient, but the result is adequate recompense. After the ulcer has healed, some form of elastic support, such as a bandage of rubber or flannel, should be worn. We cannot add too much praise for the success of this procedure.

Our Consul at Bagdad is a most worthy physician, and a man of exceptional intelligence and scientific attainments. From Bagdad there is shipped annually to the United States between five and ten million pounds of wool. According to our governmental regulations this wool must be disinfected, a labor that requires some four hundred trips to the disinfecting station from the consulate, and an equivalent of two hundred or more hours of active labor in a temperature of 120° or higher. For this frightful drudgery, to keep us from being cholera-stricken, the entire salary or fees will be $100 or less. This we glean from a private letter from our colleague. It is outrageously shameful that such a thing should be allowed. Dr. Sundberg is in his own way doing a vast amount of medical missionary work in this wretched place, whither he has been driven by his scientific zeal. There is no salary attached to his consular office. Is it not possible to make the office a salaried one, or to do something to help a noble physician struggling under adversity and in want, in order that we may be healthy?

"Some Reasons why our Prescriptions Fail."—A recent contributor to a homeopathic journal undertakes to give "Some Reasons why our Prescriptions Fail." Surely this man must be a wolf in sheep's clothing, for the expressed opinion of orthodox homeopathists would ordinarily lead one to think that homeopathic treatment never fails. More convicting still is the explanation. The failure is ascribed to two general sources: "(1) Incompetency of the prescriber and the worthlessness of his remedies, and (2) the present incompleteness of our materia medica." The homeopathic sectarian has usually praised his materia medica as being so much richer

than that of scientific medicine—some eight hundred agents, we believe, against about half the number we use. Truly appetite grows by eating! But how strange it all sounds to hear any confession such as this terribly modest one from our Hahnemannian friends!

Frank Advertising.—A method of offering commissions to physicians adopted by a Philadelphia firm of manufacturers and dealers in trusses is unequivocal. Blotting-pads are sent all physicians (even oculists!) praising the trusses, the "lady attendant," etc., but the most emphasized part of the advertisement is this, in double caps:

"IF YOU WILL SEND US YOUR PATIENTS WE WILL RECIPROCATE WITH A CHECK BY RETURN MAIL."

This is a notice to the traders in medicine, but it is also a notice to physicians where *not* to send patients.

The Turkish Bath in the United States.—The thirtieth anniversary of the establishment of the Turkish bath in America was recently celebrated in Brooklyn, N. Y., Dr. Charles H. Shepard having inaugurated the bath in October, 1863.

REVIEWS.

ANATOMY: DESCRIPTIVE AND SURGICAL. By HENRY GRAY, F.R.S., Fellow of the Royal College of Surgeons; Lecturer on Anatomy at St. George's Hospital Medical School. The drawings by H. V. CARTER, M.D., Late Demonstrator of Anatomy at St. George's Hospital, with additional drawings in later editions. A new American from the thirteenth enlarged and improved English edition. Edited by T. PICKERING PICK, Surgeon to, and Lecturer on Surgery at, St. George's Hospital; Senior Surgeon, Victoria Hospital for Children; Member of the Court of Examiners, Royal College of Surgeons of England. In one imperial octavo volume, pp. 1129, with 635 large engravings. Philadelphia: Lea Brothers & Co., 1893.

AGAIN the advancement of anatomic knowledge demands a revision of a book which, since 1857, has been the recognized text-book used by the great majority of English-speaking students of medicine. The successive issues, of which this is the thirteenth, have been utilized to perfect the work by subjecting it to the scrutiny of the foremost anatomists of a generation.

In no previous edition have the changes and improvements in every portion been so great as in this. The text has been most thoroughly revised; the splendid series of illustrations have been reëngraved wherever additional clearness could be attained, and have been reinforced with new engravings wherever completeness has seemed to demand it. The work is printed both in black and in colors. The illustrations, so long and favorably known as the most effective and intelligible anatomic drawings accessible to the student, in their present improved shape fully maintain this supremacy.

The editor has faithfully followed the lines laid down by the author, and has endeavored to render the work more practical and of more use to the student, who will hereafter have to apply his knowledge of anatomy to his practice of surgery, by introducing a considerably increased amount of surgical anatomy, and by pointing out the bearings of anatomy on the practice of surgery. In both of these objects the distinguished editor has accomplished his work in a most thorough manner, and the teacher of to-day presents to his pupil a work which is so like the original that his teacher presented to him years ago that there is always a pleasure in recommending Gray. Moreover, the surgical additions increase the value of the book and place it abreast of the times. This is particularly true of the brain and nervous system, which in the former editions were far in arrear. The muscular system, especially the muscles of the back, is not so readily acquired by an arrangement into layers as by grouping them together as taught by the Continental anatomists.

The section on the Anatomy of the Female Organs of Generation has been revised by Dr. Leonard Remfry, and will be found to be fully up to the times. The illustrations in this portion are all new, as are also many in the section upon the Male Organs of Generation. Indeed the illustrations added in this edition are not only equal to those which have made the work the standard, but are even better and clearer.

There is only one fault with *Gray's Anatomy*—it is a little too large for convenience; it has many repetitions; for surgical anatomy it is not so much used in the dissecting-room as are Holden, Weisse, and Heath. Taking everything into consideration, however, the present, thirteenth, edition is a great improvement upon former editions, and one which will be found worthy of the favor heretofore accorded to it as the *standard text-book on Anatomy*.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1892. Volume IX. Edited for the Association by OGDEN C. LUDLOW, M.D. Published by the Association, 1893.

THIS imposing volume of 834 pages proves that scientific work of a high standard and careful regard for clean conduct can well go hand-in-hand. To point out individual papers of excellence would be somewhat invidious. We can only cite one or two that happened to be upon subjects of present interest to the reviewer. Zera J. Lusk communicates valuable observations on "Mitral Stenosis in Pregnancy," which appeared in THE NEWS of January 14, 1893, p. 41. Prior to the fifth month he would produce abortion. If the sixth month is already past, the patient must remain at perfect rest, under the constant care of a physician, and her husband or the nurse be instructed in the use of chloroform. Stockton writes on the "Etiology of Gastric Ulcer" (NEWS, January 14, 1893), Charles Phelps details an elaborate study of "Injuries to the Head and Brain," and Gouley makes a strong plea for the early extirpation of tumors (NEWS, December, 23, 1892). Blake White reports a striking case of "Successful Pneumotomy for Tuberculous Abscess and Gangrene" (NEWS, January 14, 1893). Many other equally good papers are presented. The Association is to be congratulated on its work.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Volume VIII. 1893.

THE volume of Transactions under review is replete with papers of interest, and contains some of very high

order. It is impossible to even enumerate the titles, but we may indicate as among the more valuable contributions the paper of W. Gilman Thompson, on Addison's Disease; that of Forchheimer on the Intestinal Origin of Chlorosis; Theobald Smith's studies of the Etiology and Pathology of Texas Cattle-fever. J. C. Wilson contributes an interesting report of Three Cases of Pulsating Pleurisy, with abstracts and an analysis of sixty-eight cases gathered from literature. A. Lawrence Mason presents an elaborate study of Subphrenic Abscess simulating Pyo-pneumothorax, and S. J. Meltzer and William Osler contribute to the same subject. The volume is completed by a review of the Functions of the Thyroid Gland, by Francis Kinnicutt, and papers on Myxedema and its Treatment with Thyroid Extract, by J. J. Putnam, M. Allen Starr, and W. G. Thompson.

The society deserves commendation for the uniformly high character of the papers and the discussions.

RECENT DEVELOPMENTS IN MASSAGE. By DOUGLAS GRAHAM, M.D. Physicians' Leisure Library. Pp. 128. Detroit, Mich.: Geo. S. Davis. 1893.

THIS is an interesting summary of the latest contributions to the literature of massage, and is supplementary to the author's treatise published in 1890. It is valuable for its convenient translations and condensed reports of the work of a large number of foreign writers who have employed massage in medical practice much more widely than is customary in the United States. The investigations of Maggiora, of Turin, are reported with illustrations that show very beautifully the power of massage to restore the strength of muscles weakened by physical and mental labor. The experience of Zabludowski, Haig, Eccles, Breda, Castex, Millard, Casati, Poliakow, and many others is given, but unfortunately without an index.

GUY'S HOSPITAL REPORTS. Edited by W. HALE WHITE, M.D., and W. H. A. JACOBSON, M.A., M.Ch. Volume XLIX, being Volume XXXIV of the Third Series. London: J. & A. Churchill, 1893.

AMONG the papers contained in this volume Dr. Fisher's "Study of Peritoneal Sanguineous Cysts, and their Relation to Cysts of the Pancreas," will attract attention. Smith and Durham's thorough essay on "Glycosuria and Surgery" brings together a number of important facts, and will probably become a standard of reference for surgeons. F. Taylor writes on "Some Cases of Malignant Disease of the Chest and Abdomen," Hale White discusses the "Prognosis of Ascites of Various Causation," and Golding-Bird gives an interesting retrospect of "Urethral Surgery." A memoir and portrait of John Hilton add to the value of the volume.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, AT ITS FORTY-THIRD ANNUAL SESSION, HELD AT WILLIAMSPORT, 1893. Volume XXIV. Published by the Society. Philadelphia, 1893.

AMONG the able papers in this volume that on "Heart-disease or Kidney-disease," by Dr. Tyson, and "New Remedies in Diseases of the Skin," by Dr. Shoemaker, deserve special mention. Dr. Diller writes interestingly of "Hypnotism and Suggestion." Dr. Dixon presents a thorough and practical "Address on Hygiene." Dr. Nutt's paper on "Intubation" is timely and full of meat. Many of the other papers, most of which have been published in the journals, are likewise of value.

MISSOURI STATE MEDICAL DIRECTORY: Containing a carefully revised list of Physicians, Dentists, and Druggists, together with the Colleges, Hospitals, Societies, and Medical Journals of the State, arranged by counties for the convenience of Society Secretaries. Pp. 120. St. Louis: Published by *The Medical Fortnightly*, 1893.

WE are grateful for this useful little book, and wish that every State could boast of such a publication.

TRANSACTIONS OF THE VERMONT STATE MEDICAL SOCIETY FOR THE YEAR 1892. Published by the Society. Burlington, Vt., 1893.

THIS is a neatly printed and creditable volume. It contains a sympathetic memoir of Dr. Joseph Draper, and a number of interesting papers on medical topics. The President's Address on "Preventive Medicine," by Dr. Calverly, is an able plea for better public sanitation.

SPECIAL ARTICLE.

THE DISSIMILARITY BETWEEN PHYSICIANS AND HOMEOPATHISTS.

A Reply to the Presidential Address of Dr. John B. Roberts.[1]

BY SOLOMON SOLIS-COHEN, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC; ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL.

THIS communication is presented at the request of a number of members of this Society who desire a record to be made of their dissent from some of the views advanced by Dr. Roberts in his paper entitled "Points of Resemblance Between Us and Homeopathic Physicians." The subject-matter having been discussed by me at length in a paper read before the Society some years ago,[2] I may be pardoned for confining myself on the present occasion to a brief review of a few of Dr. Roberts's "Points" and to the introduction of but one counter-point.

I have read somewhere an apologue which, slightly modified to suit the present occasion, runs thus:

In the country of the Houyhnhyms, concerning which land, its inhabitants and their customs, an interesting and reliable account has been left by the late learned and ingenious Gulliver, there was at one time an agitation in favor of what was termed "liberalization of the Constitution." In furtherance of this movement there was delivered before the General Assembly, by an eminent and thoroughbred stallion, an able discourse entitled "Points of Resemblance Between Us and Jackmules."

With the great generosity and candor that were its

[1] Read before the Philadelphia County Medical Society, October 11, 1893.

[2] Proceedings, vol. ix, p. 278, 1889. THE MEDICAL NEWS, October 19, 1889.

author's characteristics, this discourse, while admitting that all mules were not alike, and that the earlier breeds had been quite obnoxious, yet claimed that in recent times a great change had taken place; that, indeed, mules were becoming every day less mulish; and it counted in favor of "the great body of mules at the present time," even down to the least fraction of an inch by which their ears had been shortened, and the last hair in the little bunch at the end of their tails, every point wherein they had never so slightly departed from the anatomy of the more lowly line of their parentage, and approached to the form and features of the noble line that they shared with the speaker. Many of the younger Houyhnhyms were moved by his eloquence to respond to the generous impulses of the advocate of fraternization; and it appeared as if his views might prevail. At this juncture a veteran "stud" arose, and with great gravity and deliberation spoke about as follows:

"My noble friend has shown most clearly and convincingly that many Jackmules have done their best to imitate Us. Let me even admit for argument's sake that he has succeeded in establishing many points of similarity. But he must grant me permission to call attention to one point of difference. There was never a mule yet but he was sired by a jackass."

Dr. Roberts pays a handsome and well-deserved tribute to the personal and social qualities of educated homeopathists. I can cordially indorse all that he has said upon this topic. The question of scientific or ethical truth, however, is an impersonal one, and should be so considered. The fact that Washington was a slaveholder did not make slaveholding right; and neither the high character of Dr. Roberts, nor that of many members of the homeopathic fraternity, can make white black or black white, make straight that which is crooked, or make crooked that which is straight.

The question before us is one of simple honesty, and to decide it needs neither learned citation of authorities nor casuistic subtleties. Either the name "homeopathist" means something or it means nothing. If it is meaningless there can be no legitimate reason for retaining it. If it has a meaning it means separation from and opposition to progressive medical science; it means an assertion of belief in a certain well-defined dogma opposed to reason and to experience; an assertion, moreover, made for effect not upon medical colleagues, but upon the lay and uninstructed public. It is only right, then, to hold those who make use of that name to all the implications of the voluntarily assumed designation.

A professed homeopathist can no more sever himself from the history of his sect than a mule can sever himself from the lineage of his sire. Without jackasses no mules; without continual Hahnemannian fecundation in each generation, no homeopathy.

I agree fully with Dr. Roberts that neither "a physician's political, religious, or social beliefs and affiliations, nor his opinion that in 'similars' he sometimes finds a remedy of value, should disqualify him" from membership in this Society. But who has ever urged that any of these things should be disqualifications? That one's possible "opinion that in 'similars' he sometimes finds a remedy of value" does not act as a disqualification Dr. Roberts himself shows in the further course of his paper, quoting, moreover, the language of the American Medical Association: "neither is there any article or clause of the Code of Ethics that interferes with the exercise of the most perfect liberty of individual opinion and practice."

What Dr. Roberts either fails to see, or refrains from commenting upon, is the fact that to hold the "opinion that in 'similars' one may sometimes find a remedy of value" is quite a different matter from labelling oneself "homeopathist." To believe that in electricity "one sometimes find a remedy of value," is not, therefore, to be an "electropathist;" to use water as a therapeutic agent in suitable cases does not make one a "hydropathist." The difference is so obvious that to enlarge upon it would be to doubt the intelligence of the Society. Equally great is the difference between one who sometimes uses a remedy that in a healthy person would produce effects resembling some of the symptoms of the disease, and one who assumes a title which, if it means anything, means that his everyday practice is designedly based upon the so-called "law of similars." In words Dr. Roberts ignores this difference; nevertheless, he practically admits it, or there would have been no necessity to write his paper. It does not require an elaborate thesis to demonstrate that twice two is four. One needs not eloquently plead for the removal of a disqualification that he admits does not exist.

Dr. Roberts is doubtless correct in his repeated assertions that "very many of those whom the public regards as homeopathists have comparatively little faith in the infinitesimal doses of Hahnemann, or in the infallibility or universality of his law," and that "to-day there is comparatively little belief in or practice of homeopathy as advocated by Hahnemann." A good lawyer would have hesitated to make such admissions in a paper written in defense of homeopathists. They prove, however, the sincerity of our former President; a proof strengthened when he further states that "the real homeopathy . . . . pays no attention to the microscopic and chemical changes in tissues and organs, but believes in selecting a remedy which . . . . causes symptoms similar to . . . . the totality of the symptoms seen in the patient."

But if this belief, which Dr. Roberts very properly characterizes as "unscientific and unworthy of credence," is, in Dr. Roberts's own language, "the real homeopathy," what kind of homeopathy is that which he says is practised by the great body of those "whom the public regards as homeopathists?" It must be an unreal, a false, a fraudulent homeopathy. And Dr. Roberts's proposition, reduced to plain English, is this: "We cannot admit to membership in this Society the real homeopathists because they are loyal to a dogma which is unscientific and unworthy of credence; but we ought to admit the false homeopathists because they only *pretend* allegiance to that dogma.

Mr. President, I have more respect for the honest, simple-minded donkey than I have for the disingenuous and uncertain mule.

There is, however, one proposition in Dr. Roberts's paper with which I desire to express my full and unqualified assent, and upon the principle enunciated in which we can all, I think, find a common meeting-ground. I, for one, should be most happy to aid in

bringing about its incorporation into the organic law of this Society. Dr. Roberts says: "The test of qualification for membership should not be the college from which the applicant received his diploma, but an education enabling him to understand and appreciate the science of medicine and an honest purpose to treat his patients by all means and methods which experience, investigation, and research show to be serviceable."

With this opinion, let me repeat, I am heartily in accord. It is quite evident, however, that such an education as Dr. Roberts describes cannot be received in a sectarian school, despite the use of any number of scientific text-books; and one has only to read the first homeopathic journal that comes to hand to see that even among the "unreal" homeopathists, while they do have considerable knowledge of the empiric practices of physicians—which practices they copy more or less intelligently, very few have an adequate comprehension of the principles of scientific medicine. But the most certain evidence that the official representatives of homeopathy in Pennsylvania do not "understand and appreciate the science of medicine" has been given by their demand for the establishment of sectarian examining boards. Anyone who elects to go before such a board, thereby declaring his lack of acquaintance with scientific therapeutics and practice, and the limitation of his studies to the theories and methods justly termed by Dr. Roberts "unscientific and unworthy of credence" voluntarily excludes himself from the ranks of the profession; voluntarily enrolls himself as a sectarian. We certainly cannot accept the certificate of such a board as evidence of an applicant's possession of "an education enabling him to understand and appreciate the science of medicine and an honest purpose to treat his patients by all means and methods which experience, investigation, and research show to be serviceable." On the contrary, it is a direct evidence of partial and narrow education; of training limited to what Dr. Roberts has well-termed "unscientific and untrustworthy" theories and practice. If, however, a graduate of a sectarian college, after sufficient practical experience to compensate for his want of school-education, should desire to enter the ranks of the profession of medicine, and should evidence his sincerity, not only by abandoning his sectarian designation, but also by refusing to permit his patients to apply it to him; and if, after due investigation, the censors should report that he was in personal character, professional knowledge, and scientific spirit, worthy of admission to this Society, it would give me great pleasure to cast my vote in his favor.

To conclude: The great point of dissimilarity between physicians and latter-day homeopathists is the profession by the latter of adherence to a dogma that is not only "unscientific and unworthy of credence," and an insuperable obstacle to progress, but that they themselves do not half believe in; an "unreal" profession of faith that may serve to attract patients, but that cannot be considered straightforward. So long as any one voluntarily makes such profession he renders it impossible for self-respecting physicians to meet him upon equal terms.

If, however, one whose personal character fits him for membership in this Society, but who had formerly professed homeopathy, becomes convinced of his mistake, and desires to join the ranks of scientific medicine, he should be freely received; provided only that he repudiates any sectarian designation and gives to the censors satisfactory evidence of his professional attainments. More than this we ought not to ask. Less than this we cannot honorably accept.

CORRESPONDENCE.

ANNUAL MEETING OF THE NEW YORK STATE MEDICAL ASSOCIATION.

To the Editor of THE MEDICAL NEWS,

SIR: The annual meeting of the New York State Medical Association has just been held in this city. This being the decennial celebration, the meeting was extended from the evening of October 9th to that of October 12th, and included the usual full scientific program, together with a number of entertainments.

The President's Address was delivered on the first evening by Dr. S. B. Wylie McLeod, of New York County. This was followed by an address by Dr. John Shrady, in which he reviewed the work of the past ten years. He called attention to the fact that one of the most prominent features had been the holding of "prepared" discussions, following the practice instituted by the British Medical Association, and adopted by many of our most conservative medical societies.

In a paper entitled "The Prevention of Disease," Dr. James G. Porteous, of Dutchess County, spoke particularly of the methods by which tuberculosis is disseminated, and read the printed directions that he gives his patients. They were cautioned against spitting on the floor or in the cars, and were directed to use a cup or wide-mouthed bottle for a cuspidor, and to frequently wash this out with hot water. They were also advised to use individual table-utensils and table-linen, and to sleep alone in airy apartments, and not to kiss others. Well persons were reminded that tuberculosis is principally communicated by swallowing the germs or receiving them into wounds, and they were warned not to kiss on the lips *anyone* who has a cough.

In a discussion that followed the reading of the paper by Dr. E. D. Ferguson on "Nephrotomy and Nephrectomy," Dr. John Cronyn, of Erie County, cited a case in which for many years a lady had symptoms of stone only in the right kidney, yet the post-mortem examination showed that both kidneys contained large calculi. This illustrates some of the common difficulties in making the diagnosis in this class of cases. Dr. Ferguson and Dr. Gouley both expressed the opinion that cystoscopic examination and catheterization of the ureters were more hazardous than an exploratory incision, and at the same time were less satisfactory.

Dr. N. P. Dandrige, of Cincinnati, in a paper on "The Surgical Treatment of Pulmonary Cavities," said that this method could be employed with advantage in cases of abscess of the lungs, pulmonary gangrene, hydatid cyst, and of tuberculous and bronchiectatic cavities. The operation is often performed by mistake, under the supposition that the operator is dealing with a localized empyema. When there are adhesions between the pleura and the chest-wall, and the cavity is superficial, the operation is simple and involves but little risk. The position of the cavity is determined by means of an

aspirating needle, which is used as a guide for the knife. After incision the cavity is packed with iodoform-gauze.

The first afternoon was devoted to a "prepared" discussion on "Lesions of the Pleura," which was opened by Dr. John Shrady, of New York County. Referring to pleurisy with serous effusion, he said that the indications for treatment were to limit the exudation in the early stage, to allay pain, to keep the bowels relaxed, to reduce the fever, and to adopt such measures as were best calculated to promote absorption. When there is enough fluid in the chest to cause intermittent orthopnea, or when the fluid half fills the pleural cavity, or when after a month it shows no tendency to absorption, it is time to aspirate. The effusion may become purulent and yet give rise to no characteristic constitutional disturbance unless some of the pus is absorbed; hence one should be on one's guard. Dr. William McCollom, of Kings County, who continued the discussion, was inclined to attribute considerable importance to the streptococcus, the staphylococcus, and the pneumonia-coccus as etiologic factors, and he thought some of the discrepancies in the observations in this direction might be explained by the fact that these different observations were made at different stages of the disease. Dr. J. Blake White, of New York County, has noted an interesting clinical fact, namely, that the tendency to clear the throat when there is no local lesion is characteristic of pleurisy with adhesion, and that a dry, short cough points to adhesions high up in the chest, whereas if these adhesions are lower down, the cough will be more prolonged. Dr. Charles A. Leale cited several cases that showed how much can accomplished in empyema without surgical interference. There seems to be a sort of revulsion of feeling in regard to thoracentesis, for in this discussion, Dr. Thomas H. Manley, of New York, and Dr. Donald McLean, of Detroit, inveighed against its use. Regarding incisions into the chest in empyema, Dr. Dandridge said that while it was exceptional for him to treat empyema without incision and resection of the ribs, aspiration certainly possesses one important advantage, viz., that it maintains the negative pressure that so materially aids the expansion of the lungs.

Dr. Austin Flint, of New York, made some remarks in the evening on "Fermentative Dyspepsia." He is firmly convinced that fermentation in the alimentary canal is due to microörganisms, and consequently he favors the use of anti-fermentatives. An experience of nearly a year with bismuth subgallate had led him to look upon it as far superior to all other remedies of this class that he has employed. It may be given in doses of five grains, in capsules or in tablets. He had followed his father's well-known practice of giving salicin in these cases, and although the results in many cases were very satisfactory, they were not comparable to those obtained with bismuth subgallate.

Those who study the various methods advanced from time to time for amputation at the hip-joint will be interested in certain statistics presented to the Association by Dr. John A. Wyeth, of New York, regarding his well-known "bloodless method." He has collected thirty-nine cases in which the method had been pursued, and the reports are the more valuable, as they represent the work of a large number of operators of all degrees of skill. In thirty-five of the cases, the amputation was performed for disease, and in four for injury. Five of those operated upon for disease died, giving a mortality of 14 per cent.; and all of those in which the operation was performed for injury succumbed, giving a mortality of 100 per cent. It should be said, however, that the latter were chiefly cases of severe railroad, crushing injuries, and hence the mortality after any operation must necessarily be very high. The operation had been before the profession since 1890, and it spoke for itself.

The question of the voluntary commitment of the insane to asylums was brought up by a paper presented by Dr. W. D. Granger, of Westchester County. He said that at the present time the tendency is toward making asylums *hospitals*, and, as far as possible, individualizing the treatment. Certain insane patients will gladly seek the advantages of asylums if they can do so voluntarily. This has been the subject of legislation in several States, but the trouble has been that after the patients' admission to the asylum they have generally been deprived of their liberty, and treated in almost the same way as those committed involuntarily. The laws of New York State now permit insane persons who are in a condition to fully appreciate what they are doing to voluntarily commit themselves to family asylums, but no time is specified, the patient being allowed to leave whenever he pleases.

Dr. Gustavus Eliot, of New Haven, Conn., contributed an interesting paper on the treatment of enteric fever. He said that as the safety of the patient depends so much upon absolute rest of both body and mind, the physician should make it a rule in every case of fever to be sure that the disease is not enteric fever before giving the patient permission to get out of bed. This condition of perfect rest should be maintained for at least a week after the temperature, morning and evening, has reached the normal. He advised beginning the treatment by administering from seven to ten grains of calomel on alternate days for four days, and then following this by the administration of iodin and carbolic acid, well diluted. He was sure that the calomel treatment not only brings about immediate amelioration in symptoms, but it also really shortens the duration of the disease. Dr. George Douglas, of Chenango County, and Dr. John H. Martin, of Otsego County, also advocated the calomel treatment, and expressed their disapproval of giving alcoholic stimulants in enteric fever. Dr. E. R. Squibb said that the beneficial action of calomel in enteric fever was probably due to the fact that when it is ingested it is first converted into an albuminate, and then slowly decomposed into the bichlorid, so that its antiseptic action was called forth gradually but continuously. In order to secure this gradual action, calomel should be given dry on the tongue, so that it may be quickly converted in the stomach into the albuminate.

Dr. Donald McLean in presenting some surgical memoranda remarked that a large experience with ununited fractures of the long bones had taught him that the most common cause of non-union was excessive violence at the time of the fracture. In cases of amputation at the hip-joint he uses the aortic compressor, and greatly prefers it to Wyeth's method of controlling the hemorrhage.

Another interesting "prepared" discussion took place on the second afternoon, and was on the treatment of

appendicitis. Dr. Frederic S. Dennis, of New York, who opened this discussion, stated that about 50 per cent. of the cases of inflammation in the region of the appendix go on to resolution, and only about 11 per cent. relapse. He did not approve of operation unless urgent symptoms had existed without abatement for forty-eight hours. Errors in diagnosis are very frequent, even among experienced and eminent practitioners, and the operation cannot be considered in itself as free from danger, although some would have us believe it a very trifling affair. The fact that one instrument-maker in New York has sold within the past year six dozen special trusses for ventral hernia occurring after this particular operation is in itself very significant. Dr. John W. S. Gouley, of New York, took the same conservative position with reference to the treatment of appendicitis, but admitted that, while in at least half of the cases an operation is not required, there are times when a life might be saved by very prompt resort to operation. Dr. Joseph D. Bryant, of New York, as a result of numerous observations carried on in the dead-house of Bellevue Hospital, had found that a foreign body was present in the vermiform appendix in about 70 per cent. of all male subjects and 40 per cent. of females. The "McBurney point" can no longer be considered characteristic of appendicitis, for it has been found in other conditions, and besides this, examinations have shown that the position of the *caput coli* is very variable, and in a large percentage of cases is not in the immediate vicinity of this "point." If acute symptoms are present, he would not postpone operation longer than three days. Rigidity of the rectus muscle is, in his opinion, more reliable as a guide than the presence of a tumor in the ileo-cecal region. Of course, if the symptoms apparently indicated perforation, immediate operation was demanded. Dr. J. A. Wyeth favored an early resort to exploratory operation, for, not only did he consider this the safer course, but there also is less likelihood of ventral hernia following the early operation.

In speaking of the proper mode of introducing the male catheter into the bladder, Dr. Douglas Ayres, of Montgomery county, pointed out that by pressing down on the soft parts over the pubes, the suspensory ligament will be relaxed, and the introduction of the instrument in some cases greatly facilitated. Dr. Gouley exhibited an exact model in bronze of the catheter found in the ruins of Pompeii. It is of the sigmoid form, and is distinctly conical, and has a single eye near the vesical extremity. Dr. Gouley is of the opinion that the catheters at present made in this country are far superior to those of foreign manufacture.

A rather novel idea was brought forward by Dr. William Finder, of Rensselaer County, in a paper entitled "Researches on the Efficiency of Vaccina after Typhoid Fever." He had found that a number of persons who had been recently ill with enteric fever were especially susceptible to vaccination, and, after verifying these results by numerous observations extending over a number of years, he ventured to present these views to the profession, so that further observations might confirm or disprove the theory that enteric fever dissipates the protection conferred by vaccination. It is his practice now to revaccinate the patients after an attack of enteric fever.

As a sort of offset to the general enthusiasm over pelvic surgery, Dr. T. J. McGillicuddy, of New York, presented a paper entitled "A Plea for the Non-operative Method of Treating Dysmenorrhea, Pelvic Inflammation, and Pelvic Abscess." His plan is to stimulate the portal circulation by free use of hot water administered by mouth and by rectum, and thus promote the absorption of pelvic exudates. He took the position that pus can be absorbed, and that, therefore, one should not be too hasty in condemning such cases to operation.

In view of a circular-letter sent out by the American Medical Association asking for an expression of opinion as to the advisability of amending the Code of Ethics, the Association ordered the following communication to be sent:

"In reply to the notice that the American Medical Association had requested the State medical organizations in affiliation with that body to express their wishes in references to any changes in the Code of Ethics, the New York State Medical Association has to state that it has made that Code one of its foundation-stones, and that it is entirely opposed to any alteration therein. This is the result of a full reconsideration of the subject, and after an experience of ten years of organization under the Code."

Dr. Thomas D. Strong, of Chautauqua County, was elected President for the ensuing year.

NEW YORK.

THE RECRUDESCENCE OF LEPROSY, AND ITS CAUSATION.

To the Editor of THE MEDICAL NEWS,

SIR: As the readers of THE MEDICAL NEWS would scarcely comprehend the full scope and purport of my recently published volume, *The Recrudescence of Leprosy, and Its Causation*, from the brief notice in your excellent journal (August 26, 1893, p. 249), I shall be glad if you will kindly afford me space for a summary of my conclusions, the result of personal investigation in many countries where this terrible disease is endemic. I can prefer this request with the more urgency from the fact that many of the sufferers from leprous vaccination are absolutely friendless, while most of them are without political representation and are unable to plead their own cause. In the pursuit of my investigations I have been repeatedly entreated to bring their intolerable grievances before the English-speaking public through the press, with a view of reaching the ears of Parliament and other legislative bodies.

These conclusions are as follows:

1. That leprosy has greatly increased during the last half-century, and that it is prevalent in many places where it was formerly unknown.

2. That whilst the opinions of medical authorities and experts vary considerably on the subject of the contagiousness of leprosy, the preponderance of authority is in favor of the theory that it is not contagious in the ordinary sense of the term, but is communicable by means of a cut, sore, or abraded surface; and this view is confirmed by my own personal investigations.

3. That other alleged factors, such as malaria, a fish-diet, syphilitic cachexia, heredity, and insanitation, are

admittedly unequal to explain the rapid growth of the disease in certain of our Crown colonies and dependencies, as well as in other countries.

4. That on one point there is much agreement, and hardly any dissent, namely, the inoculability of leprosy; and that the view of leprosy as an inoculable disease, while it is most clear to those who take the malady to be due to a bacillus, is older than the bacteriologic evidence, and is not dependent thereon.

5. That the most frequent opportunities of inoculating the virus of leprosy are afforded in the practice of vaccine-inoculation, which is the only inoculation that is habitual and imposed by law; and that the evidence here adduced is calculated to show that vaccination is a true cause of the diffusion of leprosy.

6. That the official information collected by interrogatories and otherwise has not been hitherto of a kind to show how far vaccination has determined the amount of leprosy in recent times; and that any interrogatories that may be sent out in future should not be limited to ascertaining the effects as regards leprosy, of hypothetically "pure lymph." When on very rare occasions interrogatories have been submitted they have been framed to ascertain the results of a purely hypothetic system of vaccination, which is not anywhere discoverable in practice (*i. e.*, with pure lymph, and free from hereditary taint), and the replies are therefore futile and misleading.

7. That with the exception of two groups of cases—those adduced by Dr. Roger S. Chew, of Calcutta, and Dr. S. P. Impey, of Robben Island—those reported in this volume have not been the result of special investigations, but have cropped up accidentally in the course of medical practice, and in some instances have been published by practitioners with apologies to the profession for presenting such unwelcome disclosures.

8. That the increase of leprosy in the Sandwich Islands, the West Indies, the United States of Colombia, British Columbia, British Guiana, South Africa, and New Caledonia, has followed *pari passu* with the introduction and extension of vaccination, which in nearly all these places, without previous inquiry or demand from the inhabitants has been made compulsory.

9. That as leprosy is a disease of slow incubation, often taking years to declare itself, and in its incipient stages can be detected only by practitioners of large experience, it follows that, in countries where leprosy exists, there is great danger of extending the disease by arm-to-arm vaccination.

10. Leprosy being one of the most loathsome diseases to which the human race is subject, and being practically incurable, it behooves all interested in the public well-being to do their best to *prevent* its diffusion, and as a means thereto, to discourage the practice of vaccination on that ground, if on no other.

Yours faithfully,

WILLIAM TEBB.

DEVONSHIRE CLUB, ST. JAMES'S, LONDON.

Acknowledgment.—For the unfortunate physician (see MEDICAL NEWS, October 7th) we acknowledge the receipt from O., $10; G., $1; C., $1; M., $2; M., $10; E., $1.

SOCIETY PROCEEDINGS.

THE NEW YORK NEUROLOGICAL SOCIETY.

Stated meeting, held at the New York Academy of Medicine, Tuesday Evening, October 3, 1893.

DR. M. ALLEN STARR, PRESIDENT, IN THE CHAIR.

THE PRESIDENT read a memorial of Prof. Jean-Marie Charcot (see THE NEWS, October 14, 1893, p. 433).

DR. E. C. SEGUIN gave a few personal reminiscences of Prof. Charcot. He referred to the generosity of the great physician in placing at the disposal of his students his abundant materials and the use of his laboratories, and in allowing them to receive the full credit for their labors, instead of appropriating it to himself. Many of Charcot's pupils, Bourneville, Bouchard, and others, have been helped by him in every possible way to attain honorable positions. In disposition he was not quick, hasty, or mercurial. Every thought was carefully matured, and he collected his material for a long time before reaching or publishing his conclusions. He was averse to theorizing. He was a close analyst and a devoted follower of the inductive method of reasoning. Primarily, Charcot was a pathologist, and his reputation will always rest on his achievements in this field of medicine. His work in hypnotism, by which he was greatly fascinated in later years, can only be recorded as a mere fragment—a digression which in the future will count as nothing.

DR. SEGUIN also reported a case of generalized paresis ending in complete recovery. The patient was a boy thirteen years old, who was brought for an opinion as to the nature and prognosis of a singular condition of increasing muscular weakness, which had come on during the preceding eighteen months. The family history was fairly good. The boy's mother was of a nervous temperament and for a few months had been addicted to the chloral-habit. Of six children only one other, a sister, had had a nervous trouble, namely, a mild chorea extending over several years. There was no trace of muscular disease, atrophic or dystrophic, in the family. The patient's history, previous to the onset of this disease, was negative. At the age of six years he had a severe attack of albuminuria, which left no traces. Several years later he had what seemed to be a mild attack of articular rheumatism. The boy was active and daring, and had numerous falls, none of which, however, was followed by serious symptoms. There was a history of masturbation, carried on for several years. There was no history or evidence of metallic intoxication, nor at any time was there any indication of hysteria. The only positive causative element in the case was the self-abuse, which was discontinued at the age of twelve, when the boy himself noticed that he had slight difficulty in articulation. Five months subsequently to this the patient's symptoms were first brought to his father's attention by the fact that he twice fell out of the saddle and by his suddenly dropping the oars in a boat and acting for a few minutes as if paralyzed. Even before that, it was recalled, he had become rather awkward in buttoning his clothes and in using the knife and fork, and that after reading aloud for a few minutes his articulation became thick. Very gradually he lost his energetic ways and became awkward in everything; his

attitude had changed so that he stooped, the neck hanging down and the abdomen protruding. His facial muscles lost much of their expression and his laugh was constrained and unnatural. All of these symptoms developed and progressed very slowly. The boy was subject to "sudden collapses," as his father called them, characterized by a sudden loss of control over many muscles, resulting in falls or in dropping objects from the hand. These symptoms last named suggested *petit mal*, but this affection was excluded after careful observation. The symptoms were entirely of a motor character. There was no numbness, anesthesia, neuralgia, or psychic or trophic symptom. The organic functions were normally performed; the nutrition was good. The eyes were normal. The legs were apparently strong, and the boy could rise from the dorsal recumbent posture on a flat couch and also from a squatting posture, but these acts were performed feebly, slowly, and with great effort. The spine was not tender and presented no deviation, excepting an antero-posterior one. Local paresis of the muscles was demonstrable only in the extensor group of the right forearm. No muscles showed atrophy or hypertrophy. The knee-jerk was normal. There were no sensory symptoms, excepting on exertion a sense of fatigue in the muscles of the lips and tongue, as well as in those of the forearm. On electric examination the reaction of the nerves and muscles to both currents was found normal. The sexual organs presented no evidence of masturbation. The grasp of the dynamometer was with the right hand, 11; the left hand, 16.

During two years the boy improved decidedly in motor power and skill, and his height increased six inches. The treatment from the first, in the absence of any possible pathologic diagnosis, consisted in the systematic, long-continued administration of tonics, such as mercuric chlorid, phosphorus, arsenic, and strychnin. At the same time a mild faradic current was applied systematically every day. Also, from the first, a cold sponge-bath was ordered on rising or at bedtime, followed by a thorough dry rubbing and a manipulation of all of the muscles. Another part of the treatment consisted in gentle gymnastic movements of the hands, arms, trunk, and legs.

The case was lost sight of for nearly five years, when on inquiry it was learned that the boy was in the junior class at college, that he stood well in his class and excelled in wrestling and other athletic sports. The treatment advised had been faithfully carried out for nearly three years and was followed by gradual but continued improvement in the boy's condition. His weight became 166 pounds; the circumference of his chest in expiration, 33 inches; on full inspiration, 39 inches; the circumference of the waist, 31 inches; of the mid-thigh, 22 inches; of the biceps, 13 inches. His endurance was good and he was able to raise from the ground an iron rail weighing 600 pounds. His grasp on the dynamometer became with the right hand, 72; with the left hand, 53.

DR. B. SACHS said that in the first part of the report the case reminded him of a primary muscular dystrophy of the facial-scapular-humeral type, with perhaps some involvement of the lower extremities. Such a case has recently come under his observation, with many symptoms similar to those narrated. In cases of progressive primary dystrophy, particularly in pseudo-hypertrophic conditions, he has seen marked temporary improvement follow treatment, although never complete cure. Again, in Dr. Seguin's case there might possibly have been some nuclear trouble, with a mingling of symptoms pointing to the spinal cord or medulla. If the case was one of primary muscular dystrophy, the question arises whether the cure will be a lasting one. Dr. Sachs has seen a number of cases presenting a condition of pseudo-hypertrophy in which the muscular tissue first enlarges and then rapidly atrophies.

DR. GEORGE W. JACOBY suggested that Dr. Seguin's case might have been one of polymyositis ending in complete recovery, and followed by a secondary hypertrophy of the muscles.

DR. J. F. TERRIBERRY stated that it is against the laws of pathology to assume that an inflammatory process in the muscular tissue is followed by hypertrophy of the muscle, with increased force.

DR. E. D. FISHER said that, as the boy grew six inches taller while under Dr. Seguin's care, the lesion was probably not a spinal one.

DR. SEGUIN added that he was not prepared to advance the case as an instance of a muscular dystrophy in an early stage. Neither did it resemble a case of myositis. There was no pain; there was a general weakness, which was sometimes so pronounced that the boy was unable to hold objects in his hands, or he would lose all control over his muscles and fall to the ground.

NEWS ITEM.

Price of Pamphlets on Tuberculosis.—In THE MEDICAL NEWS of September 16 we said that the Pennsylvania Society for the Prevention of Tuberculosis would supply physicians with its pamphlets without charge. So great has been the demand that the funds of the Society will not permit this, and the Secretary (Mr. E. Leslie Gilliams, 806 Walnut street, Philadelphia) has informed us that he will hereafter be compelled to charge the nominal price of twenty-five cents a hundred, express charges or postage *not* included.

BOOKS AND PAMPHLETS RECEIVED.

Certificates of Death: Their Significance and Importance, as well as their Moral and Physical Aspect. By P. C. Remondino, M.D. Pamphlet. San Diego, 1893.

Case of Supra-pubic Cystotomy Performed to Secure Continuous Drainage of the Bladder. By Cephas L. Bard, M.D. Reprinted from the Southern California Practitioner, 1893.

Report of the Kensington Hospital for Women, from October 12, 1891, to October 10, 1892.

The Electric Light Current in Medicine and Surgery. By Wm. Scheppegrell, A.M., M.D. Reprinted from the New Orleans Medical and Surgical Journal, 1893.

A Study of the Cheyne-Stokes Respiration. By Samuel Wolfe, M.D. Reprinted from the Journal of the American Medical Association, 1893.

A CASE OF DISLOCATION OF THE FOURTH CERVICAL VERTEBRA WITHOUT FRACTURE.[1]

BY A. M. HOLMES, A.M., M.D.,
OF DENVER.

IN clinical study the success of a diagnostician depends to a great degree upon the faculty of close observation of minutiæ and the ability to correctly interpret their meaning. In no department of medicine or surgery do we find a greater need for the exercise of this faculty than in that important class of cases wherein the functional activity of the cerebro-spinal centers has been impaired or destroyed, either through the various agencies classified as diseases, or through the more violent and sudden means inducing acute traumatism. In a very large percentage of clinical cases reported the accounts are so defective, lacking in precision and exactness of description, that the true nature of their lesion remains in doubt. On the other hand, there are those who will not accept any case as authentic, unless it is verified by a post-mortem examination.

The following case is presented for the consideration of this Society, from the fact of the comparatively rare occurrence of others of its kind, and on account of the distinct and characteristic symptoms accompanying it, so typical of this form of spinal injury. If such cases are properly studied, and the symptomatology correctly interpreted, they may be the means of throwing light upon some of the unsolved problems of neurology:

On February 2d, this year, at 6.30 P.M., the accident occurred which furnished the material for this paper. The patient, H. P., a male, aged forty-nine, weight 160, possessed an excellent physique. The previous health and family history were good. Being an engineer, it was his routine duty at the close of each day's work to climb to the top of a water-tank to shut off the water-supply for the night. For this purpose a ladder was placed loosely against the tank. On the evening named there were snow and ice on the ground, which caused the ladder to slip. The man fell backward a distance of sixteen feet, the back of the head and shoulders striking the ground. The fall produced instantaneous paralysis. The man was unable to move a muscle below the neck. He retained perfect consciousness, and was able to speak. The only pain of which he complained was localized, and in the lower cervical region, and was increased by movement or manipulation. He was carried to his home, only a short distance away, and placed upon a cot, in which position he remained until I saw him, two hours afterward.

I found the patient without pain, except in the back of the neck. Consciousness was not impaired. He had good control of the vocal organs, could speak distinctly, but in a weak voice, and with a slow, measured accent. To all appearances he seemed to be in a condition of extreme shock. His face was flushed, there was an anxious expression of countenance, the surface was cold, and the pulse at the wrist was not perceptible.

On placing my ear over the heart the action of that organ was found to be regular, but very weak, and only 36 per minute. The temperature under the tongue was 92.5° F. Thinking that there might have been a mistake, I took it a second time, using every precaution to prevent error, and found it the same. Respiration was exclusively diaphragmatic, very shallow, but regular, and only 10 per minute. The thoracic muscles were paralyzed. The upper part of the thorax remained perfectly stationary, while the diaphragm performed its functions normally.

There was total loss of sensation in all parts below the neck and shoulders, and not the slightest power of voluntary motion in either arm, the body, or the lower extremities. The muscles supplied by the brachial plexus were all implicated. The line of anesthesia extended around the body about two inches above the nipples. There was no line of hyperesthesia, but rather a gradual diminution from normal sensation to total anesthesia, covering a space of one or two inches, which might be termed "uncertain sensation." Partial sensation existed on the outer surface of each arm, reaching a lower point upon the left than upon the right. Soon after the accident the patient experienced a sensation of tingling in the fingers of the left hand. Well-marked priapism and retention of urine and feces existed. Sight and hearing were not affected.

With this formidable array of symptoms, it was very evident that we had to deal with a case of extreme pressure, or contusion of the spinal cord. It was also very evident that the lesion was below the origin of the phrenic nerve, as the functional activity of the diaphragm was not destroyed. It was also plain that the lesion was above the origin of the brachial plexus, as there was total paralysis of both upper extremities, and almost complete anesthesia.

I therefore proceeded to examine the spine, but previous to the examination I gave hypodermatically: Morphin sulph., gr. $\frac{1}{8}$, atropin sulph.,

[1] Read before the Colorado State Medical Society, Denver, June 21, 1893.

gr. $\frac{1}{200}$; trinitrin, gr. $\frac{1}{5}$, to relieve the pain and increase the force of the heart.

We then turned the patient on his right side, this being preferable to the left, on account of the weak condition of the heart.

Beginning at the occiput, I passed my finger slowly down the spine, pressing firmly against the vertebræ. When the space between the fourth and fifth cervical vertebræ was reached there was a distinct and abrupt depression, the more marked on the left side. Pressure of the finger on this point was extremely painful. The spinous process of the next vertebra below was quite prominent. Passing the finger further down the spine it was impossible to detect any other abnormal deviation or painful point.

I examined carefully for crepitus, but was unable to detect any, a fact that in itself was not sufficient to exclude fracture. There was some swelling of the muscles of the neck, but no indication of external contusion. The man was very muscular, and I found it quite difficult to distinguish the spinous processes, especially in the cervical region. In the left occipital region there was a contusion of the scalp, one inch in length, caused by the fall.

By a careful consideration of the foregoing history and symptoms, I gave a diagnosis of dislocation of the fourth cervical vertebra, with or without fracture, causing extreme pressure, and perhaps contusion of the cord.

In such cases the propriety of attempting reduction is not questioned by modern surgical opinion. Therefore, having the consent of both the patient and his family, I decided to attempt reduction at once, in order to relieve the compression, and as affording the only hope of restoring the function of the cord, and prolonging life. Considering the very low state of the vital powers, the administration of an anesthetic was believed to be contra-indicated.

Having placed the patient on his back, with the aid of four assistants I proceeded to exercise extension. With an assistant at each lower limb, and one at each shoulder, I took my position at the head, with one hand on either side, the forefinger of each hand resting below the inferior maxilla, and the other fingers supporting the neck and occiput. We then began gentle traction, which was slowly increased. When the extension and counter-extension reached the point that the body retained the horizontal position without touching the bed, a sudden jar was distinctly felt by each of us, and was plainly heard by all who were in the room. We then gently lessened our traction, and slowly lowered the body to the bed. Neither rotation nor flexion was practised, from fear that they might be the means of increasing the pressure on the cord. We were thus keeping within the bounds of conservatism, with the least possible risk for the patient. But if reduction had not been possible without them, I certainly would not have hesitated in resorting to them.

The man complained of no pain during the operation, and to all appearances suffered no depressing effects from it, being conscious during the entire time. Still being in the condition of shock, I ordered him to be surrounded with bottles of hot water, and brisk friction made over the body and extremities, placing also a strong sinapism over the heart, and a cantharides plaster over the seat of the injury. After an hour the pulse was quite perceptible at the wrist, but had diminished in frequency from 36 to 26. Six hours after the accident reaction was fairly established, the pulse at the wrist was stronger, the cutaneous surface warmer, the voice fuller and more audible, the respiratory act increased in volume and frequency, and the man began to experience a feeling of ease.

In simple *compression* of the cord due to dislocation the symptoms usually disappear promptly after the dislocation has been reduced. But upon making another careful test for the return of the functions of the cord, we found absolute loss of sensation, of voluntary motion, and of the reflexes. Therefore, I gave a grave prognosis, and insisted on having counsel.

Accordingly, on the following day, eighteen hours after the accident, Dr. H. T. Pershing kindly saw the case with me, and still later Dr. P. D. Rothwell. The patient was much the same as when I left him the night before, except that he was depressed by the awful consciousness of the approaching crisis. The pulse had increased to 72, and the respiration to 26. He had passed a fairly comfortable night; he slept several times with intervals of restfulness, and had occasional attacks of emesis. Retention of urine and well-marked priapism continued. We passed a silver catheter its full length, and failed to draw urine. The irritation of the catheter increased the priapism to such a degree that it deceived us into the belief that there was suppression of urine, and therefore we did not persist with other attempts.

Later in the day, twenty hours after the accident, Dr. Rothwell saw the patient, and found him very uneasy. He passed a long flexible catheter, and succeeded in drawing off over a pint of urine. Dr. Pershing carefully traced the line of anesthesia, and found it somewhat higher than on the night before. He also tested thoroughly for the deep and superficial reflexes, and has kindly furnished me with the following notes:

"The line of anesthesia ran, in front, between the first and second ribs; behind, along the spines of the scapulæ. On the right side it ran over the acromion; on the left it extended downward about two inches from the acromion, leaving a triangular space of normal sensibility over the deltoid muscle. There was total loss of both deep and superficial reflexes."

There was occasional emesis of a very peculiar variety during the first twenty-four hours. The abdominal and thoracic muscles took no part in the act. It was produced by an involuntary contraction of the diaphragm and the muscles of the stomach itself, to all appearances, without any effort or exertion on the part of the patient. Deglutition was not impaired. Liquids were given in small quantities at frequent intervals. The tongue when extended did not deviate to either side, and was devoid of any tremor. The muscles of the

face and neck performed their normal functions. The backward and forward movements of the head, as well as the lateral and rotatory movements, were not impaired.

One hour before death the line of anesthesia varied but little from that of the previous day. Priapism was slightly marked, though less than on the previous visits. The patient complained of feeling uncomfortable, and we passed a catheter, and drew off sixteen ounces of urine. The pressure of the distended bladder against the diaphragm, interfering with respiration, undoubtedly was the cause of the discomfort. In passing the catheter he did not feel the slightest sensation. When the instrument reached the sphincter vesicæ muscles it met with an obstruction. There being no history of stricture, it indicated that the sphincter vesicæ muscle was firmly contracted, and consequently not paralyzed.

Another very important point was also noticed in this connection. If in the latter part of the act the end of the catheter was raised above the level of the bladder the urine ceased to flow, but as soon as it was lowered the urine began to flow again. This would certainly indicate paralysis of the detrusor urinæ muscle, the elasticity of the bladder being alone sufficient to expel the urine when it was completely distended. The temperature had risen to 102° F.; the respiration was 28, the pulse 82. The man was perfectly rational. The voice was distinct, but he spoke with greater difficulty and less force. The face was much flushed. Respiration was very shallow; there were bronchial râles; the throat was filled with mucus; and there was inability to cough or expectorate. Death from asphyxia occurred forty-three hours after the accident.

The autopsy was conducted by Dr. Pershing twenty-four hours after death. There was a separation between the fourth and fifth cervical vertebræ, with complete rupture of all the ligaments and muscles of the right side, and separation to such an extent that the dura could be distinctly seen. The inferior articular process of the fourth vertebra passed forward and in front of the superior articular process of the fifth, lodging in the intervertebral notch between the body and the superior process of the fifth. Thus the interlocking of the articular processes maintained the dislocation, producing what Stimson terms "a complete unilateral dislocation." [1]

The cord and membranes were severely compressed between the lamina of the fourth cervical vertebra from behind, and the upper part of the body of the fifth in front, thus compressing them into nearly one-half of their former space. The meninges were not torn. There was no extra-dural hemorrhage. The entire cervical spine was removed, and has been preserved.

After the removal of the cervical portion of the spine, by using a little extension and counter-extension, rotating the upper segment, the parts could readily be displaced, the right inferior articular process of the fourth cervical vertebra slipping over and lodging in front of the superior articular process of the fifth. In reversing the order, using extension and counter-extension, and rotating the upper segment to the left, the parts went into position again with a distinct snap that could be plainly heard for a distance of several feet.

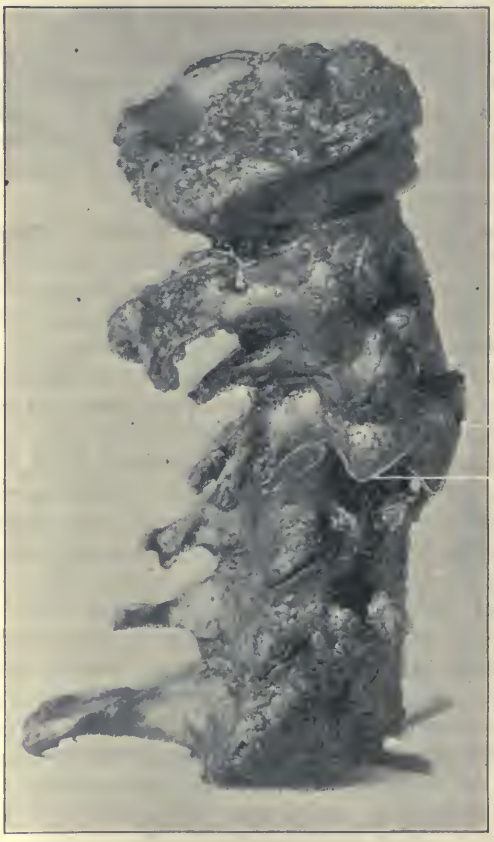
After removing the cord and membranes from the canal, the gross lesion showed distinctly where the crushing of the cord had taken place. A distinct circular constriction extended entirely around the cord at a point corresponding to the lower level of the fourth vertebra, or between the fifth and sixth cervical segments of the cord.

The cord has been preserved in Müller's fluid, but the pathologic analysis of its interior, showing the minute lesions by transverse sections, has been delayed on account of not wishing to destroy the identity of the gross lesion.

The discovery of the total absence of fracture was also a notable feature of the autopsy.

Dr. Axtell's notes of his examination of the cord are as follows:

On the anterior surface there is no macroscopic appearance of any trouble. On the posterior sur-



Specimen showing an anterior dislocation of the fourth cervical vertebra on right side.

a. Body of fourth cervical vertebra displaced forward.
b. Inferior articular process of fourth cervical vertebra.

face, opposite the fourth cervical vertebra, there is a depression in the cord, clean cut, looking as though a small tape had been bound over the cord. No inflammatory products are found in the membranes or on the cord. At the point of depression

in the cord it can be made to move readily, forward, backward, and laterally.

This is the only point where the cord can be thus bent. The cord has been imperfectly hardened in Müller's fluid. Thick sections of the cord just above and below the lesion present evidences of acute myelitis. The consistency of the cord is diminished, the bloodvessels are distended and the distinction between the white and gray matter is very slight. At the point of depression the cord is softened, and no sections can be made, as the tissue crumbles before the sharpest edge. Both the white and the gray matter seem to be a soft, crumbling mass, especially in the posterior half. Just beneath the membranes on the anterior surface the cord is of fair consistency.

Careful examination of the softened portion shows much granular matter, masses of myelin and numerous granule-corpuscles.

In this report I have endeavored to adhere as closely as possible to the true clinical phenomena. As a rule it is not well to generalize upon individual cases; but as the lesion is one of such rare occurrence, and the symptoms in this case were so typical and distinctly marked, and an autopsy also having been made to demonstrate the accuracy of the diagnosis and the character of the lesion, it seems worth while to make a brief review of some of the most important points.

In the first place the distinct vasomotor disturbance, indicated by the flushed face, the slow and feeble pulse, and the marked subnormal temperature would clearly indicate vasomotor paralysis, very probably due to injury of the cervical ganglia, situated on each side and in front of the cervical spine.

In spinal surgery the reflexes are among the most valuable diagnostic signs that we possess, although there is a wide difference of opinion among observers as to their diagnostic significance. Dr. Thorburn, of Manchester, England, who has made some excellent observations in this department of surgery, claims that in total transverse lesions of the spinal cord both the superficial and deep reflexes below the functional level of the injury are permanently and entirely abolished; while in partial lesions the reflexes are retained, perhaps exaggerated. He further claims that if the lesion causes complete paralysis and anesthesia the deep reflexes are always lost.[2]

One of the most important questions in this connection is the effect upon the spinal centers of isolating them from their cerebral connections. If there has been no error of observation in this case, I think it will bear me out with the statement that the functional activity of all the spinal centers below the lower level of the lesion were totally abolished with the exception of two: "the sexual reflex center" and "the tonic center of the sphincter vesicæ muscle." The proof that the *first* was not totally destroyed is demonstrated by the fact that the local irritation of passing the catheter increased the priapism to a very marked degree. The most plausible theory of priapism is that of Dr. Bramwell,[3] who claims that it is probably due to irritation of the "excitor" fibers, which pass from the cerebrum to the sexual reflex center. In other words, it is "a reflex act," produced by an irritation of these fibers at the point of the contusion of the cord. The fact that the local irritation of the catheter increased the condition tends to prove Dr. Bramwell's theory, in opposition to the old one of "vasomotor paralysis."

The proof that the *second* center was not paralyzed is very evident from the fact of the persistent retention of urine, without any dribbling whatsoever, notwithstanding the fact that the bladder was distended to such a degree that the pressure against the diaphragm from below quite seriously interfered with respiration. Dr. Lidell has observed that in these cases retention of urine is almost certain to exist for a time, to be succeeded by incontinence as soon as the sphincter muscle becomes paralyzed.[4] If the inhibitory fibers of the sphincter have been severed or destroyed, any voluntary inhibitory impulse sent from the brain will meet with resistance at the lesion. Consequently, if the sphincter is inhibited after there is total transverse lesion above the tonic center, it must be by "Gowers' reflex,"[5] that is, by sensory stimuli from the mucous membrane of the bladder itself. But in this case I think we have shown conclusively that both the motor and sensory power of the bladder-walls were paralyzed. Therefore, it seems to me evident, as the tonic center remains in force after the cord is completely crushed above it, that it is, at that time, *an independent spinal center, isolated from any cerebral connection.* Dr. Hughlings Jackson has observed that the highest centers of the nervous system, those that are the last to develop in the process of evolution, are the first to fail in dissolution and are the most readily affected by sudden irritation.[6] Reasoning from this data the natural inference is that "the sexual reflex center" and "the tonic center of the sphincter vesicæ muscle" are the most stable centers of the cord, as they are almost always the last to lose their functional activity after total transverse lesion of the cord.

So far as the prognosis is concerned in these cases there is very little to be hoped for. Dr. Thorburn states that it is hopeless to expect that the crushed cord can recover.[2]

Some suggest that the two segments might be innervated by transplantation of the spinal nerve roots, and thus restoring the function of the cord.[7] But this seems to be entirely too radical a measure, increasing the dangers to life, without offering any reasonable chance for improvement.

From the foregoing history, and from a rather

careful review of the sparse literature upon the subject, I make the following deductions:

1. In acute traumatic lesions of the spinal cord, when there is instantaneous and total paralysis of both sensation and voluntary motion, the probability is in favor of *crushing* of the cord rather than of *compression.*

2. When the cord is totally crushed, there being instantaneous and total loss of sensation and voluntary motion below the lesion, there is also total loss of the reflexes (the opinion of many good authorities to the contrary notwithstanding.)

3. When the cord is once completely crushed, as indicated by the foregoing symptoms, viz., instantaneous and total loss of sensation, of voluntary motion, and of the reflexes, reduction will not improve the symptoms, and surgical interference will very likely only shorten life, without offering any reasonable hope of improvement.

4. Priapism is probably due to a reflex act, rather than to a vasomotor paralysis, or to a combination of both, as demonstrated by the local irritation of a catheter.

5. Usually there is marked vasomotor paralysis, indicated by the flushed face, slow and feeble pulse, and profound depression of temperature, soon followed by hyperpyrexia.

6. Usually there is retention of urine, to be followed, sooner or later, by incontinence, unless the lesion is low enough to involve the tonic center of the sphincter, or unless the associated concussion has been sufficient to impair the function of this center. In either case there is paralysis of the sphincter and incontinence of urine from the first.

7. It is a characteristic peculiarity of acute traumatic lesions of the spinal cord that consciousness and the power of speech are very seldom lost, a very important contra-distinction to similar injuries of the cerebrum.

8. "The sexual reflex center" and "the tonic center for the sphincter vesicæ muscle" are very probably the most stable centers of the cord, as demonstrated by their persistence of action after complete isolation from their cerebral connections.

ACUTE ALCOHOLIC INTOXICATION IN INFANTS, AND THE ABUSE OF ALCOHOL IN THE GASTRO-INTESTINAL DISORDERS OF INFANCY.

By HENRY KOPLIK, M.D.,
of New York,
Attending Physician to the Good Samaritan Dispensary; Assistant Attending Physician to the Mount Sinai Hospital (Children's Ward).

The influence of alcohol and alcoholic drinks upon the organism of infants and children has been forcibly brought to the notice of the profession in an address of Professor Demme, of Berne. In this small brochure, which at first received much notice (1891) in the medical press, the influence of alcohol and its congeners was forcibly pointed out. It is surprising how little influence this work has had among physicians. The infant and child are peculiarly susceptible to alcohol, and its effects in both the acute and chronic phases have been well pictured by Demme. In the care of a very large infant and children's dispensary clientele I have noticed, during the summer months, and for the past few years called attention to the very large number of infants suffering from acute or subacute gastro-intestinal disease that are the victims of an unrestrained administration of solutions of whiskey or brandy. The parents of these infants are directed by their physicians or sanitary advisers to give the little patients minimal quantities of brandy or whiskey at stated or indefinite intervals. The mothers, in their helpless ignorance, overdose their children, adding the condition of alcoholic stupor to the weakness resulting from the effects of illness. It is an every-day experience in the heated term for me to be brought face to face with an infant very ill with cholera infantum, acute gastro-enteritis, or even simple diarrhea, which is nursing a warmed solution of a teaspoonful or more of brandy or whiskey, or gin, to half of a nursing bottle of tea or spiced water. Such infants are given these solutions for hours *continuously.* The mothers declare that it is the only thing the little patients will retain. This punch, for such it really is, stupefies the babe; it quiets the little sufferer, and lulls the mother into a false notion of improvement of the severe illness. At the outset, it must be remembered that these little patients bear alcohol as badly as they do opium. It may prove interesting to describe the condition of some of these infants as they come to me.

An infant or child that has had more alcohol than is wholesome for it will, in the primary stage of intoxication, act in a very peevish manner. From a good-natured infant, the mother tells you, it has degenerated into a crying sufferer; it throws its arms and head from side to side, refuses to be comforted, and will even strike itself or its parent. It will

try to leave the mother's arms, and then again will wish to return. In other words, the child or infant is over-restless, but not at all in the manner of children or infants that are simply sick. Looking at the features, we detect a dull, blank expression, very much like that seen in the intoxicated adult. Again, the eyes may be large and brilliant, or vacant and presenting a stare. Some infants sit up in the arms of the mother; they are weak and worn out by their illness, and during a respite from their symptoms they desire to play. If too much alcohol has been administered, however, there is a typical helplessness in the weak attempts at play. The brilliant and vacant eyes give the little ones an indefinitely quizzical expression.

In a more advanced stage of intoxication the infants present the signs of an unconquerable stupor. In spite of pains or movements they are actually soporose. They no longer notice their surroundings. At intervals, when the pains of colic are great, the infant may cry out.

That the use of alcohol among all classes is quite common in diarrheal disturbances there can be little doubt. The highest authorities seem to sanction this use. It is not surprising, therefore, that the abuse of a good remedy has become so flagrant that we must question whether the harm produced in allowing the use of alcoholics by the laity in a general way does not far outweigh any temporary benefits. If the doctor himself, or nurse, or among the poor the district nurse, could personally administer the remedy, some good might accrue; but even here I think the good in gastro-intestinal disorders can only be temporary.

Let us view this question from another standpoint. The infant, or even adolescent organism, is very susceptible to the effects of alcoholic drinks. Demme says that in his experience a dram of whiskey produced acute intoxication in a boy of fifteen years. I have now on my list of private patients a little friend of twelve years in whom a full hysterical attack, with its varied modifications, can be developed by a very small glass of sherry wine. Demme says that cognac, as used by the poor, contains 55 per cent. of alcohol; whiskey from 45 to 50 per cent.; wines from 8 to 10 per cent.; malaga or port, so much in use among children, 28 per cent. of alcohol. Bartholow says that the average sherry contains thirty-nine parts by weight of alcohol. According to Lehmann, the German wines only contain as high as 12 per cent. of alcohol. These figures are given in answer to the invariable and careless question put to us as to how much alcohol, if any, is contained in the so-called "*few drops*"? of brandy or whiskey. My studies in infant-feeding have convinced me that alcoholics, as they are administered to infants to-day, are a source of great harm in the treatment of disturbances of the stomach and intestinal functions. Small quantities, and these cannot be exactly gauged, may stimlate the functions of the stomach at first. Nausea and vomiting seem to be checked at the outset by small quantities of ice and brandy. This effect, which, in my experience, is always transient in infants, is succeeded by vomiting, which is uncontrollable and more serious than that which had ushered in the illness, to be followed by symptoms of intoxication. Mothers constantly corroborate these views of mine. Demme, quoting from Kretschy, says that small doses of dilute alcohol stimulate the production of the stomach-juices. Larger doses, or doses taken during the period of digestion, disturb and retard the stomach-digestion, or even temporarily suspend it. The same writer says that the customary addition of from one-half to one teaspoonful of cognac to the milk of children, when given for a time, as is customary among the laity, disturbs the processes of digestion. It causes chronic irritation of the stomach and dyspepsia.

During the past few years I actually have avoided, or, if necessary, forbidden, the use of all alcoholics in the treatment of the acute gastro-intestinal disorders of infancy. This rule, universal as it has been in my practice, has convinced me, through the very satisfactory results obtained, that there can be no excuse for the use of alcohol in these cases.

It is only recently that I horrified the family of a physician whose infant was mortally ill with acute gastro-enteritis. The little infant, seven months old, was as sick as it was possible for such an infant to be. It was bottle-fed, and in midsummer had been attacked by acute gastro-enteritis. It had lost five pounds in one week, and, when I saw it, was living principally upon whiskey. It was stupid with whiskey, soporose, throwing its head from side to side when distressed, the features blank, without expression to the eyes, and moreover with constant vomiting of the food. In conjunction with other modes of treatment the whiskey was immediately stopped, much against the family's wishes. The little patient recovered without another drop of alcohol, in spite of the attendant's misgivings. This case is mentioned as one in which I am certain that my ideas were followed out; also as an instance of one of the sickest infants I have ever seen recover.

I have washed out the stomachs of infants, and the fluid thus evacuated smelled strongly of brandy administered by the mother to excess. The physician had ordered it. As already asserted, I never use brandy or whiskey in any form in the acute stages of gastro-intestinal disease. It is not physiologically correct to do so. If the gastric functions are disordered, if the acidity is reduced, and as in severe cases even the enzyme is not produced in its normal quan-

tity, alcohol administered as described only makes the diseased state worse. Epstein in his almost classic paper on the nature and treatment of cholera infantum (Henoch's *Festschrift*, 1891) calls attention to the harmful use of alcoholic solutions or wine at the outset of the disease, the marked tendency of these cases to alcoholic intoxication, and the similarity of some signs of this intoxication to those of true cholera infantum. He also has found wine in large quantities in the atonic stomachs of such infants in whom there is gastric atony to a marked degree.

The two arguments in favor of alcohol that have been used at times when the stomach-digestion of infants was less understood than it is to-day are: First, that the stomach-juices should be stimulated; and, second, that we should try to foster the strength and support the heart of the little patient.

To-day the most approved method of treating an infantile stomach suffering from transient or acute disturbance is not to stimulate its functions, but to give the organ complete rest. Food is absolutely interdicted, especially such food, like milk, as is bulky and leaves a residue. The stomach is washed out (Epstein). The infant is placed upon solutions of egg-albumin for at least twenty-four hours. The best results are thus obtained by waiting for a restoration of the gastric functions. After twenty-four hours, if we find the stomach tolerant, and active symptoms have subsided, we still abstain from foods that leave residues, and give beef-juices, and gradually return to a milk-diet after all danger of gastric irritability has passed. If there is a condition of reduced acidity of the stomach we must supply the want in the shape of minute doses of dilute hydrochloric acid. If the failing strength of the patient should demand it in cholera infantum we can replace alcohol with much greater safety to the patient by the use of spartein, from $\frac{1}{64}$ to $\frac{1}{32}$ grain, every few hours, or $\frac{1}{500}$ grain of strychnin if collapse threatens to set in. Minimal doses of strophanthus and digitalis ($\frac{1}{2}$ minim of the combined tinctures every three hours) will act very satisfactorily and for a longer period of time. Camphor is very disagreeable, and therefore should not be given; the same applies to musk.

My argument thus warns against the use of alcohol as rather aggravating the conditions it is intended to relieve.

It has not been the object of this short paper to exhaust the subject of alcoholism in infants and children. I also believe with Demme that it would be deplorable should the abuse of alcohol carry with a suspension of its use at the bedside of the infant. With Demme, Binz, and Jaksch, we must all recognize the great utility of alcohol as a cardiac stimulant in diphtheria, scarlet fever, measles, erysipelas, and typhus fever. But it is here my primary object to call attention to the abuse of alcoholic drinks in the acute gastro-intestinal disorders of infancy, and also to show how the very large number of cases coming yearly under my care have been successfully and conscientiously treated absolutely without the aid of alcohol in any form.

THE VALUE OF STETHOSCOPIC PERCUSSION IN MEDICAL DIAGNOSIS.[1]

By HENRY SEWALL, Ph.D., M.D.,
of Denver, Colorado;
Professor of Physiology, Medical Department, University of Denver; Visiting Physician to St. Luke's, St. Anthony's, and Arapahoe County Hospitals.

That it is through the means of physical exploration that medical diagnosis most nearly approaches an exact science is a doctrine that should be fruit ful in good results. When a method of physical examination for which masters in medicine have claimed unusual advantages has not come into general use, there must be some strong and practical reason for it; and it will be the object of this paper to point out that reason, and to urge the value in physical diagnosis of the application of stethoscopic, or as it is more commonly termed auscultatory, percussion.

In 1840 Drs. G. P. Camman and Alonzo Clark published in the *New York Journal of Medicine and Surgery* an article entitled "A New Mode of Ascertaining the Dimensions, Form, and Condition of Internal Organs by Percussion." These authors recommended in carrying out their method a special form of stethoscope made of a single piece of wood, some six inches long and an inch in diameter, wedge-shaped at the extremity to be applied to the body, and broad at the other to fit the ear of the observer. Percussion was carried out by the use of a pleximeter, which was presumably manipulated by an assistant. No work that has been done on this subject bears the evidence of such exact and thoughtful observation as that of Camman and Clark, and their own words form an admirable description of the application and results of the method. They say:

"The observer, suppose, practises first over the heart, listening and percussing on the same region. With each blow of percussion the ear receives a sudden, clear, intense sound of high tone, attended with a degree of impulse even painful, appearing to be immediately under the instrument or produced within it, of short duration, and ending with some degree of abruptness. Now find the longest diameter of the heart in contact with the walls of the chest; it may be three inches; listen at one extremity and percuss at the other. The sound is the same in

[1] Read before the Pan-American Medical Congress, Washington, September, 1893.

character and has lost little of its energy. Percuss at the point where the lung begins to overlay the heart, the sound is instantly modified and mixed, yet its cardiac type is still preserved. Recede still further with percussion, moving by short steps toward the body of the lungs; at a certain point the sound suddenly changes. It loses its intensity and high tone; it is no longer impulsive; it is grave and distant, much more distinctly heard by the open ear than by that applied to the instrument. Again, let the observer in like manner explore the hepatic region. Within short distances the sound is sudden, clear, intense, and immediately under the instrument as before; yet it is less intense, less acute and more prolonged; it is even semi-reverberant. As he increases the distance between the points of auscultation and percussion, the sound diminishes more rapidly than over the heart, though it is not entirely lost till percussion passes off from the organ on to another medium. By this mode of exploration, the heart and liver become distinguishable through a class of signs which, judging even from the analogous consistency of these organs, would not be supposed to exist."

In 1880 T. A. McBride described (in the *New York Archives of Medicine*) a form of binaural stethoscope, composed of solid wooden pieces, by which auscultatory percussion could be conveniently carried out by a single observer. These authors restricted themselves chiefly to the determination of the outlines of the heart and liver. Various other observers, including Roussel,[1] de Mussy, Zuelzer,[2] and, according to Weil, even Laennec and Piorry, have called attention to the facility with which organs and morbid growths could be differentiated by the stethoscope applied to one side of the chest while percussion is carried out by an assistant on the opposite side. It is extraordinary, as is remarked by McBride, that, in the recognized treatises on physical diagnosis, the method of auscultatory percussion has received but little attention and no indorsement. Gerhardt[3] appears to make no reference to it. Weil[4] speaks slightingly of the method and declares that, as a rule, it offers no special advantages. Loomis[5] and Page[6] mention the procedure on the authority of Camman and Clark; Gemmel[7] incompletely describes it; but all these writers refer to the subject as if at second hand, as if they had failed to give it personal investigation. It is, therefore, not surprising that the active members of the medical profession are, for the most part, either wholly unfamiliar with the practical application of auscultatory percussion, or, in isolated instances, only use the method when some accident of experience has illustrated its value.

The reasons why physical examination by the method of stethoscopic or auscultatory percussion has not come into general use are not far to seek. In the first place, the mechanical impediments to the pursuit of the practice have been made burdensome; special forms of stethoscopes, useful only in this particular kind of examination have been recommended, and, usually, the services of a skilled assistant are required, to carry out the observations. In the second place, most descriptions of the findings of stethoscopic percussion enter so fully into the pitch and quality-differences of sound elicited by percussion of various organs as would manifestly need for their appreciation such a musical cultivation and training in the physics of acoustics as might well discourage the student in medicine from attacking so cumbersome a method.

I have never employed the special instruments described by Camman and Clark and McBride, though it seems probable that the results so obtained must be particularly striking and accurate. But it is the particular design of this essay to show that auscultatory percussion may be advantageously and readily carried out by any single observer who uses a stethoscope; that it is the easiest of all methods of physical examination; that it allows the accurate outlining of organs and deposits impossible of delimitation by ordinary means, and that, though capable of extensive development as a means of diagnosis under the acoustic skill of the observer, its limitations are so well marked as to instruct, without confusing, any ear that can hear.

My own work has been done with the simplest form of binaural stethoscope. The diameter of the bell to be applied to the body is five-eighths of an inch at its mouth, so that it can usually be inserted between the ribs of a patient. It should be remarked, however, contrary to McBride's statement, that, by this method, it makes little apparent difference whether the mouthpiece of the stethoscope overlaps the ribs or lies wholly between them.

I was first impressed with the value of auscultatory percussion on attempting to outline the stomach in the case of an old man the victim, apparently, of chronic peritonitis, whose intestines were inflated with gas. It was not possible by ordinary percussion to determine the lower border of the stomach. The stethoscope was applied over the upper left border of the epigastrium, and with the pulp of the middle finger of the right hand the abdominal wall was gently tapped, so gently that no sound was audible to the unaided ear, the finger being carried in a straight line from the stethoscope outward. With each blow of the percussing finger a peculiar shock, with a certain loudness and quality of sound, was

[1] Quoted by McBride.

conveyed to the ear, gradually decreasing in intensity as the percussing finger receded from the stethoscope until a certain point was reached; then the loudness of the tone and the intensity of the shock suddenly diminished; at the same time the quality changed, but it is desired to especially observe that quality-differences in sound are to be left to the unconscious appreciation of the examiner and are not to be depended on in this description. Having marked the spot at which this change in sound occurred, the percussing finger was carried from the stethoscope as a center along other radii, and it was found that the line joining all the points so determined represented the shape of the greater curvature of the stomach. Whenever the outline of an organ was determined in this manner the result was verified by placing the stethoscope outside its limits and percussing up to it. It frequently occurs that the boundary between two adjacent organs can be more readily determined when auscultation and percussion are performed on one than on the other.

In outlining an extensive body, as the stomach or the liver, it is frequently of advantage to shift the position of the stethoscope along the line of percussion. I have paid more attention to the determination of the outlines of the stomach than of any other organ, because the difficulties to be overcome are in this case, perhaps, on the whole the greatest. In six different autopsies the stomach was outlined in the manner described, the boundaries being marked by inserting pins into the abdominal wall perpendicular to the surface, and their position among the viscera afterward determined by section. In one of these cases the stomach was dilated, reached far into the right hypochondrium, was wholly covered by an enlarged liver, and the abdominal cavity contained free gas. In another the stomach was contracted into the form of a tube having a diameter of less than two inches. Nevertheless the greater curvature of the organ was outlined in each case with almost perfect accuracy. The greatest error occurred in a case in which the border of the stomach lay just under the free margin of the ribs; one pin was found to have been inserted into the stomach three-fourths of an inch from its edge, and another half an inch below it. It is worthy of remark that, although the stomach and colon are thus usually distinguishable, the stomach and duodenum do not appear to be, and my pins sometimes traced the course of the gut for a distance beyond the pylorus. Leichtenstern, quoted by Weil, used a somewhat similar mode of stethoscopic percussion to differentiate stomach from colon, depending, however, on the pitch and quality of the notes elicited from the two organs. But it is worthy of being insisted on that, though the pitch and quality of the percussion note vary with the organ struck, and at least unconsciously are appreciated by the examiner, the most important factors to be noticed when the percussing finger passes from one organ to another are the changes in loudness and shock of the note.

In those not infrequent instances in which the stomach gives to ordinary percussion a dull sound, stethoscopic percussion is at no loss to distinguish the true boundaries. In a recent clinical case in which this stomach-dulness made it impossible to outline in the ordinary way the contiguous borders of liver, spleen, and lung, the difficulty disappeared at once upon use of the stethoscope.

In another patient in whom the determination of the superficial area of the liver was of great importance, the liver-dulness as made out by ordinary percussion extended only over one costal interspace; stethoscopic percussion, however, showed that the liver reached the margin of the ribs, giving the organ a normal volume. The next day, after free purgation, the normal limits of liver-dulness were determinable by ordinary percussion.

Probably few examiners are capable of outlining with certainty the border between the liver and a superincumbent pleural effusion; by stethoscopic percussion, however, the separation is easily determined. In an autopsy in a case of pyopneumothorax it was found possible to define within one-fourth inch the boundaries of both relative and absolute liver-dulness, as verified by aspiration of the fluid and by section. To fix the line of division between air and fluid involved, of course, no difficulty.

The method offers valuable assistance in determining the level of effusions, pleuritic or abdominal. In the latter case spleen, liver, and kidneys can easily be distinguished. The splenic borders are readily determined when obscured to ordinary percussion by contact with a distended stomach.

The cranial sutures can usually be made out by stethoscopic percussion of a bald head or shaven scalp. I have watched in vain for an opportunity to outline, if possible, a superficial brain-tumor.

The most interesting application I have found for this method was in a case of pneumonia in which an encysted empyema developed outside the lower lobe of the left lung. The pus touched the chest-wall in contact with and parallel to the sixth and seventh ribs throughout their anterior and lateral portions. Neither by ordinary percussion nor by auscultation could the empyema with certainty be distinguished from the adjacent solid lung-tissue; but by stethoscopic percussion the cyst was outlined, and my colleague at the County Hospital, Dr. John Boice, resected a rib near the lowest point of the area so determined, and declared that no better place of

incision could have been chosen. Had the chest been opened in the ordinary region the cyst would have been missed altogether. In another case, one of a large empyema, encysted over the liver, stethoscopic percussion assisted the surgeon by exactly locating the top of the latter organ.

The delicacy of this method is nowhere better illustrated than in examination of the normal lungs. When the stethoscope is placed over one lobe and the percussing finger is made to travel across to another, there is a distinct change in the sound as the interlobular fissure is passed. Though but little attention has been paid to this part of the subject, I have on two occasions at autopsies inserted long needles with considerable accuracy into the line of the interlobular fissures as determined by auscultation percussion.

The limits of usefulness of the method of stethoscopic percussion as thus described are obvious. While a trained ear by the aid of special instruments, such as those devised by Camman and Clark and McBride could, no doubt, determine the physical condition of the organs investigated, as to their fluid, solid or gaseous contents the present paper does not treat of this possibility. The sudden diminution in the shock and intensity of an auscultation-percussion note as the body-surface is tapped by the finger moved along radii centering in the stethoscope simply means that the percussion has reached an organ, growth, or effusion outside that over which the stethoscope is placed. This result is altogether to be expected, as vibrations set up in any homogeneous body must suffer great diminution in energy whenever transmitted to an adjoining body of whatever consistence. Stethoscopic percussion must be used in conjunction with ordinary percussion and with consideration of topographic anatomy. For example, the position of the border of the left lung upon the heart can usually be accurately determined; but whether or not this line marks the lower or upper margin of the heart, the sound elicited does not make clear.

In fact, twice at autopsies needles were inserted into the margin of the lungs covering the heart, with the thought that the lower border of the latter organ had been outlined; further experience corrected such mistakes.

An advantage possessed by the method of stethoscopic percussion deserving of special mention is the feeling of certainty with which its results usually impress the examiner. In post-mortem observations I have been interested to note that when stethoscopic percussion had given distinct evidence of the outlines of organs, no mistake was ever made. On the other hand, whenever an error was committed, the examination itself had been dubious in its indications.

CLINICAL MEMORANDA.

THE OCULAR SEQUELÆ OF EXPOSURE TO THE SUN; WITH A REPORT OF TWO CASES.

BY HOWARD F. HANSELL, M.D.,
CHIEF ASSISTANT, OPHTHALMOLOGIC CLINIC OF JEFFERSON HOSPITAL; ADJUNCT PROFESSOR OF DISEASES OF THE EYE, PHILADELPHIA POLYCLINIC.

COMPARATIVELY few cases of disease of the eye have been published which have been traced to insolation as the cause. I would, therefore, assume that they are infrequent. Among sixteen thousand patients presenting at the eye clinic of the Jefferson Hospital none attributed the cause of their complaint to exposure to the sun (Hansell and Bell, *Arch. Ophth.*, Jan. 1892). Both on account of the rarity of such cases and also that a novel procedure was attempted in Case II, with moderately satisfactory results, the two cases recorded herewith are of interest.

CASE I.—H. P., eight years old, was brought to me in October, 1891. His mother stated that toward the close of the previous month, after a week of intensely hot weather, her son had been very ill with symptoms of brain-fever, and had been treated by a physician. During two days, while the fever was at its height, the boy had been comatose and delirious. The parents lived on a farm in New Jersey, and the child had been exposed the greater part of each day to the direct rays of the sun. He had had no acute attack of sun-stroke, and, until the eye-examination had been made, attention was not directed to the sun as a cause of the illness. After recovering from the acute attack he complained, mainly, of double vision. The tests showed marked internal squint from paralysis of the right external rectus. The eyeball could not be rotated outward beyond the median line, and everywhere in the common field, including the extreme left, diplopia was found. Directly in front of the patient, 6 m. distant, the images of a candle-flame were fused by a prism of 20° base out. V. in R. = 6/30; L. = 6/40. The optic discs were more pallid than normal and surrounded by a narrow ring of atrophied choroid. The arteries were normal in caliber; the veins dilated. The fields for white and colors were not taken. The diagnosis made was: Pressure upon the right abducens by exudation from a meningitis of the base, originally caused by exposure to extreme heat, and involvement of the sheaths of the optic nerves by extension of the inflammatory process. The treatment was potassium iodid, potassium bromid, each 7½ grains t. d.

In December, three months after the treatment was inaugurated, the following condition was noted. There was binocular fixation and V. = 6/6 in each eye. Muscular equilibrium was restored; the circulation in the retinæ and discs was normal, and no pathologic appearances existed, excepting the rings of disturbed choroidal pigment.

CASE II. (Exhibited before the Section of Ophthalmology of the College of Physicians.)—Lizzie McK., thirty years of age, a child's nurse, during the excessive heat of July, 1892, suffered severely from headache, but was not confined to bed. In the following October, her vision having perceptibly failed, especially in the right eye, she consulted an ophthalmic surgeon,

who prescribed R. and L. + 1.50 D., without having made a careful examination of the eye-ground. Vision continued to fail, until, in February, 1893, she was obliged to relinquish her position, and then consulted me. I found the right eye divergent and V. = 5/200, the media clear. There was an enormous swelling of the disc, greater in the lower quadrant, where it appeared as a tumor overhanging the retina. The retina, excepting in the immediate neighborhood of the disc, where the swelling from edema and exudation was considerable, was free from hemorrhages or inflammatory changes. The field of vision extended less than 10° from the point of fixation. The percipient portion of the retina was confined to that area lying close to the fovea; or stated, perhaps, with greater accuracy, the optic fibers supplying the foveal region were the only ones susceptible of conveying retinal impressions. Colors were recognized only at the point of fixation. The pupil was dilated and sluggish in its response to light and convergence. In the left eye there were the same ophthalmoscopic appearances, excepting that the swelling of the disc was less intense than in the right, and there was no greater bulging below. V. = 6/50, and the field for white and colors was concentrically limited to about one-half its normal size. The pupils were normal in size and reaction. There was no muscular paralysis in either eye. The divergence of the right was due to the very small field and dull central vision.

During the several months that the patient was under observation the divergence was variable and at times disappeared. The patient was subjected to mercurial salivation by inunction, carried to an unintentional and dangerous degree by the patient's disobedience of the directions given for the use of the ointment. The gums, tongue, and entire buccal mucous membrane were enormously swollen and covered with a layer of necrotic epithelium; every tooth was loose; saliva was constantly exuding from between the protruding lips and the breath was extremely fetid. No solid food could be eaten for two weeks. By diligent treatment with permanganate of potash sprayed into the mouth no permanent injury and no loss of the teeth occurred. After recovery she was put upon increasing doses of potassium iodid until 100 grs. daily were taken. Vision in the right eye increased to 20/70 and then fell to 5/200. The field remained unchanged. Vision in the left improved to 6/6, with enlargement of the field. After two months of the iodid treatment, strychnin sulf., gr. $\frac{1}{30}$ t. d., was substituted.

In May, no improvement resulting in the acuity of vision or in the enlargement of the field of the right from strychnin, and believing the vision to be hopelessly involved, I determined to stretch the optic nerve. The internal rectus and the conjunctiva having been freely separated from the sclera, under cocain, and held to the median side by my friend Dr. A. Hewson, who kindly assisted in the operation, a strabismus hook was passed backward with its point hugging the sclera until it reached the neighborhood of the nerve. By careful manipulation the nerve was caught in the bend of the hook and prudently, but with moderate force, drawn forward a number of times. The procedure, which I believe has never before been performed, at least under the same conditions, is a simple one. The only difficulty lies in the fact that one cannot see that the nerve is the part included in the hook. One can, however, be reasonably certain that one has secured the nerve, when by sudden traction the cornea is rotated several mm. outward, and the patient complains of seeing flashes of light and balls of colored fire. The operation is attended with considerable pain even under a liberal allowance of cocain. After the attempts at stretching are concluded the severed internal tendon is united by suture to the sclera in its former position or in advance of it. The operation is conducted under antiseptic precautions. During the six months that the patient has been under my care, the swelling of both nerves has materialy lessened, more markedly in the left, but the overhanging section in the right can still be distinctly seen. The arteries are diminished in caliber, the veins dilated and tortuous. The optic-nerve boundaries can be determined in the left, but not in the right. The latter is still covered with exudation, which has become nearly white; the former is distinctly outlined and pale. Vision in the right is 6/60, and the field is unchanged. In the left, vision = 6/6, the field is enlarged, but still concentrically contracted. The functional divergence of the right eye remains unchanged.

The only articles bearing directly on the subject that I have been able to find in accessible literature are by Alleman (*N. Y. Med. Journ.*, May 5, 1888), and by Spalding (*N. Y. Med. Record*, April 28, 1888). In them are reported the cases published up to that time. Alleman adds one case of his own. A blacksmith, while working on the second day of very hot weather, became dizzy and bewildered. He quit work at noon and walked with difficulty to his home, falling repeatedly. The following day the left side of his body was numb, and vision to the left was blurred. Three weeks later, when he presented himself at the Germantown Hospital, the right eye was normal. In the left there was a dilated and sluggish pupil and marked papillitis. There is no further report.

The changes in the optic-nerve end have been explained by Michel on the assumption that a thickened or otherwise altered condition of blood in the cerebral vessels has produced a high degree of stasis, followed by edema; by Hotz, on the theory that the papillitis is secondary to a meningitis of the base. Gowers says that insolation is an occasional cause of meningitis and influences chiefly the convexity. "In cases of death, only indications of congestion may be discoverable." Alleman thinks that the eye-symptoms are caused by a vasomotor disturbance of the local supply of blood, and refers the general symptoms—giddiness, headache, numbness, etc.—to the same cause. Hughlings Jackson claims that the group of symptoms is identical with that produced by a tumor of the cerebrum, "not as a pathological product, but by its general character of a foreign body."

In the two new cases described in this paper the ocular sequelæ must be referred to a local meningitis of the base, which was characterized by well-marked symptoms: intense headache, fever, delirium, papillitis, and transient or curable paralysis of the sixth nerve. So prominent were the discs in Case II that they suggested tumor as their probable cause. In the sense

that meningitis, attended with extensive exudation of solid matter and an increase in the contents of the ventricles, thus augments the intra-cranial pressure, it may be considered, clinically, as a tumor, and may be expected to bring about destructive changes in the origin, course, and termination of the cranial nerves. My own explanation of the paralysis in Case I is that the sixth nerve of the right side was implicated by direct pressure from exudation, and that the optic-nerve sheaths were becoming involved when the inflammation was interrupted by treatment; and of the choked discs in Case II, that the meningitis advanced as far forward at least as the optic foramina (perhaps to the scleral openings) and there produced strangulation. It was on this theory that I attempted to improve vision by operation—to separate, if possible, the adhesions between the sheath and the bony confines of the canal. That no marked improvement ensued should not militate against the justifiability and feasibility of the procedure. Had it been performed earlier, before atrophic changes had commenced in the fibers of the optic nerves, better results might have been obtained. If the fibers which convey impressions from the foveal region are surrounded in the nerve by the peripheral fibers and occupy its axis, it is reasonable to presume that the first to be destroyed from external pressure or inflammation of the sheath must be the fibers in juxtaposition to the sheath, and that the periphery of the field would be lost first. To suppose that choked discs, even of high grade, must invariably arise from the increased pressure of abnormally increased intra-cranial contents would frequently lead to error in diagnosis. Instances of large tumors without choked discs are common. Choked discs without tumors are equally common. Tumor cannot be differentiated from meningitis by the number of diopters of swelling of the disc, as is claimed. There is no constant relation between increased intra-cranial contents and the choked discs due to their presence. When, however, the tumor gives rise to a meningitis, and the inflammatory action extends to the neighborhood of the superficial origin of the ocular nerves at the base, an interference with their function may be expected. Indeed, localization can hardly be attempted without such evidence, whether it be a positive or negative. No efforts to localize a new-growth could be successful if paralyses of the cerebral nerves could be explained by attributing them to a cause so indefinite and general as increased intra-cranial pressure.

AN ULCUS ELEVATUM OF THE FACE.[1]

BY D. W. MONTGOMERY, M.D.,
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA; CONSULTING PHYSICIAN FOR DISEASES OF THE SKIN AND FOR PATHOLOGY, GERMAN HOSPITAL.

ON October 10, 1892, A. D., a waiter, aged twenty-eight, born in Italy, presented himself at the clinic of the University of California, complaining of a tumor below the left corner of the mouth. He said that two months before he had fallen on the sidewalk in a district of San Francisco known as "the Barbary Coast," and wounded himself. A pimple shortly afterward appeared at the seat of injury, which itched slightly, causing him to scratch it.[1] It then began to enlarge, and when seen on the date mentioned, it was a large, prominent, fleshy, circumscribed, convexly-rounded growth. There was a slight crust and some pus on its faintly granular surface, but most of the exudation was serous, and when well wiped and left exposed to the air it quickly became glazed from the drying serum. There was a shallow depression a little below and to the right of its center,

which, however, did not sensibly interfere with the hemispherical outline.[2] It was perfectly yielding and fleshy to the touch, without the least trace of chancrous hardness. There was no pain or itching. The skin formed a slightly raised rolled edge around the base of the tumor. On first looking at it, it did not make the impression of a chancre, but I instantly thought either of sarcoma, the surface of which might have been excoriated by irritant applications, or of that form of ringworm which causes large fleshy nodules on the bearded face, and which is called tinea kerion.

Although denying any other skin-lesion he was asked to strip, and there was found a dark-red papulo-squamous rash on the front of his chest, and a well-marked macular eruption on the abdomen. He had not known of either of these eruptions, as they had given him no trouble whatever. The macular syphilide, being especially characteristic, gave the key to the diagnosis.[3] Some scales from the rash on the chest and some hairs which were implicated in the tumor-formation on the

[1] Synonyms: Elevated papule or tubercle (Taylor); Chancre induré proéminent ou bombé (Mauriac).

[1] This case shows well the difficulty of trying to trace the source and the manner of the infection in extra-genital chancres, a difficulty which has been noted again and again in medical literature—for instance, by Siegfried Baum ("Casuistische Beitraege zur Kenntniss der extragenitalen Initialsclerose," Vierteljahresschrift f. Dermatologie u. Syphilis, 1885, p. 112). The patient in the present instance denied, and to all appearances in good faith, any knowledge of how he should have acquired his lesion.

[2] This shallow depression indicated central tissue-degeneration, which may go on to deep ulceration, altering very decidedly the appearance of the lesion.

[3] It was diagnosticated from tinea versicolor, which is sometimes mistaken for it.

face were examined microscopically, but neither the spores nor the mycelium of tinea was found in them. Furthermore those hairs of the beard which happened to be situated in the tumor were firmly set, and had no suppurative points or abscesses around them. There was also only one tumefaction instead of a number, as in tinea kerion.

There was one lymphatic ganglion indolently enlarged under the body of the lower jaw on the left side, and the posterior cervicals were also painlessly swollen, but none of the other subcutaneous lymphatics were demonstrable. There was at first no falling out of hair, no sore throat, no involvement of eyes or mouth, and no afternoon fever.

The resemblance of this dark-red, fleshy, rapidly-growing, prominent tumor of the face to sarcoma was very great, but the presence of the macular rash, and the fact that chancres, when occurring on the skin of other parts of the body—for instance, on the privates—do, although rarely, take on this peculiar form, allowed a correct diagnosis.

The patient was given the pills of the protiodid of mercury internally, and locally mercurial ointment was ordered. This course did not seem to have any marked effect on the chancre, and the local treatment was afterward changed to painting with the acid nitrate of mercury from time to time, and a salve composed of equal parts of oxid of zinc and white precipitate ointments. It now began quickly to subside, and the rash faded away. About twenty days after I first saw him his hair began to thin out in patches over his temples, but the alopecia was never very pronounced.

Taylor says the ulcus elevatum evolves out of the simple chancre erosion by an exuberance of cellular infiltration;[1] but it would seem from the patient's assertions that in this case it developed from a papule, and there does not appear to be any good scientific reason why it might not do so. Of course, we have only the patient's untrained observation, which stands a fairly good chance of being incorrect, as very few people would be likely to make the distinction between an erosion and a papule.

It would appear from a remarkable case of facial chancre, reported by Mr. Harrison Cripps,[2] that the surface of the ulcus elevatum, instead of being smooth, or granular, or only moderately papillary, may be markedly warty and dry, looking like a papillary epithelioma.[3]

The utter absence of hardness is a noteworthy fact, for the induration of primary sores of the head is particularly constant, marked, and characteristic. In fact, it was at one time held that all chancres of this region—"chancres céphaliques," as Ricord used to call them—were necessarily indurated; but this view has been modified by the clinical observation that some sores even about the head, which were followed by undoubted syphilis, never throughout their whole course exhibited the least trace of hardness.[1] Another point about this chancre was the slowness with which it yielded to treatment at first, which might have caused one to waver in opinion as regards its nature. But this seems to be an especial characteristic of the ulcus elevatum;[2] it may even not retrogress at all, but may go on to form a prominent warty mass, which must be removed by operative procedure of some kind.

When this patient was last seen, toward the end of November, the chancre was on a level with the surrounding surface, and rapidly disappearing.

[3] In Mr. Cripps' case the man noticed the growth between the lower lip and the chin two or three weeks after being cut by a barber. A fortnight later a rash appeared on his body, with sore-throat. The patient had a typical secondary squamous rash on the body when shown to the Medical Society of London ten weeks after being at the barber's.

A CASE OF POLIOMYELITIS IN A MAN AGED FORTY-FIVE YEARS.[3]

By THEODORE DILLER, M.D.,
of Pittsburg, Pa.
Member of the American Neurological Association; Visiting Physician to the Insane Department of St. Francis' Hospital.

Poliomyelitis is one of the commoner nervous affections of childhood, but is rarely seen in adults. Of 114 cases recorded by L. C. Gray,[4] the oldest was eighteen years. Some writers barely mention the fact that the disease may occur in adult life, while others state that the affection is one of childhood exclusively. Gowers[5] says: "The disease occurs at all ages, but is ten times as frequent in the first decade as in all the rest of life." Of 116 cases noted by him the oldest was in the ninth year.

In view of the extreme rarity of the disease, I have thought that the presentation of this patient, an elderly man, who is a sufferer from the affection, would not be without interest.

The patient, J. G., aged forty-five years, married, a plasterer by trade, has no specific history. He was a very hard drinker until two years ago, when he stopped drinking altogether. He has always enjoyed good health, and his family history is unimportant.

On December 31, 1892, while working at his trade, he noticed a swelling in his right hand. A certain loss of power in the hand quickly ensued. By the next morning the swelling of the hand had increased to a marked degree, and a distinct loss of power in the hand was very apparent to him. There was no heat, redness or pain about this swelling, which extended only to the wrist and involved chiefly the dorsal surface of the hand. It subsided in a few days. The loss of motor power noted as existing in the hand on the morning of January 1 (less than twenty-four hours after the swelling of the hand began) continued without any increase or diminution appreciable to the patient up to the middle of July, at which date I first saw him.

About two months after the onset of these symptoms

[5] Diseases of the Nervous System, vol. i, p. 352.

the patient noticed that the right forearm had become somewhat smaller than the left. This wasting increased slowly from the time he first noticed it.

When I first examined the man I found the following conditions: He was five feet nine inches tall, and weighed 165 pounds. The right forearm was much smaller than the left, from atrophy of the supinator and extensor muscles. The hand was deflected to the ulnar side, presenting the appearance of the "ape-hand" of certain writers. This appearance is evidently produced by the unopposed action of the muscles of the ulnar side of the forearm. There was some flatness of the back of the hand. The scapular portion of the deltoid was markedly wasted, while the clavicular portion was apparently unaffected. There was no appreciable atrophy of any of the muscles of the upper arm or shoulder other than this deltoid atrophy. In flexing the hand the little finger had nearly its normal power; the thumb was more affected than the little finger, but retained perhaps one-half or two-thirds its normal strength, while the loss of power in the index, middle, and ring fingers, particularly the two latter, was nearly complete. The man exhibited much more force in pronating than in supinating the arm.

All the extensors were very weak. The affected muscles failed to respond to either the galvanic or the Faradic current. No anesthesia or other sensory symptoms existed.

There was no loss of power or wasting of the muscles of the left arm or of those of any other part of the body. The dynamometer registered: right hand, 21; left, 84.

The painless atrophy, with the characteristic "ape-hand" made me think the affection might possibly be progressive muscular atrophy. But the sudden onset of the disease would preclude that affection. Besides this, the fact that nine months from the onset there is no atrophy of the muscles of the other arm or hand would tend to throw out this diagnosis. Progressive muscular atrophy always comes on slowly, and the paralysis keeps pace with and is proportionate to the atrophy, *i. e.*, the paralysis depends on the atrophy, not the atrophy on the paralysis—as in the patient before us.

The case might be taken for one of neuritis, involving either a single nerve or several or many nerves (multiple neuritis). It could not be one of inflammation of a single nerve, for the deltoid, supinators and flexors are not supplied by one nerve. In multiple neuritis both arms are nearly always affected, and there is always some pain. The deltoid atrophy could not depend on a neuritis, because the posterior half of the muscle is markedly atrophied, while the anterior half is apparently intact, and one nerve (the circumflex) supplies this entire muscle. If muscular atrophy resulted from inflammation of this nerve the atrophy would certainly involve the entire deltoid muscle and not one-half of it.

Although the man is forty-five years of age, and objects to having his disease called infantile, yet I think we must conclude that he suffers from infantile spinal paralysis—myelitis of the anterior horns. Certainly the onset and course of his disease corresponds accurately with the clinical picture of that affection. It came very suddenly, was painless, was characterized by palsy of certain groups of muscles, which subsequently became atrophied. The affection is monoplegic. There may have been slight fever (from 99° to 101°) at the beginning of the disease, but of this we cannot be sure, as the man was not under medical care at the beginning.

There is only one of the important signs of anterior poliomyelitis absent from this case, viz., the regression of symptoms, which consists in the return of power to certain of the muscles involved in paralysis at the onset of the disease, leaving only a portion of the muscles at first paralyzed to remain so, and subsequently to atrophy. This symptom is regarded as almost pathognomonic by Wood.[1] Indeed, the disease described by Dana,[2] under the name of chronic poliomyelitis appears to be little more than the acute form *minus* this symptom of regression. But the acute onset of the disease in this patient would forbid us labelling his affection chronic. So, in spite of the absence of the symptom of regression, I think, after looking at the case from these several points of view, that we may conclude that the paralysis and atrophy in this case were produced by an acute inflammation of certain of the multipolar cells of the anterior cornu of one side of the cord. In short, the case is one of acute anterior poliomyelitis.

I may add that under treatment, which has consisted in the administration of large doses of strychnin and the application of electricity, some improvement has resulted. When last tested with the dynamometer his record was: right hand, 28; left, 88.

WESTINGHOUSE BUILDING.

A CASE OF DOUBLE UTERUS AND DOUBLE VAGINA.

BY A. H. P. LEUF, M.D.,
OF PHILADELPHIA.

A BRIEF account of personal experience with a case of double uterus and double vagina may be of clinical as well as anatomic interest.

A woman, eighteen years of age, born in this country of German parents, and of rather stout build, was first examined by me on November 8, 1892, at which time I noticed a crescentic-shaped fringe of mucous membrane attached to the entire length of the anterior face of the cervix upon the median line. This began at the anterior border of the os, whence it passed up to the cervico-vaginal angle, and became lost upon the anterior wall of the vagina. The effect of this during a speculum-examination was to so tilt the cervix forward as to make examination difficult. It, of course, at once occurred to me that this was an instance of arrested development that might have been more interesting had the natural processes stopped sooner.

I made twelve specular and four digital examinations of this patient up to March 30, 1893, upon which date I found, mainly by accident, that she had a double uterus, of the variety known as *uterus bicornis*. The discovery was made while about to dilate the cervical canal, preparatory to curetting the body for menorrhagia. The cervix being tilted forward by the traction of the anterior blade of the speculum upon the frenum just described, I sought to depress the os with a probe by making counter-pressure. The probe slipped, and in

[1] American Text-book of the Theory and Practice of Medicine, vol. i, p. 764.

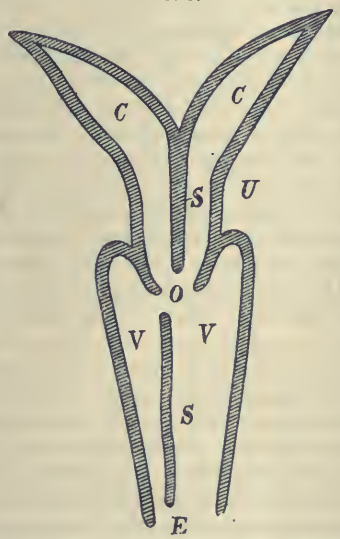
[2] Text-book of Nervous Diseases.

doing so exposed a septum within the canal a little back of the os. The view resembled that of the nares, with the anterior portion of the septum gouged out. While on previous occasions there had been no noticeable difficulty in passing a probe either to the right or to the left, I now found that this could not be done except upon its withdrawal and reintroduction. If passed into the right orifice, the probe turned most readily forward, and to the right, but could hardly be forced to the left, and then only by the spontaneous intra-uterine bending of the probe and decided discomfort to the patient. Similar maneuvers on the other side were followed by corresponding results.

Bimanual examination had been unsatisfactory all along because of the thickness and solidity of the hypogastric fat; but by a special effort I was now able to unmistakably make out the absence of a uterine body, and I could as positively distinguish the two horns of the bifid uterus.

Within the next twenty-one days I made three more specular and six digital examinations, when I found that the woman had also a double vagina. This finding was accidental, and showed that Nature had actually been as delinquent as I had regretted her not having been at the time of the first examination. During the introduction of the speculum on this day I met with some resistance, and the patient winced. The instrument was withdrawn, and the introitus opened with the thumbs and forefingers, exposing to view a crescentic edge of mucous membrane about one inch from the opening, and

Fig. 1.



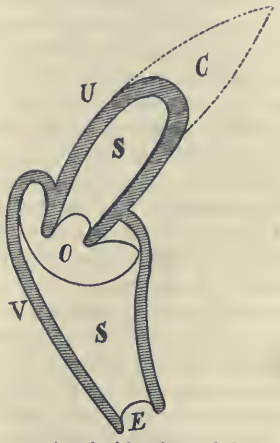
Representing a transverse section of the uterus. *U* is the uterus; *V*, the vagina; *C*, *C*, the cornua; *S*, *S*, the septum; *E*, the introitus vaginæ; *O*, the opening in the utero-vaginal septum.

almost in contact with the right side of the vagina. A more careful investigation showed the left canal to be decidedly the larger one, and this was in all probability the one through which entrance had been effected to the uterus by the speculum and the finger, as well as during coitus, which had been unattended with difficulty.

The septum was continuous to within about an inch or an inch and a half of the cervix. The finger readily detected the crescentic edge of the lower end of the vaginal septum, while the similar upper end could be distinctly felt by introducing the finger up to the os and then hooking it over the upper edge of the septum, and passing it as far down upon the right side as the length of the finger, together with the elasticity of the parts and the sensitiveness of the patient, permitted. The same procedure could be carried on in the opposite canal.

It thus required a total of fifteen specular and ten digital examinations to establish this anomaly. The

Fig. 2.



Representing a sectional side view of the uterus and vagina *U* is the uterus: *V*, the vagina; *C*, the left cornu bent away from the sectional surface and shown in dotted outline; *E*, the introitus vaginæ; *S*, *S*, the utero-vaginal septum; *O*, the opening in the septum.

difficulties in the way of an immediate diagnosis of the condition at the first examination were real and as peculiar as the condition itself. Rare as this anomaly is, its existence in the form described in this instance is still more unusual, perhaps unique. The dilatation of the left vaginal canal readily permitted the entrance of the examining finger without noting the septum. The same is true of the use of the speculum. The deficiency of the septum at its upper end kept it from view in all ordinary examinations, so that it could not be readily felt in ordinary digital explorations. It left the cervix free except at its anterior surface, and this would generally be accounted for, I believe, as I did. The stoutness of the patient, especially as regards her abdominal walls and viscera, precluded the ready recognition of the bifid uterus. The recession of the intra-uterine septum to a point far enough within the cervical canal to be invisible during the manipulations of an ordinary examination made its early discovery unlikely.

The one thing that should have called attention to the true condition earlier was the inability to explore the cavity of the uterus on both sides without the reintroduction of the probe. But I had never noticed this peculiarity until I had discovered the double canal, and this was in all probability owing to there having been no real need of intra-uterine explorations, so that it made no difference whether the probe lingered in the cavity or not, it being introduced only to determine the length of the organ, which was found to be fully three and one-half inches.

This patient had and still has very good health. She presents no other anomalies.

She was married at seventeen years of age and had been pregnant twice, on both occasions inducing abortion at the end of six weeks.

2353 NORTH SEVENTEENTH STREET.

MEDICAL PROGRESS.

Removal of a Large Vesical Calculus by Celiotomy.—MILTON (*Lancet*, No. 3655, p. 687) has reported the case of an Egyptian fellah, aged sixty years, who gave a history of having suffered with the symptoms of stone in the bladder for two years, and with total incontinence of urine for two years, although it was believed that the man had no adequate notion of the length of time. Upon examination a mass could be felt extending from the prostate to the umbilicus, and a loud click was evident on sounding. The urine was ammoniacal and contained mucus, blood, pus, albumin, tube-casts, and bilharzia eggs. The patient was bedridden and greatly exhausted. As the stone was evidently so large that it did not seem possible that it could be removed without making so large an opening in the bladder as to involve the peritoneum, it was decided that it would be safer to open the peritoneum at the beginning of the operation, and to take the necessary precautions to avoid its infection. The patient was chloroformed, and, after the usual precautions to insure asepsis had been taken, an incision was made in the abdominal wall from the pubes to the umbilicus. A small extra-peritoneal incision was then made into the bladder, in order to make sure that the mass was not constituted of several calculi, and also to permit of the cleansing of the cavity of the bladder with a boric-acid solution. As it was found impossible to detach the peritoneum from the upper surface of the bladder without opening the serous cavity, the peritoneum was incised from the bladder to the umbilicus. The lower extremity of this incision was little by little prolonged backward for about two inches, on the summit of the bladder, until its posterior limit was reached, the peritoneum being dissected from the bladder and dragged slightly forward before being incised, so as to obviate any danger of the serous surface being soiled by the contents of the bladder. As soon as the peritoneum had been opened sufficiently, its general cavity was shut off with plugs of sterilized gauze. The bladder was now incised to the full extent of its anterior and superior surfaces, and the stone was exposed. It could not be grasped with forceps, and pressure from below, with two fingers in the rectum, failed until two lateral incisions of the bladder-wall had afforded increased space, and allowed of easy delivery. The bladder was now thoroughly cleansed with a boric-acid solution, the peritoneum being closed with catgut sutures, the bladder with silkworm-gut sutures, and the abdominal incision with silver-wire sutures. A sufficient opening was left in the abdominal and vesical walls for a siphon drain, which reached to the post-prostatic pouch. The patient had a severe struggle for existence for the first eight days after the operation, his kidneys failing to act, the amount of urine sinking to ten ounces on the fifth day, and the temperature falling below normal. On the sixth day, as the siphon was clogged and would not work, the bladder was punctured through the perineum. On the thirty-fifth day, the patient having shown indications of the presence of another calculus, the perineal wound, which had closed, was reopened, and a uric-acid stone, weighing twenty-three grains, was removed. The patient's condition now improved, but as no power of expulsion was regained by the bladder, the perineal and supra-pubic fistulæ had from time to time to be reopened. The patient ate well, slept well, and went out of doors, but he never gained in weight. Two months after the first operation he began to sink, and died ten days later. For the last five days of life, in addition to his ordinary food, he was given one or two raw kidneys. Upon post-mortem examination, the bladder was found to be thickened and contracted, but otherwise healthy. The peritoneum showed no trace of surgical interference. Both kidneys were in a condition of advanced chronic apostomatous inflammation, and contained bilharzia worms. The stone removed from the bladder weighed 34½ ounces. Its largest diameters were four inches and six inches. The outer layers were constituted of magnesian phophates, but no examination of the inner layers was made, as the stone was not cut. It is believed to be the largest stone ever successfully removed from the human bladder.

Hemiplegia following Diphtheria.—EDGREN (*Deutsche medicin. Wochenschr.*, 1893, No. 36, p. 864) has reported the case of a boy, with a good family history, who had had measles and whooping-cough, and at the age of nine years an attack of diphtheria. This last illness was attended with severe vomiting. At the close of the third week, during convalescence, the little patient suddenly fell to the floor from the chair upon which he was sitting. It was not observed whether consciousness was lost or not, and whether paralysis was present or not, but on the following day it was noticed that the right side of the body was paralyzed, and that the power of speech was wanting. The patient himself was able to recall that for some time there were twitchings in the tongue and in the upper and lower extremities upon the right side. The right angle of the mouth was lower than the left; the right cheek and right half of the chin were motionless; but both eyes could be closed. The right arm and the right leg hung relaxed, though capable of feeble movement. The patient could not speak and could make only unintelligible nasal sounds. On attempts at swallowing, fluids would return through the nostrils. Sensibility was lost upon the right side, and this side was also colder than the left. Urine and feces were passed incontinently. In the course of five or six weeks the patient was able to walk about the house by supporting himself. This improvement continued, and in several weeks more he was able to speak intelligibly, though for several months in a nasal tone. The only further complication was a transitory paresis of accommodation. Examination a year later failed to reveal a cardiac lesion. Slight paresis of the lower portion of the face persisted. The tongue was protruded a little to the right. The left arm was somewhat stronger than the right. In walking there was a little stiffness, dragging and swinging of the right lower extremity, the movements apparently not being under perfect control. The

right hand became cyanotic when held dependent for a time. The ulnar reflexes were alike on both sides. The patellar reflexes were energetic and that upon the right more pronounced than that upon the left. The Achillis tendon-jerk was also more active upon the right than upon the left; and upon the right there was ankle-clonus. The sense of localization was less good upon the back of the fingers of the right hand than upon the back of those of the left hand. Electric sensibility was less perfect in the extremities upon the right than upon the left side. The electric irritability of the muscles upon the right side was diminished, but there were no qualitative changes. Considerable improvement followed treatment with electricity. A diagnosis of hemorrhage into the internal capsule of the left cerebral hemisphere was made.

The Motor Manifestations of Sciatica.—In a study of fifty-three cases of sciatica under observation at the Clinic for Nervous Diseases at Breslau, Mann (*Deutsche Archiv für klinische Medicin*, Bd. li, H. 6, p. 583) found that the affection is frequently attended with pareses, involving not only muscles supplied by the sciatic nerve, but also muscles supplied by other branches of the lumbo-sacral plexus. The flexors of the leg appeared to suffer most commonly. The paretic muscles usually displayed but slight atrophy and little or no change in electric irritability. When the paresis involved the muscles of the erector spinæ mass there resulted a typical form of scoliosis, the convexity of the curvature being directed toward the affected side (crossed scoliosis). The sciatic neuralgia may be unilateral, although the disease of the lumbo-sacral plexus, together with the disturbances of motility, may be bilateral. If, under these circumstances, the erector spinæ mass upon the side not affected with neuralgia is paretic, an homologous scoliosis results, the convexity of the curvature being directed toward the non-neuralgic side. At the same time, the possibility of the development of an homologous scoliosis as a result of spasm of the erector muscles upon the neuralgic side cannot be excluded. If the sciatica is attended with bilateral paresis of the abdominal muscles, lordosis of the lumbar spine will result—a condition that may be designated as lordotic sciatica.

Gunshot Wound of the Gravid Uterus.—Kehr (*Wiener medicinische Blätter*, 1893, No. 30, p. 391) has reported the case of a woman, thirty-nine years old, illegitimately pregnant, who attempted to commit suicide by shooting herself through the abdomen and uterus. The abdomen was opened and the bullet found to have entered the anterior wall of the uterus; bladder and intestine had escaped. The wound in the uterus was approximated by two rows of sutures and the abdomen closed. The operation occupied forty-five minutes. The subsequent course of the case was afebrile. For the first few days the woman complained of sacral pains and of a feeling as if labor were about to set in. From time to time a little bloody secretion escaped from the vagina. For eight days the urine was withdrawn with the catheter. The sutures were removed ten days after the operation, the wound having united by first intention. The patient arose from bed on the 12th day. On 14th day labor-pains set in and an uninjured fetus of about five months was expelled. The placenta failing to come away, it was found adherent to the anterior wall of the uterus, but was readily detached. The bullet, however, was not to be found. The uterus contracted well and the puerperium pursued an afebrile course. On the 10th day after the abortion the woman was out of bed, and on the 14th day she was dismissed.

Cirrhosis of the Liver in a Child.—At the recent Congress of the French Society for the Advancement of Science, d'Espine (*La Médecine Moderne*, 1893, No. 63, p. 796) reported the case of a boy, six and a half years old, who had been robust until the appearance of symptoms of hypertrophic cirrhosis of the liver, which terminated fatally at the end of three years. The liver extended two fingers' breadth below the level of the umbilicus; the spleen was enlarged; an ascitic effusion occupied the peritoneal cavity; and the veins of the anterior abdominal wall were greatly enlarged. In the course of the illness it became necessary to perform paracentesis thirty-six times. Potassium iodid had been tried, but without encouraging results. There was an absence of fever, except during the last six months of life, when there was slight elevation of temperature. There had never been albuminuria or icterus. After death, in addition to an intense interstitial hepatitis, the left pleural cavity was found obliterated, while the right was occupied with an effusion of fluid. The pericardial cavity was also obliterated, and the stomach was adherent to the liver. There was some ascitic fluid in the peritoneal cavity, together with evidences of chronic sclerotic peritonitis. There was also a perihepatitis with numerous adhesions of the liver at numerous points; and also a perisplenitis.

Diabetes Mellitus in an Infant.—Tavaria (*Indian Medico-Chirurgical Review*, vol. i, No. 7, p. 402) has reported the case of a Parsi male child, ten months old, which, following a fall out of its cradle, was wakeful and restless at night, uttering shrill cries from time to time. Earache was suspected, but there was no aural discharge and treatment was unavailing. The temperature rose to 102° and 103°, with slight remissions. It was now noticed that the child passed urine at short intervals, two or three times in the course of an hour. The total amount passed was large, although it was not measured. Flies collected in swarms about the wet napkins. The child cried constantly for drink and swallowed diluted cow's milk and mother's milk repeatedly in fairly large quantities. On examination the urine was found to contain sugar. The specific gravity was not ascertained. After the first week the child was greatly debilitated, though not emaciated. Some two weeks after the fall it was seized with pneumonia and rapidly succumbed. It had always been fed upon mother's milk and diluted, unskimmed cow's milk. The history of the case, the age of the patient, and the absence of other cause suggest a nervous origin for the glycosuria.

The Treatment of Chronic Suppurative Otitis Media by Excision of the Auditory Ossicles.—At the recent meeting of the British Medical Association, Milligan (*British Medical Journal*, No. 1706, p. 563) reported 15 cases of chronic suppurative inflammation of the middle ear treated by excision of the membrana tympani and the

auditory ossicles, and announces the conclusion that in cases of chronic suppurative disease of the middle ear accompanied by perforation of Shrapnell's membrane and the presence of parietal and ossicular caries, and in which careful local treatment has failed to effect a cure, the membrana tympani and the auditory ossicles should be excised. As a rule, the purulent inflammation ceases or greatly diminishes as a result of the operation, while such symptoms as vertigo, tinnitus, etc., are either cured or greatly relieved, and recurring attacks of headache are prevented. The power of hearing is usually either improved or remains unaffected, although in a few cases it is rendered a little worse. In cases of chronic disease of the attic, with a normal atrium, only the membrana flaccida Shrapnelli being perforated, the excision of the membrane and the ossicles, or the performance of some similar operation, is probably the only means of cure.

The Diagnostic Significance of Acetonuria.—HIRSCHFELD (*Deutsche medicin. Wochenschrift*, 1893, No. 38, p. 914) has found that upon a diet exclusively albuminous and fatty, acetone is excreted in the urine in increased amount. The addition of carbo-hydrates to the diet will prevent the development of acetonuria, *i. e.*, it leads to the destruction in the organism of the acetone formed. The fact whether or not a notable amount of the albumin of the body is destroyed has no influence upon the development of acetonuria. If large amounts of acetone are excreted in the urine diacetic acid will also be found to be present. In cases of diabetes in which the carbo-hydrates ingested are not largely burned up in the body acetone is excreted in large amounts. A diminution can be brought about by giving large amounts of carbo-hydrates or by adding glycerin to the diet. Some patients that died of diabetic coma presented progressive acetonuria in association with increasing loss of strength. No other than the diabetic forms of pathologic acetonuria is at present known. In all of the other conditions in which acetonuria has been observed (fever, carcinosis, gastric disorders) this was to be ascribed to a poverty of the diet in carbo-hydrates. In these conditions the acetonuria can be made to disappear by the administration of amylaceous or saccharine food.

Scarlatina Followed by Endocarditis.—LEA (*Medical Chronicle*, vol. xviii, No. 6, p. 395) has reported the case of a girl, seven years old, in which on the ninth day of an attack of scarlatina a systolic bruit became audible at the apex of the heart. The child had previously enjoyed good health, and had never had rheumatism. When she first came under observation, four days after the onset of her illness, the heart-sounds were normal. The murmur increased in intensity and was transmitted to the axilla. The urine at first contained no albumin, but on the twelfth day a faint trace was detected. Death took place on the thirteenth day. Upon post-mortem examination the left ventricle was found dilated, the cardiac muscle pale and smooth. Upon the auricular surface of the mitral leaflets were numerous vegetations. There was no evidence of pericarditis. Two days before death gelatin-cultures were made from blood obtained from a finger, and in the course of three days colonies of the streptococcus pyogenes developed. Cultures made from the vegetations upon the mitral valve also led to the development of the streptococcus pyogenes and of streptococci as well.

Scarlatina in a Man aged Seventy-nine.—HOWIE (*British Medical Journal*, No. 1706, p. 578) has reported a case of scarlatina in a man seventy-nine years old. The patient has sore-throat, the soft palate, fauces, and pharynx being intensely red and one tonsil presenting small, white patches. The pulse was 84, and the highest temperature 100°. There was no well-defined rash—only a slightly reddened prominence of the cutis at the various points of emergence of the hairs on the skin of the legs over the tibialis anticus muscle. No source of infection was known. After nearly three weeks the hands desquamated freely. In another case of scarlatina in a man, aged fifty-two, the rash was well-marked, although discrete. The children living in the same house were subsequently similarly stricken.

Posterior Luxation of the Lower Jaw.—BISCHOF (*Münchener medicin. Wochenschr.*, 1893, No. 31, p. 584) has reported the case of a man, nineteen years old, under treatment for pulmonary tuberculosis, who presented some difficulty in deglutition, to determine the nature of which a pharyngoscopic examination was undertaken. Suddenly, while attempting to open the mouth to the utmost, a snap was heard and the jaw was elevated. Thereafter the lower jaw could not be moved. The teeth of both jaws were correspondingly approximated posteriorly, but anteriorly the lower teeth were somewhat behind the upper. Examination gave so much pain that it was not pursued further. It was concluded that the lower jaw had been displaced posteriorly, but the condition of the patient forbade attempts at reduction.

To stain Tubercle-bacilli, CZAPLEWSKI (*Arb. aus dem Path.-Anat. Inst. zu Tübingen*, 1892, B. i, H. 3; *Monatsh. f. prakt. Derm.*, B. xvii, No. 4, p. 174) recommends the following procedure: The sputum is first spread in a thin layer upon a slide, dried in the air, and carefully passed through the flame of a Bunsen burner. Then carbol-fuchsin is added, and heated until the vapor of steam arises, when a solution constituted as follows is dropped upon the slide held obliquely, until the surface is cleared: hydrochloric acid and sodium chlorid, each 2½ parts; distilled water, 100 parts; a solution is made, and alcohol, 500 parts, added. The slide is then washed with water, permitted to dry in the air, and finally a drop of some immersion-oil added that can be readily removed by xylol.

The Nature and Pathogeny of Scrofula.—At the recent Congress of the French Association for the Advancement of Science, BLOCH (*La Médecine Moderne*, 1893, No. 63, p. 792) contended that scrofula is neither an affection of the lymphatic system nor an alteration of the blood, nor yet a disturbance of nutrition, but the result of a derangement of the bodily equilibrium, a perversion of development in one or several organs during intra-uterine life. The condition is thus of the nature of a degeneration, a morbid deviation from the normal type, which predisposes to certain affections, tuberculous and otherwise. It may be a manifestation of a morbid heredity, neurotic, tuberculous, or alcoholic, or a result of syphilis in father or mother.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

TRAUMATIC HYSTERIA.

FEW subjects are of more practical importance to the general physician, to the surgeon, and to the expert in nervous diseases than the exact nature of the nervous disorders following trauma. Considering this importance we think it remarkable that the subject remains still somewhat obscure, in spite of the otherwise luminous writings of the many scientists, in this country particularly, who aim to make a specialty of treating it both in court and out. It is said to have been not without cause that BENTHAM feared metaphors, but it might be with better cause, if he lived now, that he feared euphemisms. This whole subject is clouded with euphemisms. Of these the most objectionable, because most frequently employed, are "traumatic neurosis," "traumatic neurasthenia," "spinal concussion," and, if we dare call it an euphemism, "railway spine." These terms have evidently a common source—the wish to avoid the use of any expression that may convey the idea that the patient's condition is dependent in any degree upon a mental state. This wish is made obvious by the fact that any term connoting a mental state is rarely to be found as a designation of this traumatism in the works of recent American neurologists; and, we are not venturing much if we say, in the works of all recent neurologic writers outside of France. The source of this wish is not hard to be determined. In the exigencies of expert testimony, amidst the perils to justice in a trial by jury, it is felt instinctively that the admission of the presence of a mental element in a litigant would be fraught with great danger to the success of his suit in a trial for damages. This, we do not hesitate to say, is the motive.

That such a motive is the best adapted to confuse the subject is easily demonstrated. It tends to do this, first, because the mental element in these cases is paramount. In fact, in those cases in which no organic defect can be demonstrated (and these alone concern us here), the mental element is the essence of the affection. Hence, to ignore it, or to attempt to disguise it under euphemistic terms, is to put constantly in the background an element so essential that without a due regard for it no just idea of the subject can be either obtained or inculcated; and secondly, because this motive leads to a division into distinct categories of cases that are essentially of one and the same nature. We mean by this that traumatic cases, marked by most or many of the permanent stigmata of hysteria, and by nothing else, are separated, especially if the patients are litigants, from the great class of hysteria in general to which properly they belong. This leads to a confusion in nomenclature, and, far worse, to an error in fact. Let us examine briefly into this phase of the subject.

The same symptoms serve for the two classes of patients; that is to say, the inter-paroxysmal symptoms of hysteria proper serve also for the cases of "traumatic neurosis." This is indeed Protean and chameleon-like! Among the most important of these symptoms are the following: Various areas of anesthesia, either hemi-anesthesia or anesthesia in geometric figures—purely hysterical symptoms—these areas changing either by transfer from one side to the other or by alterations in size, shape, and location; paralyses, often associated with segmental anesthesia of the part (a very uncommon association in any but hysteric paralyses), showing a tendency, although not always, to recover on suggestion, *i. e.*, under moral influence or after a favorable verdict, and not presenting true atrophy or reactions of degeneration; contractures, often most persistent, as of an arm or of a hand on the arm; tremor, simulating most closely that of organic disease, and yet one of the most important and characteristic of the permanent stigmata (its presence after trauma ought always to suggest hysteria, especially in men);

incoördination and various *bizarre* affections of the gait known as astasia-abasia—a well-recognized hysterical symptom; contraction of the visual fields, alterations in the color-fields, monocular diplopia, and amblyopia of one or both eyes—the very earmarks of hysteria; finally, neuralgias and hyperesthesia, especially about the head and spine.

To class all these, or any combination of these, as indicating anything other than inter-paroxysmal hysteria is to run a grave risk of confusing an important subject and of committing a solecism in science.

Whence comes this aversion of writers in the English and also in the German language to the term *hysteria?* Is it an ethnic prejudice, or is it in the present case a shy regard for the prejudices of courts? BRODIE, in England, ROMBERG and VALENTINER, in Germany, demonstrated long since that hysteria is sufficiently frequent in both those countries; while in later years GUINON, GILLES DE LA TOURETTE, and the contemporary French school have shown incontestably that one of the most common causes of hysteria is trauma. But in Germany quite recently, and in England and America even more recently, a current of totally different ideas, under the influence of OPPENHEIM, has been established. This school seeks to establish a special neurosis, due to trauma, to which the name of hysteria is denied, but which is based upon many of the permanent stigmata of hysteria. This, as we have seen, has no justification in nosology.

We can illustrate this subject best with a brief reference to a very interesting case. PEL (*Berlin. klin. Wochenschrift*, 24, xxx, June 12, 1893) reports the case of a carpenter who fell from a high scaffold and was picked up unconscious. After regaining consciousness he exhibited during a period of about one year a variety of symptoms, the most important of which were the following: occipital headache and pain in the cervical spine; weakness in the right side, followed later by hemiplegia; vertigo and general weakness, which prevented his continuing work, to which he had returned after four weeks; later, depression of spirits and somnolence; increased knee-jerks; for a while normal use of the limbs during dorsal decubitus, but astasia-abasia while standing; later, with the onset of the hemiplegia, there was hemi-analgesia, hemi-anosmia, hemi-amblyopia, and bilateral loss of taste; later still, a typical hystero-epileptic crisis occurred. On the negative side the patient had no vomiting, no hemorrhage from ear or nose, no incontinence of urine, no choked disc, nor any change in visual or color fields. He died from catarrhal pneumonia more than one year after the accident, and a thorough autopsy revealed no organic lesion that could explain the symptoms.

To conclude, it seems necessary that the idea that hysteria is synonymous with simulation must be eradicated before this subject of hystero-traumatism can be placed for American readers in an advantageous scientific position. This idea at best is but a vulgar error. Those who entertain it are likely to find simulators in inverse proportion to their own expertness. The plea we make is for consistency in nomenclature, which is the first essential for clearness in scientific thought and expression.

FURTHER FACTS REGARDING THE BACILLUS AËROGENES CAPSULATUS.

WE have already on two occasions in these columns referred to the pathogenicity of the bacillus aërogenes capsulatus, and to the symptoms and lesions to which it is capable of giving rise in the bodies of men and animals. Examples of infection in human beings are now being reported from different quarters, and it seems probable that they are not so uncommon as was at first believed. P. ERNST, of Heidelberg (*Virchow's Archiv*, Band cxxxiii, Heft 2), records two interesting cases. The first was that of a woman of twenty-six, who had aborted at the fourth month, the fetus being partially decomposed. Septic endometritis followed and soon proved fatal. At the autopsy, made three hours after death, the walls of the uterus were found to be partly gangrenous and to contain bubbles of gas. Scattered throughout the liver and heart-muscle were necrotic nodules surrounding cavities filled with gas, and bubbles of gas could be seen in the bloodvessels all over the body. The second case was that of a man, fifty-five years of age, who died of peritonitis subsequent to perforation of the intestine. After death, bubbles of gas were found in the bloodvessels everywhere, and the liver was thickly studded with little cavities containing gas (*Schaumleber*). The bacilli were particularly abundant wherever the gas was present, and ERNST, by anaërobic cultures and experiments on animals, proved the organism to be identical with that described by WELCH and NUTTALL.

The description of an unusually interesting case

has recently appeared in the *Columbus Medical Journal*. A woman of thirty-five, a patient of Dr. S. H. Steward, was suddenly seized one morning with a severe chill. This was followed by pain of such intensity in the back and in the right leg and thigh as to require for its relief the administration of morphin. About ten hours after the onset the subcutaneous tissues of the body from head to foot became emphysematous, and the surface of the skin assumed a diffuse scarlet discoloration. The woman complained of feeling numb and bloated, and her urine was suppressed. She died quite suddenly some fourteen hours after the initial rigor, although conscious and capable of carrying on conversation up to within three minutes of her death. After death the gaseous distention rapidly increased and became extreme; the ruby-red discoloration of the skin gradually changed to a yellowish-brown tint. Dr. J. F. Baldwin, who was consulted with regard to the case, suggested the possibility of an infection with the gas-bacillus and urged that a post-mortem examination be made. At the autopsy inflammable gas was found everywhere, the blood-vessels especially showing the characteristic beaded appearance. The uterus gave evidence of a recent abortion and no doubt represented the portal of infection. Dr. Graham examined the blood bacteriologically, found the bacilli, and was able to reproduce by injection into animals the typical phenomena with which our readers are already familiar. This case goes far to confirm the view previously advanced that the numerous cases recorded as instances of death due to entrance of air into the uterine veins after abortions and injections have really been instances of infection with the bacillus aërogenes capsulatus.

It is curious to note that similar cases were recorded, more than a century ago, by John Hunter, although naturally he could not understand their full significance. The types of infection observed at that time agree so well with those recently described that we cannot refrain from quoting the following from his *Lectures on Surgery:*

"In these cases the body immediately after death becomes emphysematous; this emphysema, though it does not occur during life, would yet appear to be an effect of life, for it depends on disease as the body is dying. . . . It occurs immediately after death, or perhaps in the act of dying. . . . I have myself seen several very remarkable instances of its occurrence. The first was that of a young lady about four months gone with child, who, in March or April, about two or three in the afternoon, was suddenly taken ill with a fit, of which she shortly died. She was opened the next morning at seven o'clock, when the body was found swelled with air extravasated in the cellular membrane; the mesentery, intestines, liver, and heart were loaded with air, the blood worked out of the larger vessels mixed with air, and the body had become very offensive. Another case of this kind occurred at St. George's Hospital in a man who had an encysted tumor in the upper belly of the right rectus muscle, which contained a fluid. It was opened on Friday, and on the Monday following he became ill, and died at one o'clock. He was opened seventeen hours after death, and was found emphysematous, just as in the former case. This appears to be similar to what is commonly termed sphacelus, being a species of mortification occurring before death or in the act of dying. . . . A man at St. George's Hospital had the operation for popliteal aneurism performed. . . . The case went on well till the sixth day, when ulceration took place in some part of the artery; . . . considerable bleeding took place and recurred several times afterward . . . (and) in the end (was) the cause of death. Immediately after the first bleeding I observed the foot and leg of the diseased side to become cold as high as the middle of the calf. . . . Before he died, (in) the upper part of the leg . . . a vesication formed, discharging a bloody serum, and they became darker, as if blood was diffused in the cellular membrane, and edematous, or rather, emphysematous."

How the soul of the enthusiastic student of hedgehogs would rejoice could it be made conversant with the satisfactory explanation of these cases which the science of bacteriology has afforded.

THE DISCOVERER OF SURGICAL ANESTHESIA.

To the vast majority of the present generation, surgical anesthesia is simply a fixed fact—one of the available advantages of modern life, like the railroad or telegraph. When people must have a tooth drawn, they expect to inhale nitrous-oxid gas; if any other and graver operation is necessary, they look, as a matter of course, to ether or chloroform for the prevention of pain. They care no more to inquire who discovered either of these agents than they do about the inventor of the first wheel or the first lever. Yet it is well within the memory of many now living that the announcement was made that the surgeon's knife was robbed of its ancient terrors.

It is somewhat curious to look back at the early history of this great improvement, to which our attention has been called anew by an article recently published by Dr. Grandy, of Atlanta, Ga., and to note that in the changed conditions of the present day the actual facts would be much more readily established. Hardly had the medical pro-

fession become aware of the boon conferred upon its members and upon their patients, when a most unseemly struggle began between rival claimants to its paternity. MORTON, the dentist, who first notified DR. WARREN, of Boston, that he believed surgical operations could be done without pain by the inhalation of a certain vapor, undertook to obtain a patent for this article under the name of "letheon." Whether or not he ever succeeded, we have been unable to learn; but, in fact, sulphuric ether was freely used as an anesthetic by the profession at large within a very short time after the publication of DR. WARREN'S experience with it. A strenuous controversy arose between MORTON, WELLS, and JACKSON, the two latter claiming the credit of suggesting the idea which MORTON carried out and continued for many years. It was not for the honor of priority, but in the hope of pecuniary profit by an award from Congress, that this battle was fought.

And here we may recall the joke of DR. O. W. HOLMES, when a monument to the discoverer of anesthesia was proposed, and the question came up which of the claimants should be named. "O," said the witty doctor, "just put 'MORTON—JACKSON—WELLS—Either.'"

But the fact seems to be that nearly five years before DR. WARREN acted upon MORTON'S suggestion and operated upon a patient under the influence of ether, a modest practitioner in the town of Jefferson, Ga., CRAWFORD W. LONG by name, had actually tried the same experiment, and repeated it with success in a number of cases. *He it was who first discovered surgical anesthesia.* He was led to it by observing that persons inhaling ether, as was then often done for amusement, were unconscious of pain from injuries sustained while under its influence. It was a true philosophic deduction.

Be it remembered that in those days communication with the great centers was far more restricted than now, and that medical journals were not published at all the cross-roads throughout the country. Moreover, operations were more rare, especially in small villages such as the one where DR. LONG carried on his practice. It is, therefore, not surprising that his light was eclipsed by those which shone in more prominent situations.

Abundant evidence of LONG'S priority in this matter was published by him in 1849, but attracted little notice. He also sought to obtain from Congress substantial recognition of his merits, but it does not appear that his application did more than prevent MORTON'S success in a like effort. And, indeed, great as have been the benefits accruing to mankind from the discovery of anesthesia, it may be questioned whether a recompense in money, especially if given in response to a demand, would not take off the fine bloom from a noble and dignified service, giving it a commercial aspect. It would be one thing for a Republic to make an exception to the proverbial ingratitude of such governments, and bestow a princely award upon a benefactor of the race; it is quite another thing for that benefactor to rise and request payment for his good deeds.

We trust that DR. GRANDY is well-informed as to the intention of the State government of Georgia to place a statue of DR. LONG in the Capitol at Washington. Such a tribute to his memory would be just and proper. The discovery of anesthesia must always rank among the great achievements of humanity.

EDITORIAL COMMENTS.

The Philadelphia County Medical Society and Nostrums.—At a meeting of the Philadelphia County Medical Society, held October 18, 1893, the following resolution was unanimously adopted:

"WHEREAS, Dr. James E. Reeves, of Chattanooga, having denounced the so-called "Amick Cure" for consumption as a quack nostrum, and stated that its proprietor was not a physician in good and regular standing, was accused of criminal libel; and

"WHEREAS, The grand jury has ignored the indictment brought against him, be it

"*Resolved*, That the Philadelphia County Medical Society congratulates Dr. Reeves on his bravery, a bravery unfortunately too rare at the present day, and tenders him sympathy in the persecution to which he has been subjected;

"*Resolved*, That no person who makes, deals in, or advertises as a cure a quack nostrum, that it is say, a preparation the composition of which is kept secret, can be termed a physician in good and regular standing, because such action is *ipso facto* sufficient to cause forfeiture of membership in this or any other County Medical Society governed by the laws of the American Medical Association.

Resolved, That a copy of these resolutions, duly attested with the signature of the President and Secretary and with the seal of the Society, be forwarded to Dr. Reeves, and that they be handed to the press for publication."

Every medical society in the United States should pass similar resolutions. The indifference or pusillanimity of the medical profession in the face of the outrageous nostrum-traffic of the country, carried on within and without the profession, is one of the gravest evils and dangers that afflict the profession. There should not be another day's delay!

The Wilder Quarter-Century Book is for youthful America the first instance that we know of the beautiful German custom of celebrating and honoring great teachers by

the *Festschrift*. At the close of his twenty-fifth year of service in Cornell University "some of his former students" have united in loving gratitude to present Professor Wilder a collection of original papers on physiologic investigation. The volume is a simple but handsome large octavo of some 500 pages, and contains a series of admirable papers, among which is a study in evolution, on "Temperature and Vertebræ," by President Jordan, of the Leland Stanford Junior University; one by Professor Comstock on "Evolution and Taxonomy"; one by Mr. Pierre A. Fish on "Brain Preservation"; one by Professor Gage on "Brook Lampreys," and a number of others. Six of sixteen of the articles are by physicians: Dr. E. R. Corson discusses "The Vital Equation of the Colored Race and its Future in the United States"; Dr. Theobald Smith writes of "The Fermentation Tube, with Special Reference to Anaërobiosis and Gas-production among Bacteria"; Dr. W. C. Krauss treats of "Muscular Atrophy considered as a Symptom"; Dr. H. M. Biggs contributes "A Bacterial Study of Acute Cerebral and Cerebro-spinal Leptomeningitis," and Dr. V. A. Moore describes "The Character of the Flagella on Three Types of Bacilli."

The book has numerous illustrations, chief of which is a fine etched portrait of Professor Wilder. It was presented at the quarter-centennial celebration of the opening of Cornell University, held at Ithaca, October 6, 7, and 8, 1893. What a perfect method of expressing the grateful honor of pupils, whilst at the same time furthering scientific progress—and there are few men so worthy of such honor and devotion as this true scientist, gentleman, and friend, whose pupils and whose friends, indeed, are all of us.

Damages are Recoverable for Injuries Resulting in Miscarriage.—When a married woman is so injured by the negligence of another as to miscarry, her husband can recover damages for the loss of the child. So holds the Superior Court of New York City, General Term, in the case of Butler *vs.* Manhattan Railway Company. Here was an action brought by the husband to recover for injuries sustained by his wife, who was struck in the side by the gate which the train guard was closing. Damages were assessed by the jury in the sum of $2250, which was approved on the appeal. It is also to be noted that it was contended that the trial judge erred in excluding the testimony of two physicians as to what the woman told them of her physical history when they treated her at the Women's Hospital, inasmuch as by testifying to these facts herself she waived her privilege of excluding the physicians' testimony. The court, however, held otherwise on this point, especially because when asked about the statements made at the hospital, she had only said that they gave her two doses of medicine for her nervousness, and she did not know what statement she made after that. One of the doctors came to take her statement, but she did not recollect what she said. From this the court held that it could not be said that the witness opened the door of the consultation-room to the jury and undertook to give them a statement of what occurred between herself and the physician.

The Maternity Hospital.—To the medical mind there is no feature about the Abstract of the Report of the Board of Governors of the Maternity Hospital, just published, so gratifying as an analysis of the mortality. Among 132 cases treated during the year ending September 30, 1893, there were no deaths referable to the conditions that brought the patients to the hospital. Two women died from unavoidable causes, one from pulmonary tuberculosis, and the other from chronic nephritis. Of the 134 children born but 5 died. Three children were born still. Among 1875 women delivered during a period of twenty years, and of whom some nine-tenths were primiparæ, there were but 23 deaths (1.23 per cent.), 11 of which were due to septic causes (0.59 per cent.), and 12 to non-septic causes (0.64 per cent.); but for more than four years, among 565 women confined *there has not been a single death* due to preventable causes. Institutions that carry on work with such a record as this can never be too generously supplied with money, and the work itself makes a most earnest appeal for hearty support. Mr. William H. Ingham, 308 Walnut Street, is the Treasurer of the Board of Governors, and will be glad to receive donations.

"The Doctor" is the title of the engraving of a beautiful picture by an English artist, Fildes. So utterly wretched have usually been the attempts to unite medicine and painting that this remarkable instance deserves and has already received a merited success. The face of the physician is a perfect representation of the ideal nineteenth-century physician, a combination of intellect and conscience such, indeed, as is shown in thousands of real men. His mind and heart are equally absorbed in the problem of the disease and in the little sufferer before him. The intensely human element so admirably portrayed in the picture rivets the attention and teaches a lesson not soon to be forgotten by any observer.

Earnest Attempts to Raise the Standard of Entrance.—From the president of a medical college a medical student received a letter praising in the highest terms the tremendous advantages of attendance at the writer's college. The letter closes with these suggestive morally-strabismic words: "We hope that you will visit the College at the beginning of the Session of 1893–94, and become acquainted with officers and members of the Faculty and the students. We feel certain that you will be pleased and decide to matriculate with us. In doing so you will find that our requirements for admission are not more exacting than those with which our many students in the last eight years have found it easy to comply, and that we fully appreciate that many applicants are not fresh from school. I am yours, ——."

The Negro as Physician.—Among the encouraging signs of the elevation of the condition of the colored race in the United States, none is more hopeful than the growing number of colored medical students and physicians. It is somewhat strange that there should have been so many good lawyers before the medical necessity had hardly been thought of. Our medical schools should do all within their power to welcome colored students. It needs only the least humanity to recognize what great possibilities of good, both for this unfortunate race and for the medical profession, will lie in the existence of a trained body of colored physicians to carry to their own

people the science and the medical care they need so much.

An Omission.—The editor of the *St. Louis Clinique* and Charles L. Kerr, M.D., Falls City, Nebraska, will no doubt be interested, if not surprised, to learn that the dominant idea of an instructive paper on "Inductions in Making up a Diagnosis," which appeared in the September number of the *Clinique*, as well as three of the six columns of the text of the paper, is to be found in an address delivered by Dr. Lauder Brunton at the inaugural meeting of the New London Medico-Chirurgical Society, on December 17, 1891, and published in the *Lancet* and *British Medical Journal* for January 2, 1892. The failure to give the appropriate credit is no doubt an omission that both editor and contributor will be glad to make good.

SPECIAL ARTICLE.

NATIVE AND FOREIGN MEDICINE IN CHINA.[1]

BY J. G. KERR, M.D.,
OF CANTON, CHINA.

WHEN we consider the state of medicine in such a country as China, a feeling of surprise and disappointment will be experienced to find that it remains in a very crude and primitive condition. Physicians in cities and villages are numerous, but it cannot be said that there is a medical profession. There are no medical schools, no medical periodicals, no medical societies of any kind. Medical literature is abundant; but it is not to be compared to that in other departments. Physicians, as a rule, do not belong to the literary class, but their education must be sufficient to enable them to read the medical books and write prescriptions. The law prescribes no qualifications, and anyone is at liberty to practise who chooses to do so. Works on the practice of medicine, describing diseases, and giving recipes for their treatment, together with treatises on medicines and their uses, comprise the books which are read by those who aspire to practice.

When it is stated that the sciences do not enter into the education of Chinese scholars, and that anatomy, chemistry, physiology, and pathology are unknown as branches of medical education, it will be seen that the curriculum is very limited and that all practice in China is purely empiric. Taking a glance, however, at the vast population, upon which, during so many centuries, an innumerable host of physicians have had an opportunity of experimenting, we would expect results in the means of curing disease far beyond what have been attained. The books contain many prescriptions which are regarded as standard remedies in given cases, and there are numerous secret medicines which have a wide circulation, but so far as I know there are no remedies which would be an addition to our means of combating disease.

The *Pun-tso*, the standard work on materia medica is in thirty-two volumes, and describes medicines derived from the three kingdoms of Nature. These may be divided into three classes. 1st. Such as are common to us and to them; 2d, Those that are inert; and 3d, Those that are unknown to us. Those included in the third class consist mostly of vegetable substances, and when the botany of China is thoroughly studied many of these will prove to be known to us, and to belong to either the first or second of the classes named.

The theories which guide the administration of medicines are of such a nature as to obstruct the acquisition of correct knowledge. The organs of the body are supposed to hold certain relations to the five elements, earth, air, wood, fire, and water, and the relations which a given medicine is supposed to hold to one of these elements decides the applicability of the medicine. It is thus seen that clinical observation could not lead to a correct knowledge of the virtues of medicines as therapeutic agencies.

The Chinese have never in any department of knowledge inaugurated and carried out processes of investigation with a view of arriving at truth and eliminating error. They are, therefore, destitute of scientific knowledge, and in so important a matter as the use of remedies for the removal of disease they possess no methods that are the result of careful observations conducted on rational principles.

Having no knowledge of chemistry they use all medicines in the crude state, and having no accurate knowledge of the virtues of simple medicines, their compounds are made up of numerous ingredients put together in accordance with the fanciful theories referred to. Notwithstanding all the ignorance and absurdity involved in the theory and practice of medicine, the people have great faith in their medicines, and take more than any other people. Confidence in their doctors is not so well established as it is in the medicines. If one or two doses of a prescription given to a patient does not produce the desired effect another physician is called, and it is no uncommon thing for a patient to be prescribed for by three or four doctors in one day.

The entire ignorance of anatomy precludes any proficiency in surgery, and in fact no one of their numerous physicians pretends to perform the simplest surgical operation. The opening of abscesses or the removal of tumors is not attempted. The tying of an artery seems never to have been thought of, and the fear of hemorrhage has prevented the use of any cutting instrument. The extraction of teeth when they become loose, or the application of a poultice, or of splints to a fractured bone, may be said to comprise the whole of surgery as known in the oldest and most populous nation of the earth. As a consequence, all the diseases and injuries that are capable of relief by surgical aid go on, involving life-long misery or resulting in death.

No attention is paid to hygiene, and no measures are adopted by the public authorities for the protection of communities from epidemic diseases or for the isolation of patients suffering from contagious diseases.

Hospitals for the cure of the sick, asylums for the insane, the deaf and dumb, and for incurables, are unknown. These institutions exist only in Christian countries or where Christianity takes them. The friendless poor are often cast into the streets to die, the insane and incurable who become a burden to the family die

[1] Read before the Ohio State Medical Society, Put-in-Bay, June, 1893.

from neglect or ill-treatment, and there is reason to believe that not a few of them are put out of the way. The head of a family has the power of life and death over its members, and it would not be strange if the quickest and surest method should be taken to get relief from the burden and danger of an insane member.

To remedy such a state of things in India, the second most populous country of Asia, the British Government has established 1600 hospitals and dispensaries, and has opened 18 medical schools for the instruction of native youth, and thousands of qualified native physicians are now engaged in practice in that country. Twenty-five asylums are provided for the insane, with all the best methods and appliances known to the profession in Europe and America. The benefits conferred upon the human race by the labors of medical men—all the improvements of modern scientific research and toilsome experiment—have been given the millions of India without any effort on their part, without even the asking. For this grand work by our kinsmen and professional brethren of the British Isles, Christian civilization must have the credit.

The Empire of China is under the rule of a native dynasty, and has been slow to adopt the modern improvements of Western nations, except such as would conduce to the power of her army and navy. The Christian churches in Europe and America which have established agencies in that Empire for the propagation of Christianity have appreciated the sufferings of the people arising from the ignorance of their physicians, and have organized a system of medical missions which have done a vast amount of good and have prepared the way for the introduction of modern medicine and surgery into that great Empire.

The first medical missionary to China was Dr. Peter Parker, who landed in Canton in 1834. He established a hospital in 1835, which he conducted for twenty years, and which since 1854 has been under my charge. The Medical Missionary Society in China, the first of its kind in the world, was founded in 1835, and under its patronage the medical work in Canton has been sustained for more than half a century.

After the war with England in 1840–52, five ports were opened to foreign commerce, and in these hospitals were established, with missionary physicians, and as the country was further opened by the war of 1857–58, the number of hospitals increased, so that now there are more than 60 hospitals, between 40 and 50 dispensaries, and about 130 medical missionaries, of whom 25 are women. Besides the medical and surgical work done in all these hospitals and dispensaries, giving relief to tens of thousands of patients whom their own physicians could not cure, medical books have been translated into the Chinese language, and native students have been trained in the principles of Western medicine.

It is thus seen that medical missionaries, aided by their societies in Europe and America, are doing for China, by a slow and gradual process, what the British Government did for India in a comparatively short time. They are placing in the hands of the Chinese the benefits of all the labors of the men who brought to such perfection the means of curing disease and relieving suffering, which has made our profession such a blessing to the human race.

A few facts in reference to one or two lines of practice will give some idea of the vast benefit conferred on the Chinese by Western medicine. The first operation for the removal of urinary calculus was performed in 1844 by Dr. Peter Parker in Canton. In sixteen years he operated on 32 cases. In 1865 there were 17 operations; in 1869, 35 operations; and in 1875 the number of lithotomies and lithotrities amounted to 50. Since that time they have averaged in the Canton Hospital more than 50 each year. Last year my young associate, Dr. J. M. Swan, a native of Ohio, operated on 59 cases, with 57 recoveries and the results of 2 not known, and Dr. Mary Niles has operated on 2 cases in the female. Altogether not less than 1600 operations for urinary calculus have been performed, the most of them in Canton, giving relief from a disease which has caused untold suffering and death to thousands, and for which the native doctors had no means of cure.

Every physician knows the terrible dangers to which women are exposed in cases of difficult labor, and how often death may be warded off by methods that modern science has placed in our hands. We cannot compute the number of women and unborn children annually doomed to death in an empire of 300,000,000 of people for the want of the methods and the skill possessed by all our physicians. Dr. Mary Niles, the lady physician in charge of the female department of the hospital in Canton, reports her obstetric practice for 1892 as follows:

Dead before arrival of physician	5
Forceps deliveries	31
Requiring version	7
Craniotomy	7
Delivery of head left *in utero*	1
Manual assistance	5
Extraction of retained placenta	9
Placenta previa	1
Sundry cases	38

Altogether, 104 cases, in 5 of which mother and child were both dead before the foreign physician was called, and more than 50 of the remainder required operative interference. The instance in which the body was torn away by the native midwife and the head left *in utero*, a like case having occurred to me some years ago, shows how utterly helpless these people are in the presence of difficulty, and to what barbarous treatment the midwives, in their ignorance and desperation, resort. Multiply these figures of one year for one city by the hundreds of cities and thousands of villages, and you get a glimpse of the sufferings which fall to the lot of women in an empire which is without the blessings conferred by rational medicine and surgery. Then multiply the thousands who suffer and die in one year by the years of a century, and the result shows by contrast what an inconceivable amount of good is conferred on the human race by the science and skill of the medical profession of to-day. This simple computation will also give some idea of the humane and philanthropic work in which medical missionaries are engaged, even if there be left out of the count the vast good done by them in removing prejudice and conciliating the people.

In the department of dentistry the Chinese have, strange to relate, anticipated by centuries the profession in Europe and America in the insertion of artificial.

teeth. Utilizing the femur of an ox, and sawing a circle of half or three-quarters of an inch from the shaft, a section of this circle is used sufficient to fill the vacant space in the mouth. The section of the bone is then dressed with a file, so as to imitate the teeth to be replaced, and through holes drilled in each end, copper wires are passed to fasten it to the adjoining teeth. These artificial teeth are designed more for good looks than for purposes of mastication, and as the cost of inserting three or four teeth amounts to about 25 or 30 cents, this means of remedying uncomely defects is within the reach of all.

American and English dentists of high standing have practised their profession in Hong Kong, Shanghai and other cities open to foreign commerce, and have employed Chinese young men to assist in the mechanical part of the work. With the talent for imitation for which the race is noted, these young men have not been slow to avail themselves of the opportunity of learning the more delicate parts of the work performed by the dentist himself. A number of these young men have been successful among their own countrymen, and with foreign instruments and material, are superseding the crude and unsatisfactory work of the native artists. They have not yet attained to skill in the treatment of diseases of the mouth, as this requires scientific knowledge, but that will come in time.

The theory that toothache depends on the presence of worms in the decayed teeth is universally believed, and is demonstrated by a process peculiarly Chinese, and which was investigated some years ago by Dr. Rogers, a dentist of Hong Kong, and myself. The native operator holds back the lips with a wooden spatula while he works around the offending tooth with a pointed instrument until there is a flow of saliva and blood. Adroitly turning the spatula and placing the other end in the mouth, a piece of delicate paper attached to one side is moistened by saliva, and the worms, confined under it, are liberated and become mixed up in the bloody saliva. With a pair of forceps the operator picks them out and satisfies the patient.

Cholera is a disease which is now attracting special attention in the country. It is endemic in India and China, and spreads over these countries from time to time as an epidemic. In China no measures are adopted for the purpose of protecting communities from disease or to prevent the spread of epidemics. The dense population, the want of drainage, the impure water-supply, and the presence of decaying animal and vegetable matter in the streets and canals under tropical heat, afford the best possible conditions for the generation and propagation of cholera. The absence of statistics renders it impossible to say whether the mortality of this disease is greater where preventive hygienic measures are disregarded, but the rise, progress and decline of epidemics seem to follow very much the same course as in countries where the most stringent measures are enforced.

It is a notable fact that the epidemics of cholera in the United States have been introduced only from Europe. This was not strange when there was no steam connection between our western coast and Asiatic ports. During the last eighteen years regular lines of steamers have been carrying many thousands of passengers sailing from Hong Kong and calling at Yokohama. During this time several epidemics of cholera have prevailed in China and Japan, and although steamers have brought passengers from infected districs and called at an infected port, yet the disease has never been introduced by Chinese immigrants. In many instances the steamers have been quarantined because of smallpox, but so far as I know, never because of cholera.

I refer to the subject of fever only to say that yellow fever, the scourge of inter-tropical America, has never been known to occur on the east coast of Asia. Canton is in the same latitude as Havana, and the inter-tropical countries and islands of Asia are much more populous than the Central and South American States and West India Islands. The fact that yellow fever does not prevail is most remarkable, and for this fact that part of the world may well be devoutly thankful.

This brief outline of native and foreign medicine in China is sufficient to show that the populous countries of Asia afford wide fields for research in the various departments of science connected with our profession. To botany and chemistry we look for the development of the resources of the vegetable and mineral kingdoms in those unexplored regions, and from which valuable additions may be made to our armamentarium.

In the study of disease under conditions of climate, sanitary surroundings, and habits so entirely different from those known to the profession in Europe and America we may look for that increase of knowledge which comes from an enlarged view of subjects under investigation.

For the antiquarian, and for those who are interested in the origin and influence of the fanciful theories of disease, and curative agents universally accepted by so large a portion of the human family, the history of native practice in China affords an inexhaustible field of study.

There are at this time about 130 medical missionaries located in various parts of the empire, who study the language of the people and become familiar with their habits and surroundings, and whose duties require them to study their diseases. There are also more than 100 European and American physicians engaged in private practice in the foreign communities of the open ports. Some thirty of these are connected with the Imperial Maritime Customs Service, and are required by the rules of the service to write semi-annual reports of their observations on the diseases of the port where they are located, which are published as Customs Medical Reports.

From all these observers in this new field we may look for valuable additions to our knowledge, but time is required, as the native sources of information are untrustworthy, and all statistics must be gathered under unfavorable circumstances by the observers themselves.

When I went to China, in 1854, but one work on foreign medicine had been prepared in the Chinese language. This was an outline of anatomy and physiology, by Dr. Benjamin Hobson, medical missionary under the auspices of the London Mission. This was succeeded by three other manuals by the same author, on surgery, practice, and obstetrics, and one on natural philosophy. These five volumes were well adapted for introducing the science and practice of medicine, of medicine and surgery, and obstetrics, to the people of that empire, and they attracted the attention of scholars and officials in

high positions. The work on anatomy and physiology was republished, with all the illustrations, in the best style of native art, by an official of high rank, and a complete edition of the five volumes was issued in Japan, and laid the foundation there for the early acceptance of Western medicine by the leading men of that empire.

As much of my time as could be spared from the daily duties of hospital and dispensary work was devoted to translating medical books. To the works of Dr. Hobson have been added a treatise on chemistry, four volumes; one on materia medica, four volumes; surgery, seven volumes; theory and practice, five volumes; physiology, four volumes; diseases of women, five volumes; diseases of the eye, one volume; diseases of the skin, one volume; Gray's *Anatomy* has been translated by Dr. Osgood, an American, and also by Dr. Dudgeon, an English physician, and the *Companion to the British Pharmacopeia* has been translated by Dr. Hunter, and other works are in course of preparation.

We have now text-books on the chief branches of medical science, translated into the Chinese language, which, in its written form, is the same throughout the whole empire, and these books reach the physicians of the most populous nation in the world, and will in time revolutionize the medical practice which is now so highly esteemed because of its antiquity.

Medical classes are formed in connection with many of the missionary hospitals. A medical school has been organized in Hong Kong, under the patronage of British officials and leading merchants in that colony, and the introduction of scientific and rational medicine into China is assured.

While you, in common with the members of the profession throughout this country and Europe, are engaged in earnest labors to increase our knowledge and to add to the means of relieving suffering and prolonging life, the humbler, but not less important, task devolves on us who have devoted our lives to the work of medical missions, of transferring the knowledge which you have accumulated to the languages of Asia and Africa and the Islands of the Sea, and thus of conferring upon vast multitudes of our fellow-men the inestimable blessings, not only of true religion, but of rational and scientific medicine.

CORRESPONDENCE.

VACCINATION AND LEPROSY.

To the Editor of The Medical News,

Sir: Your brief though characteristic review (The News, August 26, 1893, p. 249) of "The Recrudescence of Leprosy and its Causation,"[1] by Mr. William Tebb, F.R.G.S., leads me to venture to send for publication, with your kind permission, the following medically certified cases of leprosy due to vaccination, for which I am indebted to memoranda in the case-book of Dr. Roger S. Chew, of Calcutta:

Mabel P., a Scotch lassie, aged seventeen, a leper for the last eight years, was brought by her mother, who stated that she was vaccinated when she was seven years and a half old. About six months after vaccination, which was successful, symptoms of leprosy began to develop, and she flew here and there to every medical practitioner to save her child, but to no avail, as the disease kept increasing.

Daidas, a native palki-bearer, was a leper twenty years. He was a healthy young man. At twenty-one he was forcibly vaccinated, and a year afterward leprosy commenced at the seat of the vaccine marks.

Jahoorie was a twenty years' leper. Previous to vaccination his history was healthy. When he was seven years old the operation was carried out, and the disease first showed itself six months afterward, commencing as a white patch over the vaccine site. The description of the symptoms of this case is painful and disgusting.

Turning to Dr. R. Hall Bakewell's evidence before the Vaccination Committee of the House of Commons, England, I find testimony, though not certified, that I think quite as convincing, if we desire not the colloquialism of being hair-splitters.

Question 2564, and Dr. Bakewell's answer, are as follows:

Question. Have you had experience of any case in which leprosy has been introduced?

Answer. I have seen several cases in which it seemed to be the only explanation. I have a case now under treatment, of the son of a gentleman from India, who has contracted leprosy, both the parents of English origin. I saw the case of a child last year who, though a creole, of the Island of Trinidad, is born of English parents, and is a leper, and there is no other cause to which it is attributable. Sir Ranald Martin, who is a great authority on these points, agreed with me that leprosy arose from vaccination.

As by the best leprosy authorities in the world the alleged factors for this causation of leprosy, such as heredity, contagion, insanitation, syphilitic cachexia, a fish-diet, malaria, etc., are set at naught, it is worth while to give the names of some of the distinguished men in the domain of dermatology who admit that vaccination is capable of transmitting and aiding the progress of this much-dreaded malady. They are: Sir Erasmus Wilson, Dr. John Hillis, Dr. Liveing, Prof. T. W. Gairdner, Dr. Tilbury Fox, Sir Gavin Milroy, Dr. A. S. Black, Dr. Edward Arning, Prof. H. G. Piffard, Dr. Walter Gibson, Dr. Blane, Dr. Sidney Bourne Swift, Dr. P. Hellat, Prof. Henri Leloir, Dr. S. P. Impey, Dr. H. S. Orme, those already quoted, and others.

The most important cases as to the invaccination of leprosy of my cognizance are those of Prof. Gairdner's adduction, and to be found at pages 139–144 of "The Recrudescence of Leprosy and its Causation," wherein are brought together for the first time some of the most incriminating facts, comprising some 100 pages of closely marshalled testimonies, nearly all medical, and in many cases certified, as to the communication of leprosy by means of vaccination.

In the face of Mr. Tebb's carefully prepared statistics and thorough reasoning, backed up as argument has seldom been backed up before, it would, in my opinion, be the height of insanity to maintain that arm-to-arm (compulsory) vaccination is not to blame as a partial cause of the leprosy revival.

I think you will agree with me that Mr. Tebb deserves,

[1] London: Swan, Sonnenschein & Co.

not the abuse but the thanks, not only of the medical profession but of everybody else.

In anticipation,

Yours faithfully, JOSEPH COLLINSON.

WOLSINGHAM, CO. DURHAM, ENG.

SPONTANEOUS CURE OF A STRANGULATED HERNIA IN A CHINAMAN.

THE following communication has been placed in our hands and is of sufficient interest to be worthy of publication:

DEAR DR. WILLARD: In your lecture on "Complications of Hernia," reported in THE MEDICAL NEWS of April 29th, the remarks concerning nature's method of curing strangulation suggest to me that you may feel interested in a case that I saw about two years ago.

A stout healthy boy of eighteen or nineteen applied for closure of an artificial anus that existed in his scrotum. On examination I found a fistulous opening admitting several fingers, near the most dependent portion of the scrotum on the left side. From this there was a prolapse of four or five inches of small intestine, and odorless fecal matter was oozing. By manipulation the protruding intestine could be returned to the scrotum quite easily, but the size of the hernial tumor could not be appreciably reduced. Where the intestine was adherent to the scrotal skin the dividing line between skin and mucous membrane was scarcely more marked than it is normally at the anus.

The history in brief was that from early childhood there had been a reducible left scrotal hernia. About two years before I saw the patient symptoms of strangulation had developed suddenly, without known cause. The tumor became hard, red, hot, and very painful, and could not be reduced; there was marked constipation and vomiting (neither the boy nor his father remembered whether the vomiting was stercoraceous or not). No treatment was undertaken, and the condition persisted for several days (the patient was not sure of the exact time), growing worse as time passed. At the end of three or four days the tumor burst, discharging some pus and much feces. The pain in the tumor and the sense of constriction at the external ring were relieved at once, and all other symptoms improved rapidly. From that day no fecal matter passed per rectum. The anus was tightly constricted, and the patient refused to allow a rectal examination to be made. By wearing a large suspensory of his own contrivance the boy was able to work about his father's farm. The fistula was evidently low down in the small intestine, as the patient was stout and well nourished, but the feces were without odor.

Respectfully,

DR. GEORGE YARDLEY TAYLOR.

PEKING, CHINA, July 27, 1893.

NEWS ITEMS.

The Eighth International Congress of Hygiene and Demography will be held at Budapest, late in August or early in September, 1894, under the patronage of the Emperor of Austria.

The Biography of Ephraim McDowell.—We are notified by the publishers of *The Biography of Ephraim McDowell* that the book is out of print. Both they and we have received numerous complaints from persons who have paid a supposed agent in advance for the work and have failed to receive it. We advise against any business with a travelling agent, and especially against paying in advance for a copy of the work.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1894, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College, Dr. Charles W. Dulles, on or before May 1, 1894.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelop having on its outside the motto of the paper and within it the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

Mutter Lectures of the College of Physicians.—A series of ten lectures entitled Surgical Pathology and Surgery of the Spinal Cord, the Vertebræ, and the Peripheral Nerves, will be delivered by Dr. De Forest Willard at the Hall of the College of Physicians, Thirteenth and Locust Streets, on Tuesdays at 8.30 P.M., from October 17th to December 19th inclusive. Members of the profession are cordially invited to attend. At the lecture on October 17th the following subjects were considered: Experiments in nerve-suturing; end-to-end suturing; flaps of nerve-substance; interposition of foreign substances; methods of repair: microscopic appearances; primary and secondary suturing; degeneration of divided nerves. On October 24th: Nerve-stretching; pathologic conditions; neurectomy; neurotomy; excision of large nerve-trunks; excision of Meckel's ganglion; nerve-spasm, etc. On the remaining dates the lectures will take up, on October 31st: Neuritis; pathologic degenerations; bruised nerves; gunshot wounds of nerves; traumatism. On November 7th: Fractures and dislocations of vertebræ; primary and secondary degenerations; pathology; results of traumatism; paralyses, etc. On November 14th: Localization-symptoms; pressure-symptoms; pathology; methods of relief, mechanical and surgical; laminectomy. On November 21st: Caries of the vertebræ; pathology of tuberculous processes; deposits about the cord; pressure-paralysis; methods of relief, mechanical and surgical; removal of pus and other deposits. On November 28th: Spina bifida; varieties; removal of contents; removal of sac; syringomyelia; pathology; Morvan's disease. On December 5th: Anterior poliomyelitis; possibility of its infectious origin; epidemic poliomyelitis; surgical measures. On December 12th: Antero-lateral and posterior spinal sclerosis; pathology of the system-degenerations; traumatism a cause; infection; arthropathies; suspension. On December 19th: To be announced.

ORIGINAL ARTICLES.

RESULTS OF VAGINAL HYSTERECTOMY.

BY ANDREW J. McCOSH, M.D.,
OF NEW YORK;
VISITING SURGEON TO PRESBYTERIAN HOSPITAL, NEW YORK; PROFESSOR OF SURGERY IN NEW YORK POLYCLINIC, ETC.

AN operation must be judged by its results. While in the last few years reports of a large number of cases of vaginal hysterectomy have been published, yet the results recorded have apparently not been sufficiently favorable to convince all surgeons that the operation is comparatively safe and satisfactory. For instance, it is claimed by some excellent gynecologists that in carcinoma of the uterus high amputation is attended with better results, and of course with less danger, than is vaginal extirpation. There can be no question but that in many cases high amputation has been followed by most excellent results. I have recently seen two patients on whom this operation had been performed, seventeen and thirteen years ago respectively, who now have no sign of relapse. In both cases the operator was Dr. T. G. Thomas, and the diagnosis of carcinoma was confirmed by the microscope.

Vaginal hysterectomy, however, as a recognized surgical procedure is of recent date, and while a sufficient number of cases have been recorded for us to form a just estimate of its mortality and of the relative proportion of patients who are well two years after operation, yet we have records of only a comparatively small number of patients who have been followed for five years or longer. It is from this latter class of cases that our conclusions must be drawn as to the proportion of radical cures effected. The dangers of extirpation must of course always be greater than those of high amputation. I think it has already been shown that the results of extirpation are more favorable as regards length of life after operation, than are those of the less radical operation, and as time advances cases are accumulating in favor of hysterectomy, and that in spite of the fact that this operation is done on many patients who would have been declared inoperable were high amputation the only surgical means at our disposal. It is important that all cases should be published, and especially those that have been under observation for a number of years. The longer the list the more nearly correct will be our conclusions. It is difficult to follow hospital cases for many years, yet if operators would take pains to hunt up all patients operated upon four years ago or longer and report on their condition, a comparatively just estimate of the average number of radical cures could be reached. The mortality of the operation may be estimated at about 10 per cent. Winter reckons 8.4 per cent. in 474 operations, and Krukenberg reckons the mortality at 15 per cent. in 243 cases operated on at the Berlin Frauenklinik.

The main object of this paper is to record my personal results. No new methods are recommended and no new instruments are presented. The operations are classed as 1st. For carcinoma; 2d. For prolapse.

FOR CARCINOMA OF THE UTERUS.

All the cases of vaginal hysterectomy that I have ever performed are reported, and they cover a period from August, 1888, to September, 1893. The operations were 16, the deaths none. Fifteen of these patients have been followed; 1 has disappeared from view. Of the 15 who have been kept under observation, there are at the present time (August, 1893) in good health and perfectly free from malignant disease:

Five years after operation	1 patient.
Four " " "	1 "
Two " " "	1 "
One and a half years after operation	1 "
One year " "	2 patients.
Half " "	2 "
Less than three months after operation	4 "

There have died from return of the carcinoma at the end of thirty-three months 1 patient, and at the end of seven months 1 patient. There are alive, but with return of the disease either locally or in other organs, three years after operation 1 patient, one year after operation 1 patient. We thus see that of the 16 patients operated upon 4 have had a return of the disease. Unfortunately this will not be the final ratio, for with the exception of the patients who are in perfect health at the end of five and four years after operation, the cases have not been followed for a sufficiently long time to warrant any decided opinion as to their chances for cure.

I will mention in this connection two other patients with carcinoma of the body of the uterus, who were operated on by the combined vaginal and abdominal methods. One of these cases on whom I operated more than four years ago (fifty months), had a uterus as large as one at a pregnancy of three

and a half months; she is at present in perfect health, with no sign of relapse. The other patient, operated on two and a half years ago, is also in good health, with no trace of malignant disease. Four years at least must elapse before we can even pretend to regard a patient as cured. Indeed a number of relapses have been reported after the expiration of more than four years. I have recently seen a patient who four and a half years after extirpation was apparently free from disease; six months later, however, carcinoma recurred in her pelvis, and she died in another half year. Still such late relapses are uncommon, and if a patient is well at the end of four years we can feel comparatively safe in predicting that there will be no return of the *original* growth.

I have extirpated the uterus for carcinoma by various methods 21 times; at the end of more than four years 3 of these patients and at the end of two years 5 are well and entirely free from return of the disease, so far as can be determined by personal examination. At the end of one year 9 patients are apparently perfectly well.

When extirpation has been possible, I have always chosen this operation in preference to any other. I consider that a case is unsuitable for vaginal hysterectomy if either the broad ligaments or bladder are infiltrated. If a uterus is more than double its normal size, I consider abdominal hysterectomy the safer operation.

Before reporting the history of the vaginal cases I will briefly describe my method of operation. It is unwise, I think, to lay down any special plan, to be followed in every case. The details of the operation must constantly vary, both in the manner of their execution and in their sequence, according to the peculiarities of the case. My general plan, however, is as follows: The patient is placed in the lithotomy-position, with the buttocks elevated on a hard pillow. The vagina, vulva, and neighboring parts are cleansed in the usual surgical manner, and rendered as nearly aseptic as possible. A Sims or a modified Simon speculum is used to draw down the posterior vaginal wall and perineum. If there is any cauliflower-growth from the cervix it is scraped off by the spoon or sharp curet. Any ulcerated surface is cauterized with the Paquelin cautery, after a fresh scrubbing with 1 to 1000 bichlorid solution. The cervix, if any remains, or the edge of the vagina, is seized with vulsellum forceps, and the uterus is dragged downward toward the vulvar orifice. The anterior vaginal wall, with the bladder, is then dissected by scissors from the cervix, the incision being made at least half an inch away from the edge of the neoplasm. The separation of the anterior wall of the uterus from the bladder and vagina, as far laterally as the broad ligaments, is then completed up to the peritoneum, which, as a rule, is not opened at this stage. The posterior vaginal wall is then separated, and the peritoneal cavity freely opened in Douglas's pouch. A finger can now be passed in behind the broad ligaments, and with another finger in front these can be easily palpated, and their exact condition determined. If the edge of the vagina bleeds, the hemorrhage is controlled best by a running catgut suture. The lower part of each broad ligament, (perhaps a fourth of the entire length) is then secured, generally with a ligature, and that part of the ligaments is cut loose from the uterus. This organ will generally then be considerably freed, and can be pulled lower down. The next portion of each ligament is next secured, and cut in a similar manner. Either before or after this the peritoneal cavity is freely opened over the anterior part of the fundus. This can generally be done by tearing with the finger, though sometimes the peritoneum is so tough that a sharp instrument is needed to make the opening. The upper portions of the ligaments are then secured and cut, and the uterus is free. It is sometimes easier at the upper part of the ligaments to tie (or clamp) on one side only, and, cutting the uterus free on this side, drag the organ outside the vulva, where the remaining portion of the ligament can be secured.

After the uterus has been removed, careful inspection is made to ascertain if hemorrhage has ceased. Occasionally a few bleeding points need a catgut ligature, and sometimes the ligatures in the broad ligaments need to be reapplied. If the ovaries and Fallopian tubes appear healthy, they are not disturbed, unless they fall downward into the opening, in which case they are removed. If the adnexa, however, are infiltrated with inflammatory or other material, the ovaries and tubes are removed, and also as much as possible of the ligaments. In most of my cases I have sutured the peritoneum to the cut edge of the vagina. This is done partly to stop the oozing of blood from the cut edge of the vagina and partly to cover up the raw bleeding surface that remains between the vagina and the peritoneum. I think this a good rule to follow, though in the few cases in which this detail has been omitted no harm has resulted. In only a few cases have I closed the peritoneal cavity by sutures. There may be some advantage in this, but I have not found it to be necessary.

The stumps of the broad ligaments are drawn gently downward, and a roll of iodoform-gauze is placed in the opening extending up to the peritoneum, but not inside the cavity. A pad of sterilized gauze is placed over the vulva, and is renewed as often as may be necessary. The iodoform-gauze pad is removed on the fifth or sixth day, and the vagina gently irrigated. The patients, as a rule, are out of bed by the fourteenth

day, often by the ninth. The temperature has in two or three of the patients risen on the fourth or fifth day to 101°, but in the other cases it has never risen above 100°. As a rule very little shock has followed the operation, and but little pain is experienced.

As stated before, the plan sketched is often altered. Sometimes it is easier to begin the separation behind. Sometimes better access can be gained to the broad ligaments by tipping the fundus forward or backward.

Shall the broad ligaments be secured by clamps or by ligatures? As a rule, I prefer ligatures. In most cases they can be applied without much difficulty. In certain cases, however, in which the uterus cannot be drawn freely downward or in which, on account of the patient's condition, it is necessary to adopt the most rapid method, clamps are preferable. The use of clamps is followed, I think, by more pain and perhaps necrosis of more tissue than is the case when ligatures are employed; but these disadvantages may be trivial when compared with the greater safety and rapidity with which clamps can be adjusted in certain cases. The ordinary clamps used in abdominal work, with a long curved biting-surface and short handles, are all that is needed. They are removed at the end of thirty-six or forty-eight hours.

I think, however, that ligatures are to be preferred, and there must be very few cases in which they cannot be applied. I pass them threaded in a full curved, rather short but heavy needle, held in an ordinary needle-holder. In most of my cases I have employed fine silk for ligation of the broad ligaments. I never feel quite secure after the ligation of considerable masses of tissue with catgut, and always think that there is greater liability for the knot to loosen and for portions of the pedicle to draw out. It may be prejudice, but I am always better satisfied when the broad ligaments have been ligated with silk, and as more tissue can be embraced by the ligature fewer are needed, and time is thus saved. I have seen no great disadvantage in the use of silk. In a very few cases (three of sixteen) it has acted as a foreign body, and after the lapse of a few weeks has induced a certain amount of vaginal discharge. If left alone these ligatures would probably have come away of themselves, but it is a very simple matter to introduce a speculum, grasp the ligatures in a pair of forceps, and by a gentle pull they will slip off almost painlessly, and the patient will at once be rid of this petty annoyance. As a rule, however, no inconvenience has been experienced from the use of silk.

It may be of interest to mention that the great majority (80 per cent.) of these operations were performed in the public operating-room of a large general hospital, and the patients were placed in the common ward with the usual variety of cases, septic and aseptic, which a general hospital collects.

Case I.—A multipara, aged forty-nine years, with carcinoma of the cervix extending to the internal os. The operation was performed in August, 1888. A cauliflower-growth was burned off by Paquelin cautery. The broad ligaments were secured by five clamps. No suture of the peritoneum was used. The patient sat up on the fifteenth day. Examined July, 1893, no trace of disease in the pelvis was found, and the general condition was excellent.

Case II.—A multipara, aged fifty-three years, with carcinoma of the cervix, involving the edge of the vagina. Operation was performed in the Cancer Hospital August, 1888. The broad ligaments were secured by six clamps. In September, 1891, there was a return of the carcinoma at the apex of the vagina. Death occurred in June, 1892.

Case III.—A multipara, forty-two years of age, had carcinoma of the fundus, involving the entire uterine body down to the internal os. She was operated upon in 1889 in the Presbyterian Hospital. The broad ligaments were secured by clamps. The patient sat up on the twelfth day. The examination, July, 1893, showed no return of the disease, and the general health was perfect; the body-weight was 225 pounds.

Case IV.—A multipara, aged thirty-nine years, with carcinoma of the cervix. The operation was performed in July, 1890, in the Presbyterian Hospital. The lower part of the broad ligaments was secured by ligatures, the upper part by clamps. In November, 1892, there was a return of the disease. The woman was alive in July, 1893.

Case V.—A married nullipara, aged forty-three years, with carcinoma of the cervix. The operation was performed in April, 1891, in the Presbyterian Hospital. The broad ligaments were secured by clamps and ligatures. The patient sat up on the fourteenth day. Although she has disappeared from observation, she was free from disease three months after the operation.

Case VI.—A multipara, a patient of Dr. W. C. Walser, presented carcinoma of the cervix and posterior wall of vagina, extending downward to the vulva for two and a half inches. The entire thickness of the posterior vaginal wall was infiltrated with the growth, a rounded area two and a half inches in diameter being involved. She was operated upon October, 1891. The uterus was first removed, both ligatures and clamps being used. The entire posterior vaginal wall was then removed, from its upper end to a point just above the posterior commissure. It was more or less adherent to the rectum, and at several points the rectal wall was partly torn, leaving intact the mucous coat alone. A great part of this separation was done while one finger was in the rectum. The patient lost a considerable amount of blood. The operation lasted one and three-quarter hours. The patient rallied well, however, and was out of bed by the twenty-

first day. In July, 1893, she had no sign of return of the disease.

Case VII.—A multipara, thirty-two years of age, with carcinoma of the cervix. The vagina and broad ligaments were apparently free from disease. She was operated upon October, 1891, in the Presbyterian Hospital. Both ligatures and clamps were used. The patient had a rapid convalescence, but the disease returned in four months, and as the woman was desirous of another attempt at cure celiotomy was performed in June, 1891. A carcinomatous mass was removed from the cicatrix at the apex of the vagina, but the intestines were found infiltrated and the pelvic glands involved. No attempt at radical removal of the disease was made. The abdomen was closed and the patient made an uneventful recovery. She died four months later.

Case VIII.—A multipara, forty-seven years of age, with carcinoma of the cervix. The operation was performed in July, 1891. The broad ligaments were tied with silk ligatures. The patient was out of bed on the twelfth day. She was examined in July, 1893, and no sign of a return of the carcinoma was found; her condition was then good.

Case IX.—A multipara, aged forty-nine, had carcinoma of the cervix, and was operated on in July, 1892. The ligatures were examined July, 1893. No return of carcinoma was found and the general health was excellent.

Case X.—A married nullipara, aged fifty-one; carcinoma of the cervix. The operation was performed in July, 1892. Ligatures and clamps were used. The left broad ligament was found to be infiltrated and was in part removed. The patient had always been known as a bleeder, and a great deal of oozing of blood followed the operation, which required a large number of ligatures and suturing. The patient in July, 1893, was in a very low condition from carcinoma of the stomach and other abdominal viscera.

Case XI.—A multipara, aged thirty-nine, who had carcinoma of the cervix. The operation was performed June, 1892. The broad ligaments were secured by ligatures. The patient was examined July, 1893, and no sign of a return of the growth was found, the health being good.

Case XII.—A multipara, forty-two years of age, with carcinoma of the cervix and of the lower half of the uterine body and edge of the vagina. She was operated upon in March, 1893. The broad ligaments were secured by ligatures. The woman sat up on the tenth day, was examined in August, 1893, and no sign of a return of the growth was found. The patient had gained twenty pounds in weight.

Case XIII.—A multipara, aged forty-three, with carcinoma of the cervix and of the lower part of the fundus. The operation was performed in March, 1893. The broad ligaments were secured by ligatures. The patient was examined in August, 1893, and found to be in perfect health, with no trace of the disease.

Case XIV.—A multipara, aged thirty-nine, with carcinoma of the cervix. The operation was performed in the Presbyterian Hospital, August, 1893. The broad ligaments were secured by ligatures (catgut), and the patient was out of bed on the eleventh day.

Case XV.—A multipara, aged forty-two, with carcinoma of the cervix. The operation was performed in August, 1893. The broad ligaments were secured by silk ligatures, and the patient was out of bed on the twelfth day.

Case XVI.—A multipara, aged thirty-nine, with carcinoma of the cervix and edge of the vagina. The operation was performed in August, 1893. The broad ligaments were secured by silk ligatures, and a cylinder of vagina an inch deep was removed from the upper end, and the peritoneum was sutured to the cut edge. The patient was out of bed on the eleventh day.

The foregoing record comprises all of my cases of vaginal extirpation for carcinoma. In certain other cases I have begun the operation with the hope that the entire uterus could be extirpated, but have been forced, on account of the involvement of the bladder or of the broad ligaments, to limit myself to high amputation. While there are a certain number of these cases suitable for abdominal hysterectomy, I have never seen one that, in my opinion, was suitable for sacral hysterectomy. There may be exceptional cases, but my experience with the operation has led me to the conviction that, when a uterus cannot be removed by the vagina or abdomen, it is better to refrain from any radical operation. By sacral operations I mean any of the methods by which the uterus is removed through the back, whether by sacral resection or perineal incisions. The same argument does not apply to carcinoma of the uterus and of the rectum. In excision of the latter organ, even if the disease is not eradicated, the danger of intestinal obstruction will probably be removed. In disease of the uterus no such danger threatens the patient.

FOR PROLAPSE OF THE UTERUS AND VAGINA.

In ordinary cases of prolapse of the uterus, even when complete, the plastic operations usually adopted in such cases (perineorrhaphy and colporrhaphy) are as a rule adequate to effect a cure. In such patients more serious operations, such as vaginal hysterectomy or abdominal hysterorrhaphy, are unjustifiable. There are certain cases, however, of complete prolapse of the uterus and vagina that the minor plastic procedures are utterly inadequate to cure. Such cases are found among working-women, when a large uterus and an enormously hypertrophied vagina hang constantly outside the vulva, and have so hung for many years; the bladder has been dragged completely outside, the rectum has been pulled downward so as to be almost doubled on itself, and the pouches behind and in front of the uterus are filled with intestine, which slips upward and downward according to the position of

the patient. In such patients the vagina has apparently been the main factor in the prolapse, for it is very much lengthened and widened, and its muscular and cellular tissue is enormously increased, the wall being often an inch in thickness. The prolapsed mass may be as large as an adult head, and sometimes is irreducible. Perhaps among private patients who can and will take good care of themselves the combination of perineorrhaphy, colporrhaphy, and Alexander's operation, with the wearing of a pessary afterward, may nearly always render them comfortable. In working-women, however, who neglect themselves and are obliged to lift and carry heavy burdens, such operations are in my experience almost invariably attended by failure. When the patient leaves the hospital a brilliant cure has apparently been effected, and at the end of three months the cure may still persist, but in another three months or in a year the condition of these unfortunate women is generally as bad as before operation. I know that this is a strong statement, and is directly opposed to the reports of some of our prominent gynecologists, men for whose opinion I have the greatest respect, but I simply state my own conviction, and one that has been partly formed from observation of patients who have been operated on by these same surgeons, who maintain that the plastic procedures suffice in every case.

If plastic operations on vagina and perineum will not cure such patients, to what other procedures can we resort? Will vaginal hysterectomy be sufficient, or is abdominal hysterorrhaphy the more satisfactory operation? I consider that either one is justifiable in such conditions. In my experience vaginal hysterectomy *alone* is not sufficient to effect a lasting cure. When reinforced by perineorrhaphy and colporrhaphy it may give satisfactory results in most cases, but extirpation alone, without the aid of the minor procedures, has been followed by failure in nearly all of my cases.

Six patients whose uteri have been extirpated for the cure of aggravated prolapse have come under my observation. Four of them were operated on by myself, the other two by able surgeons of this city. In three of the six the hysterectomy has been reinforced by perineorrhaphy or colporrhaphy. One patient alone has been satisfied with the result obtained. In this case I reinforced the entire posterior vaginal wall and built up the perineum. In two patients the result may be classed as a partial success. In one of these hysterectomy alone was performed; in the other perineorrhaphy was added (both cases were operated on by me.) In three cases the result has been a failure, and the patients are but little better off than they were before operation. At the end of a year, in each patient a larger mass, of the size and character of the original tumor, only minus the uterus, protruded from the vulva. In one of them (operation by the author) hysterectomy alone had been performed; in another perineorrhaphy, and in the third lateral colporrhaphy had been added. In the last case, at the end of eight months, the woman's condition was so wretched that she begged for further operative relief, and in response to her appeal I opened the abdomen (with patient in the Trendelenburg posture) and with considerable difficulty drew the cicatrized apex of the vagina up into the abdominal wound, and in that situation carefully sutured it to the peritoneum and recti muscles, covering it with the external oblique muscle and the skin. At the end of six months the result was highly gratifying; the vagina was still somewhat roomy, but there was no sign of cystocele, rectocele or protrusion outside the vulva. The patient was comfortable and happy.

The result in this patient has been so satisfactory that I have persuaded one of the other cases of failure to undergo the same operation.

A short record of the four cases operated on by myself follows:

Case I was in a married multipara, aged forty-two years, with prolapse that had existed for twelve years. Perineorrhaphy and presumably colporrhaphy had been performed four years previously in one of our city hospitals. The prolapsed mass had been irreducible for six months. It was the size of the crown of an ordinary Derby hat, extending outside the vulva to a length of twelve inches. It measured 19 inches across the circumference. Reduction was impossible, even after two weeks' rest in bed, with ice-bags, etc. She was operated on in July, 1891. The uterus was extirpated, the posterior vaginal wall reduced in size, and a perineorrhaphy added. This patient died a few months after the operation from renal and cardiac disease. The result may be classed as a partial success, though had the woman lived longer it would I think have been classed as a failure.

Case II was in a multipara, thirty-eight years of age, with prolapse that had existed for ten years, and of about the same size as in Case I, but reducible. The uterus was extirpated in July, 1891, and almost the whole of the posterior vaginal wall was removed. The weight of the vaginal tissue was ten ounces. This left a large triangular gap, the edges of which were united, and a high perineum was formed, to partially close the outlet. This patient, at the end of two years, has still a very voluminous vagina, but there is no prolapse, and I consider the result satisfactory.

Case III was in a multipara, aged thirty-nine years, with prolapse for fourteen years, the size of a large cocoanut. Operation was performed in August, 1892. The uterus was extirpated. In six months the patient was as uncomfortable as before the operation, and the case may be classed as a complete failure.

Case IV was in a multipara, aged forty-one years, with prolapse for nine years as large as in Case I. The woman had on two previous occasions sub-

mitted to operations for cure of her trouble. The uterus was extirpated in March, 1893. At the end of five months the prolapse had partially returned, and doubtless will have fully returned in another three months. So convinced is the patient of this that in October she means to re-enter the hospital for an abdominal elytrorrhaphy.

Of the two patients operated on by other surgeons both are dissatisfied with the result of the original operation, and refuse further operative interference on account of the unsatisfactory result following their first attempt.

The details of the operation do not essentially differ from those of hysterectomy for carcinoma, except that the whole procedure is performed outside the vulva. The operation, however, is somewhat tedious and is attended with considerable loss of blood. When the uterus is removed an enormous raw surface remains, consisting of the inner surface of the vagina. This surface continues to bleed persistently, and the bloodvessels seem to have very little contractile power. In spite of numerous ligatures the oozing persists, even after pressure by clamps, sponges, gauze, etc., has been exerted for some time. I do not refer now to the broad ligaments, which of course have been tied in the usual manner, and cause no trouble, but to the free capillary and venous hemorrhage from the spongy surface of the vagina, out of which the uterus has been dissected. I have found that an attempt to stop this by means of ligatures is endless, and that the best means for its control is a continuous catgut suture. A comparatively small area of vagina is dissected off the uterus by scissors, and a needle threaded with fine catgut is carried out and in just under this bleeding surface, and a complete circumsuture of the area is made. Then a further dissection is made and another line of suture, and so on, until the uterus is free. In one of my patients, even by this method, I could not completely stop the hemorrhage, and I was compelled, after wasting considerable time, to fold the vagina inward on itself, bringing one bleeding surface against the other, and there suture them together around the entire circumference. On account of this tendency to bleed the operation is somewhat tedious and should not be practised on weak patients.

It may be that a larger experience may modify my views, but at present it is my judgment that vaginal hysterectomy for the cure of aggravated prolapse is an unsatisfactory procedure, and that, as a rule in such cases, abdominal hysterorrhaphy (hysteropexy) is the preferable operation.

Prof. Küstner, of Dorpat, has been elected to the chair of Obstetrics in the University of Breslau, in succession to Fritsch, who has been called to Bonn.

SOME OF THE THROAT-CONDITIONS OBSERVED IN GOUTY SUBJECTS.[1]

BY SOLOMON SOLIS-COHEN, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC; ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL, ETC.

THE term "gouty subject," as used in this paper, has perhaps a somewhat wider range of meaning than can strictly be ascribed to it, if only those are to be termed gouty who have suffered with articular inflammation, or who exhibit characteristic deposits. In this country, at least, a much larger number of persons suffer with other than articular manifestations of the uric-acid diathesis, their symptoms being varied, and often obscure, until the cause is discovered upon examination of the urine, which shows more or less constantly an excess of urates and uric acid, and often contains calcium oxalate and excess of phosphates. In both classes of patients the upper air-passages are frequently affected, and while the gouty diathesis cannot be affirmed to be the sole cause of the local manifestations, it doubtless acts as both a predisposing and a modifying influence.

Harrison Allen[2] has sharply discriminated between gouty sore-throat and the lithemic throat, and has reported a number of instances of the former condition. He has also given such references to literature as are of value in this connection. I am not inclined, however, possibly because of a more limited experience, to make equally sharp distinction with Allen. Sir Wm. Roberts[3] has well shown the important difference between uric acid gravel and gout, the offending materials in the latter case being deposited in combination as urates in the true interior of the body, while in the former they are deposited as uric acid, on a doubling of the external integuments; yet even he admits that the underlying conditions are virtually the same. Reasoning upon clinical analogy and without direct histologic evidence, it seems to me that cases of the class treated of in this communication occupy what may be termed a middle position; the phenomena depending in large part upon irritation due to offending materials in the circulation, but in less part upon actual deposition in the fibrous tissues.

A large number of cases would have to be recorded in detail by different observers, and a careful analysis made, before characteristic signs of throat-gout could be laid down. Reference should be made to the valuable studies of Hinkle,[4] with whom, however, I

cannot agree in assuming that the cases reported by Ingals as instances of rheumatic sore-throat were of a gouty nature. This paper does not aim to present more than the general results of personal observation, extending over a number of years, but necessarily dealing with a limited number of cases.

The condition, depending as it does upon a permanent error of metabolism, is probably in most, if not in all, instances a chronic one, with a tendency to paroxysmal exacerbation, under the influence of extrinsic or intrinsic exciting causes. Among the most frequent of such exciting causes are exposure to cold or to wet, and indiscretion in diet.

The frequent dependence of chronic sore-throat on diathesis has been recognized by systematic writers. Thus, concerning the causation of "chronic catarrhal sore-throat," J. Solis-Cohen says:[1] "The disease is not usually a sequel of acute sore-throat, but becomes gradually developed without attracting much attention. *It may exist with any diathesis.* Sometimes it is a mere manifestation of disorder in the intestinal tract." And again, concerning treatment, he remarks: "As this affection may coexist with *a variety of diatheses*, the systemic treatment will vary in accordance with the constitutional requirements. *Alkaline laxatives* are usually indicated."

Attention being as a rule first directed to gouty sore-throat during a paroxysm of exacerbation, its diathetic origin may be overlooked; and the case may be mistaken for one of the ordinary forms of acute inflammation. Inflammation, however, is not a necessary feature of the disease, and in my own experience the most prominent symptoms have been sensory; pains and perverted sensations of various kinds being referred to circumscribed regions, often described as "spots," in which no structural alteration adequate to explain the symptoms can be discovered. In one of the most marked cases that has come under my observation, that of a married lady, some forty-five years of age, who is of a gouty family, and has gouty deposits in the finger-joints, the spot most frequently pointed out as the seat of the discomfort is in the left pharyngeal angle just behind the free border of the soft palate. This, however, is not the only location of pain, which is variously described as stinging, burning, pressing, or like that caused by the presence of a foreign body. Sometimes the discomfort is referred to the neighborhood of the epiglottis; sometimes to the side or the base of the tongue; sometimes to several points at once. These spots are often painfully sensitive to the touch, and can thus be accurately localized. The patient has an idiosyncrasy to cocain, and it could not therefore be determined whether or not the application of this drug would abolish the localization of pain.

Similar localization is found in many, but not in all cases, and usually fails when cocain has been applied, though this is not invariable. I have been of the opinion that when sensitiveness persisted after application of cocain the trouble was deep-seated in the fibrous structures.

In some cases pain is referred to a part apparently unrelated with the one touched, but the association is constant, and the impression left upon the mind of the observer is that the error is in the reference, few persons being able to describe accurately the exact seat of a sensation in the throat.

Sometimes, and more especially during an acute paroxysm, visible alterations of structure are manifested at the painful spots. The most usual appearances are the presence of dilated bloodvessels—veins or capillaries, several of which may cross one another at such a spot. Sometimes a single large bloodvessel is found; sometimes there is a dusky coloration of the mucous membrane; sometimes an enlarged and reddened follicle. Often, however, there is no apparent difference from the surrounding membrane, which sometimes presents general congestion, and sometimes nothing out of the ordinary. When congestion exists it may be patchy or uniform. Usually the coloration resembles that of corned beef; sometimes it is dusky red, or even purplish.

In the larynx, the epiglottis and the arytenoid eminences seem the favorite seats of morbid sensation, the former usually exhibiting a network of dilated vessels resembling a veil, the latter a slight tumefaction and reddening. In two cases, in young men, I have seen what appeared to be inflammation limited to the neighborhood of one crico-arytenoid joint. There was pain on respiration and phonation, vaguely referred to this region. I have frequently seen similar appearances at the inception of an attack of acute rheumatic tonsillitis. In some cases there is during the more acute stages a characteristic diffuse laryngitis, much resembling, and perhaps identical with, the form described by J. Solis-Cohen[1] as occurring in young adults addicted to over-feeding and the abuse of condiments.

In these subjects the tongue is red or reddish-brown, thick, puffy, with prominent papillæ, with a somewhat thick coating at the base, extending in streaks toward the tip. The mucous membrane of the pharynx, palate, and palatine folds is relaxed, puffy, and usually congested. The mucous membrane of the larynx, and especially of the arytenoid eminences, and of the ary-epiglottic folds, is similarly puffy, and always congested; the vocal bands

[1] Diseases of the Throat and Nasal Passages. Second edition, p. 178. New York, 1879. Italics are mine.

[1] Op. cit., p. 474.

are pink or red, the color being deepest at their posterior insertions. A pellet of mucus is usually adherent to the meso-arytenoid fold, and as a rule mucus is found in other portions of the larynx as well. The voice is hoarse; the hoarseness is greatest in the morning and after meals. There is a constant desire to clear the throat of mucus; the expectoration is greatest in the morning. The patients often complain of a feeling of fatigue after slight use of the voice. This sensation of tiredness may be referred to the larynx or to the pharynx. The conditions described may pass off in a few days; they may persist for ten days or a week; or they may merge with the chronic symptoms.

In the pharynx, the tonsillar and peri-tonsillar structures and the angles of junction of the posterior and lateral walls have seemed to be most frequently affected. There may be enlarged glands. The tongue and its glands are often involved. The mucous membrane of the tongue or of the cheeks sometimes presents whitish patches of cornified epithelium (leukoplakia buccalis). When the distressing sensations are referred to the rhino-pharynx, Luschka's tonsil may be tumefied and reddened. In young patients the pharynx and larynx are often covered with grayish, tenacious mucus; in those past middle life the pharyngeal and palatal membrane is often dry and pale, exhibiting a network of enlarged and tortuous vessels, or mottled with livid patches.

Relaxation of the palate is common, and in some subjects paroxysms of nasal obtruction, with or without coryza, are met with. This was noticeably the case in a man aged fifty-four years, a neurasthenic, with gouty deposits in the drum-membrane, and in whom at other times nasal respiration was perfectly free; there being no structural deformity that would impede the passage of air. During these paroxysms of obstruction the turbinates would be puffy and pasty-looking; the posterior wall of the pharynx would be apparently bulged forward, and the soft palate would likewise appear puffy and pale. There would be an annoying sensation of a foreign body between the throat and the nose, and efforts at hawking, though ineffectual, would be continually repeated. Examination would not reveal sufficient accumulation of mucus in this region to account for the sensation. In this case the hard and soft palate were occupied almost constantly with a network of large, bluish vessels, which during the paroxysms referred to became still more tortuous and darker in color. Upon one occasion I proposed scarification, but the patient—perhaps wisely—would not consent. In some cases tubal catarrh exists, and sensations of distress are referred to the ear. In a case similar to the one just cited, pain was referred to a point marked externally by pressing the finger just behind the angle of the jaw, whence it radiated into the ear. In a few cases spasmodic choking in swallowing and spasmodic obstruction of respiration, laryngeal and bronchial, have been observed. In one case an attack almost resembling croup was followed by an outbreak of articular gout.

The diagnosis in these cases, while suggested by local appearances and symptoms such as have been described, depends upon recognition of the constitutional condition, and cannot be affirmed in the absence of the ordinary evidences of such constitutional disorder. Urinalysis gives the most important evidence in cases in which there has been no articular inflammation or deposit.

Local treatment is palliative only, and it should be sedative and protective; irritating and stimulating applications are counter-indicated. Astringents may be cautiously employed during paroxysms of exacerbation. For this purpose I have found the glycerole of tannin applied by cotton wad, or a spray of zinc sulpho-carbolate in rose-water (five grains to the ounce), the most useful. Cocain is badly borne by some patients, inducing spasmodic phenomena. When well borne it is useful to relieve pain. Applications of fluid extract or concentrated infusion of coca will at times be feasible and useful in cases in which the alkaloid cannot be employed. I have likewise found aconitine oleate (2 per cent. in oleic acid, freshly made and flavored with oil of almond) a useful analgesic application. Menthol (from 2 to 5 per cent. in liquid petrolatum, as a spray; from 5 to 10 per cent., topically by cotton wad) is occasionally of great service; in some cases, however, it cannot be tolerated. Bromoform (topically by cotton-wad) has given relief in one or two cases in which other applications were inadmissible. In chronic cases solution of iodin and carbolic acid in glycerin (of each one grain to the ounce, with one and one-half grains of potassium iodid to facilitate solution) applied to the spots of painful sensation, or brushed over the entire pharyngeal wall, is of service.

Before making any of these topical applications, whether in acute or chronic cases, the parts should be cleansed by an alkaline and aromatic spray. In quite acute pharyngitis a gargle of hot milk and borax, or of plain hot water, or hot alkaline solution, often gives great relief. Guaiac is likewise of benefit. In acute laryngitis alkaline sprays, followed by the inhalation of the vapor of hot water impregnated with benzoin and paregoric, are useful. For permanent relief, of greater or less degree, dependence must be placed on dietetic, hygienic, and medicinal measures appropriate to the uric acid diathesis. It is unnecessary to detail these here, but I would like to record my favorable experience in this connection with strontium bromid.

ILLUSTRATIVE CASES.

CASE I.—Mrs. L., aged fifty, for some years has had attacks of tingling and sensations as of the presence of dust (hardly intense enough to suggest the presence of a feather) at the left side of the throat. When this feeling is experienced she is forced to cough, and with the cough comes a sensation of strangling. The cough is short, at first sharp, afterward, with the strangling sensation, muffled. There is never any expectoration. The pharyngeal mucous membrane is irregularly reddened and thickened, and there are a number of prominent follicles, surrounded by reddish whorls of dilated vessels. The larynx is diffusely congested, the color being deepest over the arytenoid eminences. There is no mucus in the larynx or pharynx; Luschka's tonsil is reddened and prominent. There is no turbinate engorgement, and though the septum is slightly deflected to the left, nose-breathing is, and has always been, free.

The patient has frequent attacks of shooting pains in the fingers, joints, and about the knees. There are gouty changes in the last joints of the ring and middle fingers of the left hand. For some years she has been compelled to rise at night to urinate. The urine at times is burning.

The patient belongs to a family of good livers, some of whom have had articular gout. She is very stout and has a sallow and flushed complexion.

Urinalysis showed the presence of free uric acid as well as excess of urates and calcium oxalate. The specific gravity was high; no sugar or albumin was found.

A spray of liquid petrolatum, with 5 per cent. of menthol and 2 per cent. of cocain, was prescribed to be used three times a day, and whenever the unpleasant sensations were experienced. The diet was carefully regulated, outdoor exercise directed, and strontium bromid given in doses of thirty grains three times a day before meals. Under this treatment the patient rapidly improved, and up to date (ten months) there has been no return of the paroxysms.

CASE II.—Mr. M., aged fifty-two, of full habit, sallow and flushed complexion, complains of ringing in the ears, of a pain darting from the ear to the throat, and from the throat to the ear, sometimes felt externally behind the angle of the jaw. There is a constant desire to clear the throat, but very little mucus is ejected. The nose feels stuffed up. At times there is a burning sensation referred to a definite spot in the pharynx. The palate is relaxed and covered with a network of bluish vessels. There are a number of enlarged follicles in the pharynx, which is irregularly streaked with red and bluish patches; between these the intervening membrane is quite white. A sensitive spot is found just beneath one of the enlarged follicles on the posterior wall. The patient recognizes this as the seat of the burning. There is considerable tumefaction of the posterior wall of the pharynx toward the lateral angles. The septum is slightly bent, though not sufficiently to obstruct respiration, and the lower and middle turbinates are red and swollen. The tongue is heavily coated, and the papillæ are prominent. Some accumulation of thick, tenacious mucus is seen in the vault of the pharynx. The mouths of the Eustachian tubes are widely open, and the whole structure appears much larger than normal. No mucus is detected in the Eustachian tube, and air enters it freely. The drum-membranes are opaque and show gouty deposits. The patient is a dyspeptic; his urine shows excess of urates, calcium oxalate, no albumin, no sugar.

A spray of menthol and cocain in liquid petrolatum was prescribed, but the strength had to be reduced to 2 per cent. of menthol. The rhinopharynx was wiped clean every morning with a cotton wad saturated with a 2 per cent. solution of cocain. Counter-irritation over the mastoid processes with tincture of iodin was from time to time employed, and iodin, carbolic acid, and glycerin solution applied twice a week by a cotton wad to the nasal passages. Regulation of diet and antilithic treatment internally were kept up. The patient slowly improved and was dismissed from treatment in the course of three months. He had become largely rid of his distressing symptoms, though not altogether of the roaring in the ears. Once in a while he returns for local treatment, which seems to give him relief.

CASE III.—Mr. C. H., aged thirty, a travelling salesman, for a year or more has had frequent attacks of hoarseness, with a feeling of "rawness" in the throat. There is no pain in swallowing. The attacks last about a week. The intervals of freedom vary from a month to six weeks. The present attack has lasted longer than usual—some ten days. There is a slight hacking cough and a desire to clear the throat. There is no trouble in breathing, nasal or otherwise. The tongue is heavily coated, the pharynx congested in streaks, the larynx slightly congested, the epiglottis flaccid, the arytenoid eminences puffy. There is pain referred to the upper part of the chest, but no physical sign of pulmonary lesion. The heart is normal. The patient is a very stout man. He uses tobacco largely, and drinks beer moderately. He is a hearty eater and a gourmet. The urine is 1034 in specific gravity, of acid reaction, and contains urates, uric acid, and calcium oxalate in excess. Diet was regulated. A solution containing strontium bromid and strontium lactate, 15 grains each, was given in water, before meals. The patient was ordered to drink hot water one hour before meals. Zinc sulpho-carbolate spray was applied locally. Relief was reported in four days. There has been no return of discomfort as yet.

Dr. Isaac N. Kerlin, Chief Physician and Superintendent of the Pennsylvania Training School for Feeble-minded Children, at Elwyn, died on October 25, at the age of sixty years, as the result of a cardiac lesion, of which he had been the victim for a number of years. Dr. Kerlin was the Superintendent of the Training School from 1864, having previously been Assistant Superintendent. He was held in the warmest affection by all who knew him, and was generally respected for his professional attainments.

HORNY EPITHELIUM OR SUMMER GRANULATIONS—ITS RELATION TO CONJUNCTIVITIS TRACHOMATOSA; IMPRACTICABILITY OF TREATMENT BY EXPRESSION.[1]

BY JOS. E. WILLLETS, M D.,
OF PITTSBURG, PA.;
LATE CLINICAL ASSISTANT AT THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE; ALTERNATING OPHTHALMIC SURGEON TO PITTSBURG FREE DISPENSARY, ETC.

CONJUNCTIVITIS TRACHOMATOSA is an affection that is characterized by a peculiar roughness, hyperemia, and swelling of the conjunctiva. These changes are sometimes seen as hypertrophied papillæ, again as diffuse excrescences, arranged in rows on the palpebral fold, and from their shape and gelatinous translucency, resembling the spawn of fish or frogs, but of a slightly pinkish or yellowish tint. The appearance of the conjunctiva is much modified by the greater or less development of these excrescences and hypertrophied papillæ. Thus, from a practical point of view, the distinction of several varieties of the disease is essential, as these differences affect not only the course, but also the treatment and the results of the disease. There is fortunately one rare form, which, while being mixed, is not the form commonly described in books as mixed trachoma, as that refers only to its association with the papillary form. The form referred to is a variety associated with a pathologic condition, on which we find but little written, but which is spoken of as horny epithelium, or summer granulations. In this affection the external appearance is much the same as in follicular trachoma. There is a redundancy of the upper lid, with slight ptosis, but on everting the lid we find that the granule is apparently displaced by horny or teat-like elevations. These horny excrescences are not the enlarged papillæ described by authors under the head of "mixed trachoma," in which disease the papillæ sometimes enlarge so as to completely conceal the trachoma-granule by overlapping it.[2] Again, in describing trachoma diffusum Stellwag says:[3] "We have large growths which sometimes project like a cock's comb over the tarsal border." These are enlarged papillæ, not granules. I do not refer to these growths. Clinical observation has shown me that in mixed trachoma the granules are in a minority, the papillæ in all stages of hypertrophy, and that when any of the papillæ have developed as large as these horny elevations, they do not otherwise resemble them, inasmuch as they are isolated and pedunculated, but the horny excrescences are cone-shaped or teat-shaped, and not isolated. Nor do we in the papillary form, with extensive papillary hypertrophy, find as even a development, nor is the arrangement as symmetrical. Their appearance suggests that these elevations are proliferated trachoma-granules due to some action the cause of which is unknown.

Histologically, trachoma is simply an aggregation of leukocytes in the lymph-follicles, which by their increased number push aside the conjunctival tissue, compressing its fibers in such a manner that it has been mistaken for a fibrous capsule or membrana propria. It differs from the follicle in follicular catarrh in being an *active neoplasm subject to change.* The granules may undergo fatty degeneration, and thus be absorbed, or they may be transformed into tough connective tissue.[1] This is not the case in follicular catarrh, these follicles being simply normal lymphoid spaces not subject to change. They are seldom associated with papillary hypertrophy, and never lead to shrinkage of the conjunctiva, to pannus, or any of the distressing sequelæ of the trachoma-granule, and present the type of a disease devoid of danger, frequently getting well without any treatment whatever, and leaving no trace behind.

The true trachoma-granule, as it increases in chronicity, has its leukocytes converted into connective-tissue fibers, which form a true hypertrophic base to each granule, and which we find in all stages of development in any given case of chronic trachoma. It is not only possible but very probable that, due to some peculiar diathesis, non-hygienic measures, or bacterial influences, we have an exaggerated proliferation of these leukocytes into connective-tissue fibers; we have instead of a simple hypertrophic base to each granule a continued hypertrophy, until we have these teat-like or horny excrescences, which are known as horny epithelium or summer granulations. These growths are always associated with the trachoma-granule in some one stage of its development; their pathogenesis is the same; their analogy and association with trachoma suggest them to be a later or hypertrophic stage of that affection, fortunately a rare one, not necessarily following every case, but existing in a certain percentage of cases due to some special existing cause not known, and would be better designated under the head of conjunctivitis trachomatosa hypertrophica.

The subject of trachoma, in any one of its forms, has assumed a new interest in recent years, as we have more effective operative measures, and can now cure in a few sittings what we formerly only relieved after long and varied treatment. The treatment by expression which originated many years ago, and which has been carried out with many different contrivances, has now, since the introduction of Knapp's roller-forceps, become generally adopted

as the quickest and most effective one, except for the hypertrophic form just spoken of. This form of trachoma, if we choose to class it as trachoma, is not amenable to treatment by expression, there being nothing to express; the teat-like processes are simply squeezed and bruised by the rollers, and the case is aggravated; and so it is to a certain extent with the papillary form and also the cicatricial form. Infiltration cannot be squeezed out, and where the granules are few and scattered the irritation of the hypertrophied mucous membrane by the *undue* pressure of the rollers will cause a reaction not looked for, and little benefit is derived on account of the enlarged papillæ forcing the rollers over the granule, and not permitting proper expression unless *undue* force be brought to bear on the rollers. It is in cases of this kind that operators failed to recognize the importance of the fact that the amount of pressure brought to bear on the rollers should be lessened in ratio to the amount of existing hypertrophy, and that they should not be used unless granules are present. Because of this fact the desired result was not obtained and the forceps laid aside. I have seen three different operators in as many different cities use the roller-forceps in the papillary form when there were no granules present. These surgeons were necessarily disappointed with the rollers as an operative measure.

The recent series of 114 operations of the various forms of trachoma treated by expression, conducted by Dr. Knapp at the New York Ophthalmic and Aural Institute, in which I participated while his assistant, and which are reported in the January number of the *Archives*, 1892, have shown that the forceps is best adapted to that form of trachoma in which there is something to express, namely, the follicular variety. Of 64 cases of this form, 54 were cured at a single sitting; 8 failed to report, and 1 was afterward operated on by the grattage-method. This case I remember was purposely left for two sittings, as a case operated on the day previously, a little girl, showed a deposit of fibrinous coagulum on the conjunctiva of the lower lid of the left eye, which produced a partial entropium. This was torn up with a squint-hook. Dr. Knapp thought it better to subject the succeeding case to two sittings, as he feared the same result. The patient did not return to have the operation finished, and was afterward operated on by the grattage-method by Dr. Weeks, of New York. I was surprised to hear this case reported at the New York Academy of Medicine some time later, as a relapse of the squeezing-method. In 140 operations I have seen but very few relapses, my first operation, at the Post-Graduate School of Medicine of New York, being one of them. The conjunctiva was profusely studded with granules, but on account of imperfect etherization the granules were not all expressed, to which fact the result may be attributed. To use Dr. Knapp's expression, "the conjunctiva should be milked" with the rollers, applying just sufficient pressure to evacuate the granules, which is very little; the tactile sense alone should be sufficient guide to the operator. It has been asserted in my hearing that one objection to the rollers was that enough pressure could not be brought to bear on them to express the granule, and that the handles were frequently in contact before the desired effect was produced. Such excessive force is an unwarranted procedure, and detrimental to the successful termination of the operation.

It requires less pressure in follicular trachoma, in which the granules are the most profuse, than in any other variety, and most pressure in the mixed form with hypertrophied papillæ; on account of this it is well to treat the latter form with a solution of sulfate of copper for a week or more, until the papillary hypertrophy is considerably lessened, permitting the *granule* to become the more prominent, when it is readily expressed, much less pressure being required.

Dr. Knapp's series of operations has demonstrated the following important facts: First, that the cure of trachoma is not dependent on germicides,[1] the cures resulting from the grattage-method probably being due to the more or less perfect expression of the granule, and not to the incorporation of bichlorid of mercury, to which it is attributed. Secondly, that the granules can be expressed without injury to the conjunctiva; whereas by the grattage-method they are only imperfectly expressed, and then at the expense of mutilation of healthy conjunctiva. Thirdly, that the cure is dependent on the thoroughness of the operation alone.

Too much cannot be said in favor of this recent valuable addition to ophthalmic surgery. By no other means at our command can we so completely eradicate these bodies without injury to the conjunctiva, curing the disease, I may say, in its incipiency, before those many distressing sequelæ appear, which so often destroy vision, and in a very large percentage of cases leave the patient with one or more of those structural changes, as a life-inheritance of a disease over which we previously had but imperfect control. We must on its merits, appreciate the roller-forceps as the operative measure *par excellence* for trachoma folliculaire. Its superiority over the grattage-method is plainly apparent. The inability to completely remove the granule from the fornix and bulbar conjunctiva, and the liability to injure the cornea, during the irregular scrubbing-process, combined with the necessary compulsory

[1] Knapp: Archives, January, 1893.

mutilation of the healthy conjunctiva, in the effort to thoroughly incorporate the bichlorid of mercury into the granule, to say nothing of the frequent relapses and severe reaction, are all well-founded objections to this method. There are no relapses following the squeezing-method, the so-called relapses being simply unfinished operations, due to imperfect expression.

WESTINGHOUSE BUILDING.

PRECISION IN THE DIAGNOSIS OF INTRA-ABDOMINAL DISEASE.[1]

BY EDWARD A. BALLOCH, M.D.
INSTRUCTOR IN MINOR SURGERY, MEDICAL DEPARTMENT OF HOWARD UNIVERSITY, WASHINGTON, D. C.

FIVE cases that I have seen during the last four years may serve as a text for what remarks I have to make on this subject. I will briefly give the clinical histories:

In the summer of 1889 a patient was left in my care by a prominent local physician who was leaving the city for his vacation. He informed me that the man had an aneurism of the abdominal aorta. A few days after his departure I saw the patient and, upon superficial examination, found an oval, strongly-pulsating tumor in the median line of the abdomen. With the idea of aneurism in my mind I must own that I gave comparatively little attention to the patient, who continued to attend to his work, with brief intervals of illness of an indefinite nature. Upon the return of my friend, I handed the case over to him, apparently neither materially better nor worse than when I took charge of it. A few weeks later he told me that he was in some doubt as to the correctness of his former diagnosis, and suggested that we examine the patient thoroughly, with a third physician. This was done and, the patient being placed in the knee-elbow position, the supposed aneurism was easily pulled away from the aorta and the diagnosis of abscess of the liver was made without difficulty. The aspirator drew off several ounces of stinking pus, but in the course of a few days the abscess burst into the lung and death ensued.

In October, 1890, I was consulted by a young man, thirty-five years of age, for persistent hiccough. A careful examination of the abdomen and its contained viscera, by the usual methods, revealed nothing abnormal, and the hiccough was regarded as of nervous origin, and a prescription given for a pill of hyoscyamus and belladonna. I heard nothing more from the patient until March, 1891, when he sent for me again. I found him in another attack of hiccough of three days' duration. He informed me that his former attack had been immediately arrested by the treatment adopted. I accordingly repeated it, but this time without success. Still under the impression that the hiccough was of nervous origin, and deceived by my former success, I ran the gamut of the antispasmodics and like remedies, without avail. Several repeated and careful examinations revealed nothing more than slight tenderness over the liver and a few areas of sensitiveness over the abdomen, the location of which shifted from time to time. At this time the lungs were also carefully examined, with a negative result. The pulse was continually rapid and weak, and this fact, together with a slight but persistent rise of temperature, aroused my suspicions; and after watching the case for about a month, I became satisfied that it was one of tuberculosis of the peritoneum. This diagnosis was soon after corroborated by the involvement of the lungs, and before long it was confirmed by an autopsy.

During the winter of 1891 I was asked by a medical friend to see a patient under his care and give my opinion as to the nature of the affection. I found the case to be one of intra-abdominal disease, characterized by the presence of a long, oval tumor in the median line, midway between the umbilicus and the ensiform appendix. The tumor was very hard and pulsated strongly. The patient's statements were vague and contradictory and there was a complete absence of any symptoms of trouble with the digestive apparatus. The man was well nourished and ate well. As a matter of routine I placed the patient in the knee-elbow position, when I was able to completely isolate the tumor from the aorta and to determine that it was connected with the pyloric end of the stomach. I accordingly told my friend that, in my judgment, he had to deal with a case of carcinoma of the pylorus. He thereupon informed me that the case had been seen by a member of this Society justly renowned for his diagnostic acumen, who had pronounced the case to be one of aneurism of the celiac axis. I replied that time would settle the question. The patient died soon afterward, rather unexpectedly, and the autopsy showed a carcinomatous growth almost completely surrounding the pyloric end of the stomach.

The fourth patient presented a large, doughy, non-pulsating and immovable mass in the right side of the abdomen, between Poupart's ligament and the liver. There was absence of any symptoms relating to the digestive tract and not much pain. My opinion was that there was a malignant growth within the abdomen, probably originating in the mesenteric glands. The autopsy showed a primary carcinoma of the gall-bladder, the large mass being a hematoma caused by the encapsulation of blood effused from an ulcerated bloodvessel.

The prominent characteristic of the last case I shall mention was severe, localized pain extending over a period of six months or more. The pain began in the left side of the abdomen, but finally shifted to the right side and became severe and agonizing, shooting down the right sciatic nerve, and being worse at night. There was at no time absolute elevation of temperature. The pain was intermittent in character and resisted all known anodynes. The urine was several times examined and found to be normal, except for excess of urates, and there were no disturbances of sensation, and no paralysis, or other indication of disease of the spinal

[1] Read before the Medical Society of the District of Columbia at its meeting, October 11, 1893.

cord. There was no discoverable tumor. This man was subjected to many and prolonged examinations by at least six different physicians, each of whom had in his mind the possibility of aneurism, but excluded that disease on account of absence of tumor, pulsation, or bruit. The opinion finally agreed upon was that the man was suffering from the effects of pressure upon the nerves forming the lumbar plexus on the right side, and that the pressure was applied outside the spinal canal. The cause of the pressure was not determined. The autopsy revealed an aneurism of the posterior part of the aorta, just above the celiac axis, with extensive erosion of the bodies of the eleventh and twelfth dorsal vertebræ, death being due to rupture of the sac.

Here are five cases of intra-abdominal disease selected at random, each differing in its nature from the others, and in all of which the diagnosis was more or less obscure.

I had thought my experience with such cases to be particularly unfortunate, but in view of the many like cases constantly being laid before this Society I am encouraged to hope that my own feeling of uncertainty in the diagnosis of intra-abdominal disease is, perhaps, shared by others. It is with this hope that I venture to bring the subject to your attention, trusting that such discussion as my remarks may elicit will tend toward clearing up the obscurity now surrounding it, and possibly enable us to fix upon some criteria of accurate diagnosis.

In the diagnosis of intra-thoracic disease we are greatly aided by instruments of precision and have practically to determine only the nature and not the location of disease. In disease within the abdomen the case is different. Not only is the number of organs and structures many times greater, but we sadly miss the aid of the many mechanical devices that help us in our examination of the thorax and its contents. Many of the organs and structures are deep-seated and all overlap one another to a greater or less extent.

There are two ways of dealing with this subject. The one is to discuss the relative value of each symptom and sign of abdominal disease, and the other is to discuss the different conditions likely to baffle us, and to endeavor to find some indication in each that may be relied upon with some degree of certainty. For the purpose that I have in view the latter seems the preferable plan.

Accordingly, let me first ask your attention to carcinomatous disease of the stomach. This is not an infrequent affection. According to Welch's statistics, primary carcinoma of the stomach forms 21.4 per cent. of all cases of carcinoma. Yet there is no symptom of carcinoma of the stomach that may not be simulated by other forms of disease. The pain, marasmus, vomiting, hemorrhage, and anemia are not pathognomonic. Gastric carcinoma and pernicious anemia have been repeatedly confounded.

It is a well-known fact that in many cases of gastric carcinoma free hydrochloric acid is persistently absent, but it is not so in all instances. The latest investigations of Ewald and other observers show that it is also absent in many other diseases. It seems to be settled that for this acid to be absent there must be destruction of the mucous membrane of the stomach. Provided this membrane remains intact free HCl may be present to the last. We are more justified in excluding carcinoma when HCl is constantly present than we are in affirming the existence of malignant disease when this acid is absent.

The one comparatively certain sign is the presence of a tumor connected with the stomach; yet even here we stray into the region of uncertainty. In the first place, as Osler very truly says, there is very little of the stomach that we can palpate. Allow me to quote the following from his recent work on the *Practice of Medicine:*

> "At least two-thirds of the organ lie in the left hypochondrium beneath the ribs, and so are practically out of reach. . . . Practically in health there is available for diagnosis only a part of the anterior surface of the stomach and the pylorus, which is sometimes, but not always, overlapped by the liver. Tumors limited to the cardia, even when extensive, cannot be felt at all. Tumors involving the fundus, the posterior wall, and the greater part of the lesser curvature cannot be detected, unless very large. Tumors of the pylorus, of the anterior wall, and of a large part of the greater curvature are in inacessible situations."

This opinion will, I am sure, be indorsed by every physician of practical experience. It is worth while remembering that the tumor may be found in the most unexpected localities. In one case it was located just above the symphysis pubis. When a tumor is found we cannot be certain that it is connected with the stomach. It may belong to the left lobe of the liver, the pancreas, the omentum, or to the transverse colon. Not even when we have found our tumor and located it in the stomach can we be certain that it is carcinomatous. A circumscribed induration and thickening from ulcer may deceive us. There are cases of simple, non-carcinomatous hypertrophy of the pylorus, with stenosis, in which diagnosis even after death is impossible without microscopic examination. Finally, there may be cases of carcinoma of the stomach without any tumor at all. These exceptional cases are fortunately very rare. Practically I think that when the symptoms are those of grave disturbance of the functions of the stomach, and in addition thereto we discover the existence of a tumor, we may predicate malignant disease with a fair degree of certainty. There is, however, no one sign or symptom to which we

can pin our faith. Every test must be applied and every resource exhausted. There are many cases of gastric carcinoma in which the diagnosis is unfortunately but too clear. These need not concern us. It is the doubtful cases in which we need light. The diagnosis is to be made not from the presence of any one symptom, but from the coëxistence of several. I desire to emphasize the value of the knee-elbow position, in addition to the dorsal position, in examining for tumors at the pyloric end of the stomach.

Tuberculosis of the peritoneum is a term used advisedly that a distinction may be drawn between it and tuberculous peritonitis. In the latter affection the signs of peritonitis are usually well-marked, while a microscopic examination may be needed to detect the presence of tubercle after death. In the former disease there are few or no signs of peritonitis, yet the autopsy may reveal a peritoneum studded with tubercle. It is of this tuberculosis of the peritoneum that I desire more particularly to speak. It is probably the most latent of all intra-abdominal diseases. In some cases it may not cause a single symptom. In other cases there are vague complaints of dull pain and digestive disturbances. When the disease affects the omentum an ill-defined tumor may be made out by palpation. When one considers that these tumors have led to operations, under the belief that strangulated hernia existed, and that in one-third of the cases in which the abdomen has been opened in this disease the operation was performed for supposed ovarian cyst, the necessity for care is apparent. A somewhat extended experience in this disease has taught me to rely largely on the temperature-record as a guide. Whenever I meet with a case presenting ill defined abdominal symptoms, in which there is a persistent evening rise of temperature, the possibility of tuberculosis of the peritoneum immediately presents itself to my mind. The rise need not be large, perhaps not over a degree or two, but its persistence is suspicious. If with this evening rise there occurs an occasional subnormal morning temperature, the probability becomes almost a certainty. Should the lungs become involved, the diagnosis, of course, becomes clear. But in tuberculous affections it is our duty to make as early a diagnosis as possible if we are to hope for successful results from treatment. In many cases of this disease the abdomen has been opened, usually as a result of an error in diagnosis. But, whatever the motive, the operation has had an undeniably beneficial effect on the tuberculosis, and in a large proportion of the cases has led to a rapid amelioration of the symptoms and even to a cure. To such an extent is this true that I believe we are justified in recommending this operation as a remedial measure in this disease.

Like tuberculosis of the peritoneum, aneurism of the abdominal aorta is an affection in which the earlier the diagnosis is made the more hope we have of success in treatment. Unlike tuberculosis, however, it is here that absence of pyrexia should be a finger-post to successful diagnosis. It is not the plain cases, in which all of the characteristic signs are well marked, that need concern us. It is the cases like the one of which I have given a summary that call for careful examination and thought. What shall guide us in cases when we can detect no tumor, no pulsation, no thrill, and no bruit? I am not prepared to lay down any certain rules, but, judging from my experience in the case outlined, I should consider that pain, persistent and severe, involving any of the nervous plexuses in the abdomen, associated with absence of pyrexia, should lead us to suspect this affection. This, of course, is true, provided there be no discoverable disease of any abdominal viscus and no symptoms of disease of the spinal cord. Gross mentions a sign that may prove of value in detecting aneurisms of the first part of the abdominal aorta, and particularly those situated at the back part of the vessel. It is a murmur, heard by listening over the eleventh and twelfth dorsal vertebræ. It must be remembered that excessive pulsation of the aorta is a common symptom, and, in itself, is no guide at all in the diagnosis of aneurism. Some authorities lay down the rule that a diagnosis of aneurism of the abdominal aorta should not be made unless we find a definite tumor that can be grasped and lifted up, and in which expansile pulsation can be felt. If this is so, then the diagnosis of aneurisms just below the diaphragm, particularly if they involve the back part of the vessel, can never be made, because in these cases none of these tests can be applied.

Hepatic abscess is a symptom of so many diseases that one is hardly justifiable in regarding it as an entity. However, it is often a condition demanding relief, and it may assume more importance than the particular disease that causes it. It is a very insidious affection; in many cases symptoms are completely absent; when they are present they point to the liver as the seat of the disease. They are not characteristic, however, as the dull pain, malaise, jaundice, enlarged liver, and digestive disturbances may be simulated by other affections. In my opinion our main reliance should be placed on the presence of signs of sepsis, such as an irregular and intermittent pyrexia, accompanied by rigors and sweating. When with these symptoms are associated an enlarged liver and a discoverable tumor, we cannot go far astray in pronouncing the case to be one of hepatic abscess, particularly if we are able to find the focus from which the infection starts. In doubtful cases aspiration is warrantable,

and even an exploratory incision. If there be any discharge it should be examined for the *ameba coli*.

The subject of morbid growths within the abdomen is too vast to allow me to take up time in discussing it. The same is true of many other obscure conditions. One of these, movable kidney, which is exciting no little interest at present, has lately been exhaustively set before you. As the object of this paper is rather to furnish a basis for discussion of intra-abdominal disease than to attempt any dogmatic statements thereon, I shall bring it to a close by a few general conclusions that may serve to give direction to whatever discussion may follow.

In the first place it is my opinion that the diagnosis of intra-abdominal disease requires and demands a higher order of skill, knowledge, and acuteness than the diagnosis of any other class of disease. There is no chance here for slipshod work or hurried investigation. Not one, but many and prolonged examinations, must be made. Each and every symptom and sign, however minute and seemingly unimportant, must be noted and weighed. Some cases involve an analysis of nearly all the secretions and excretions of the body. In this connection let me lay stress upon the great value of examinations in the knee-elbow or knee-chest position. It seems to me that one may derive more satisfactory results from this than from any other single aid to diagnosis. I believe that it should form a routine part of all examinations of the abdomen and its contents. The importance of an early diagnosis must be apparent to all. Here, if anywhere, the maxim of the fathers, *obsta principiis*, is of eminent value. The remarkable fatality of these obscure diseases emphasizes the necessity of early diagnosis and treatment. If we wait too long the day for help passes and we are condemned to the painful necessity of seeing our patient slowly die while we must stand by with our hands tied, so far as affording material aid is concerned. In each of the cases forming the basis of this paper the propriety of an exploratory incision was considered. The results showed that it would have been of little avail in any. Within what limits this procedure is justifiable my experience does not qualify me to speak. It would gratify me to have this point discussed and some rules formulated for our guidance.

With this brief sketch I submit these remarks to you for discussion. If any point of value or any aid in diagnosis shall be elicited, I shall be personally grateful. It may be that some of us by reason of greater skill and experience have succeeded in solving the problems that vex the rest of us in this matter. If so, I trust that the Society may have the benefit of their wisdom in order that we may reach more rapidly the goal toward which we are all earnestly pressing—the accurate diagnosis and successful treatment of disease.

CLINICAL MEMORANDA.

CHOLECYSTOTOMY NECESSITATED BY OBSTRUCTION OF THE CYSTIC DUCT.

By GEORGE S. BROWN, M.D.,
of Birmingham, Ala.

P. H. L., white, twenty-five years of age, a contractor, and a strong, hearty man with a splendid personal and family record, has lived all his life out of doors. On July 1, 1893, at 11 P.M., after having eaten a hearty supper, he was awakened from sleep by severe colic in the epigastrium. The usual household remedies failed to give relief, and he suffered all night. At 11 A.M. on the next day I saw him, and at once administered a hypodermatic injection of morphin (½ gr.), and gave him an ounce of castor oil by the mouth. He vomited the oil at once. The vomiting, which soon became bilious in character, continued at frequent intervals all of that afternoon and night; and the pain was so severe as to necessitate repeating the morphin injection about every four hours. At 4 A.M. on July 3d I was hurriedly sent for. I found the man with all of the symptoms of a general peritonitis. His temperature was 103°, his pulse 110; the belly was swollen, hard, and tender; the legs were drawn up, and the face anxious. Vomiting was frequent. A rupture of some kind being suspected, preparation was made for an exploratory incision. By the time our arrangements were completed, however, about two hours later, the pulse and temperature had fallen a little, and the left side of the abdomen seemed not quite so tense. It seemed probable now that the peritonitis would prove to be limited to the right side, and we therefore deferred the exploration.

Although the chances were in favor of the appendix being the seat of trouble, no tumor was discoverable in that region, and the pain and tenderness were greatest in the epigastrium, although the whole right side was tense and sensitive. During the next forty-eight hours the patient was in constant pain, and he was again given morphin (gr. ½) with the needle every four or five hours. He had hiccough now at times, and complete obstipation. All of this time we had been using enemata of every kind without result. The localized peritonitis in the epigastrium was clear enough now, and as he said that he thought he had swallowed some plum-seeds just before his attack began, obstruction from them was considered possible, with appendicitis, some trouble with the gall-bladder, and volvulus.

On the fifth day after the attack began, a little fecal matter came away in the warm-water enema. He was then given one-drop and two-drop doses of croton oil cautiously, until he had taken in all fourteen drops, over a period of two days. All of this moved his bowels very slightly. He was then given ten grains of calomel, which had the desired effect. On the eighth day the pain and fever and tenderness began to subside, and on the tenth day his pulse and temperature were normal, and he had no pain and only slight tenderness.

His diet was limited to peptonized milk, and during the three days in which he had no fever he complained that even a very small quantity of the milk made him

feel unaccountably full. On the night of the thirteenth day, after having taken more of the milk than usual, he had a painful vomiting attack, and the old pain and fever gradually came back. After daily examinations of the hepatic region, a slight fulness of the liver was apparent. The right side was an inch larger than the left, and there was a visible fulness of the intercostal spaces in the axillary line.

On the sixteenth day the obstipation returned. On the eighteenth day the temperature reached 102°. On the seventeenth the temperature remained at 102°, the pulse was 110, and patient was altogether worse. On the eighteenth he was again given ten grains of calomel, with no result. At this time a tumor in the region of the gall-bladder was apparent, and a slight jaundice appeared for the first time.

At 8 A.M. on the twentieth day I cut down on this tumor. It was found to be the transverse colon, the border of the liver, and the gall-bladder, all massed together by inflammatory material, undoubtedly the result of the localized peritonitis of two and a half weeks before. The gall-badder was greatly distended, but was covered in front by the colon. With a little difficullty the adhesions were broken up, and the gall-bladder was exposed.

I now attempted to break through the adhesions sufficiently to palpate the ducts, but on the escape of a little bile, the attempt was abandoned and the torn adhesions were packed with gauze. I now stitched the gall-bladder to the abdominal wall and freely incised it. It contained eight or ten ounces of dark-colored bile. On introducing the irrigator about a tablespoonful of hardened particles was washed away. None of them was hard enough to be called a stone, nor could any stone be found with the forceps. The pouch-like cavity was about five inches deep. The wound was dressed with a strip of gauze for drainage. More of these particles were washed out on the second and third days, and on the fourth day the wound was discharging a large quantity of golden-yellow bile. At this time the jaundice had disappeared, and the pulse and temperature were again normal.

The patient now gained strength very slowly up to the fourteenth day. As he had no fever or pain, and was eating and sleeping well, this slowness seemed to be directly due to the large quantity (at least two pints every twenty-four hours) of the bile he was losing. One or two lumps of the inspissated bile came away on the dressing every day, and an occasional washing brought away more.

On the fourteenth day after operation, he again complained of fulness after eating; his stools became putty-colored, and the amount of bile from the fistula markedly increased. He was put upon full doses of sodium phosphate. The amount of fluid was now very much increased, and very much diluted, so that it was almost colorless; this seemed to be due directly to the sodium phosphate.

On the night of the eighteenth day he had another severe attack of colic, and on the next day the bile again appeared in the stools, and the amount discharged from the fistula very rapidly diminished, so that from that time on the dressings were only slightly stained.

This last attack of pain the patient thought was due to the omission of the sodium phosphate, because the fluid discharged immediately became thicker and less in quantity. And it seems to me that this was a very good explanation, in that it probably allowed a piece of inspissated bile to lodge in the common duct. After this the bile had an uninterrupted flow into the duodenum, and from this on the recovery was rapid. The fistula was entirely closed six weeks after the operation.

I think it most probable that this patient's trouble was caused by a small stone, which first lodged in and then ruptured the cystic duct. Had it been in the hepatic or common duct there could not have been the free flow of bile which he vomited all through the first day and night. After this the inspissated bile which was present in the gall-bladder allowed the bile to enter, but acting as a valve prevented its outflow into the intestine. The escaping stone and a small quantity of the fluid were sufficient cause for the localized inflammation.

I was rendered invaluable advice and assistance in this case by Drs. Cunningham, Wilson, and Thomas D. Parke, of this city.

AN INSTANCE OF SPONTANEOUS HEALING OF AN ULCERATIVE TUBERCULOUS LARYNGITIS.

BY CHARLES P. GRAYSON, M.D.,
OF PHILADELPHIA,
ASSISTANT PHYSICIAN, DEPARTMENT OF DISEASES OF THE THROAT AND NOSE, HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

ALTHOUGH, since the introduction of the surgical method of Heryng for the treatment of ulcerative tuberculous laryngitis, instances of its cure are becoming more frequent in direct proportion as adoption of the method and its skilled application to suitable cases becomes more general, examples of the spontaneous healing of this kind of laryngeal ulceration have not yet been recorded with sufficient frequency for them to have become commonplace.

The subject of this report presented himself at the throat-department of the University Hospital, August 21, 1893. He had never been examined or received any treatment prior to that date.

The facts of his history pertinent to this report are these: The patient, Samuel H., twenty-five years of age, single, is a baker by trade. There have been no deaths in his immediate family, his parents, two sisters, and a brother, being vigorously healthy. He himself has never been confined to the house a single day by sickness since childhood, having been, up to the beginning of his present illness, particularly well and strong.

With several friends he celebrated the 22d of February, 1892, by getting moderately tipsy, and during the afternoon and evening he did a great deal of shouting and singing. He does not remember that on the next day his voice or throat seemed any the worse for wear, but on the afternoon of the 24th his voice began to fail him and by nightfall had become extinct. The feeblest whisper required much effort and was provocative of considerable pain. There was no cough worth mentioning, nor was there any dyspnea or dysphagia.

With no other treatment than the enforced rest that his throat received, the pain attending attempts at phonation gradually disappeared during the ensuing two weeks, but, coincidentally, the voice failed to reappear.

Shortly after the inception of this throat-trouble the patient began to lose flesh and strength; this has con-

tinued, not rapidly, but without interruption, until now he scales fully forty pounds less than at the date of its commencement. On one of the intensely hot days of July, 1892, he was compelled by an attack of weakness to leave his work, and within an hour or two after reaching his home had quite a sharp hemorrhage, losing probably (allowing a margin for the customary exaggeration) about four ounces of blood. In spite of this alarming incident he returned to his work the next morning, and since that time has had no recurrence of hemorrhage. A slight cough, however, added itself to his other symptoms at this time, remained slight for several months, but since the beginning of the past summer has much increased. With this exception, his further history to the date of his application for treatment is uneventful.

Although it was the throat that was first examined, it may be well to precede the report of the condition of this part by a brief statement of the accompanying pulmonary disease that was investigated immediately afterward. On the right side consolidation was found extending from the apex of the lung to below the second rib. Bronchial breathing was present, but no râles. Below this, beginning on a level with the nipple, was another area of consolidation, over which sub-crepitant râles and other signs of softening were detected. The tubercle-bacillus was abundantly present in the sputum.

The laryngoscopic examination disclosed an epiglottis perfectly normal in everything but color, which was a trifle below the tint of health. The ary-epiglottic folds were equally well-looking, as was also the greater portion of the ventricular bands. A large part of the posterior extremities of these, however, had been destroyed and replaced by cicatricial tissue. Upon the anterior surface of the meso-arytenoid fold a characteristic tuberculous vegetative growth was found.

On both sides only a narrow ragged fringe of the vocal bands remained. Their anterior thirds had been least affected, but even here ulceration had deeply indented their substance, leaving the free margins extremely irregular and the upper surfaces disfigured by welt-like ridges, somewhat resembling exuberant granulations. Posteriorly the bands had been destroyed to their outermost limits; the vocal processes had been unable to resist the progress of the ulceration, and these, too, had melted away.

The examination that disclosed all this destruction failed to reveal the least trace of then-active disease. Cicatrization had occurred wherever the ulcerative process had previously existed, and the probe demonstrated its firmness and maturity. The sloping surfaces of the ventricular bands were uneven at certain points, due, presumably, to isolated foci of infiltration, but these, during the three months that the patient has been under observation, have been perfectly quiescent, no tendency to renewed softening and disintegration having displayed itself.

Success in bringing acute laryngeal tuberculosis to a standstill, even through the most judicious and skilled treatment, is so extremely rare that an instance like this of its spontaneous cure is of more than ordinary interest.

Before dismissing the case it will not be a waste of time to indulge in a moment's speculation as to where the tubercle-bacillus secured its first foothold. Was the disease primary in the larynx or did its establishment in the lung antedate its laryngeal manifestation?

Did the rough usage of the throat eighteen months previously occasion a simple but violent catarrhal laryngitis leading to epithelial erosions; and was it through such breaches in its protective covering that the omnipresent bacillus effected its entrance into the deeper tissues?

Or, on the other hand, was the lung the original site of infection, and was the young man's constitutional vigor such as to hold the disease there in abeyance until the unfortunate excess of February 22d reduced his vitality to such a degree that the hitherto inactive bacilli improved the opportunity to become aggressive, to widen their dominion in the lung, and to subsequently colonize the larynx?

If we recall and group a few of the scattered incidents of his history, I think there will be little hesitation in deciding as to which of these two possibilities is the more probable. The patient and his mother, each of whom has been separately and closely questioned, concur in the statement that the young man enjoyed unimpeachable health up to the date of that fateful little spree. The entire absence of any history of illness preceding the present attack, therefore, lends added significance to the succession of events that have marked its course. These are:

The non-recovery of the voice after the other symptoms of a severe simple catarrhal laryngitis had disappeared; the progressive loss of weight and strength *following* within some weeks the onset of the throat-trouble; the hemorrhage occurring about five months after its commencement, and this followed by the establishment of cough; and, finally, the complete suspension of the tuberculous process in the throat while it insidiously extended its lodgment in the lung, until now it seems upon the point of duplicating there the destruction that attended its earlier occupation of the larynx.

MEDICAL PROGRESS.

Gravidity of Eleven Months' Duration. — Bensinger (*Centralblatt für Gynäkologie*, 1893, No. 35, p. 816) has reported the case of a woman, twenty-seven years old, who had borne two children, six and two years before respectively, after normal pregnancies, without artificial interference and with an uncomplicated puerperium. In May, 1892, she aborted in the second or third month of pregnancy. She menstruated in the week from August 10 to 15. Early in September she noticed signs of pregnancy, and her opinion was confirmed by her attending physician. According to her calculation the pregnancy should have terminated toward the close of May, but it was not until the 12th of July, after a gravidity of eleven months, that labor set in, and was readily terminated without interference. On account of a previous rupture of the perineum, the head encountered no obstruction, but the passage of the shoulders occasioned some difficulty. The placenta was large, the amniotic liquor scanty. The child was twenty-three inches long and weighed more than thirteen pounds, and in all other dimensions corresponded to the prolonged duration of the pregnancy.

Rheumatic Dacryoadenitis.—LAGRANGE (*Annales de la Polyclinique de Bordeaux*, 1893, No. 16, p. 33) has reported the case of a man, twenty-two years old, with a strong personal and family history of rheumatism, in whom there suddenly developed a swelling of the upper lid of the right eye, which was attended with pain and a sense of weight and increased lachrymation. There was also intense pain on the corresponding side of the head. Upon palpation, a hard, ovid body, about as large as an almond, and conveying an impression of being the lachrymal gland, was felt beneath the lid. This was painful to touch, and could be replaced with a little pressure, at once, however, springing forward when the pressure was removed. In view of the history and attendant circumstances, a diagnosis of rheumatic dacryoadenitis was made, and 300 grains of sodium salicylate were prescribed, to be taken in the course of four days, together with a purgative, hot effusions, and rest in bed. At the end of this period the patient was almost entirely well. He was now directed to take sixty grains of sodium salicylate daily, and after the expiration of another four days the cure was complete.

The Apoplectic Pulse is the name given by DANA (*The Post-Graduate*, vol. viii, No. 8, p. 276) to a condition of the radial artery at the wrist, marked by fulness, without great hardness, the vessels generally being dilated and tortuous. Disease of the kidney or heart is not necessarily present, although the latter organ is a little dilated. Thrombosis, with hemiplegia, is a common complication, characterized especially by mental and cerebral disturbances. The pulse is of great amplitude; the pre-dicrotic notch is deep and close to the percussion-wave; the dicrotic notch is deep and the dicrotic wave is short; the total area of the wave is small. The phenomena are essentially due to an impoverished condition of the blood or to some diathetic irritation, such as that of rheumatism, gout, or lithemia, or other condition causing contracted kidneys. The subjects of this condition improve most rapidly upon use of the tincture of ferric chlorid and sodium salicylate. Spartein, strophanthus, or digitalis, given occasionally, will do good. The diet should include vegetables, fruit, a little meat, and a moderate amount of milk.

Sensory Disorders in Diabetes Mellitus.—VERGELY (*Gaz. hebdom. de Méd. et de Chirurg.*, 1893, No. 32, p. 376) reports the results of a study of the sensory disorders encountered in cases of diabetes mellitus, including the record of a half-dozen illustrative cases. He has found that peripheral disorders of sensibility are frequent in diabetics, derangements of the pain-sense and of thermic sensibility being the most common. In some cases thermo-dysesthesia, thermo-hyperesthesia, thermo-anesthesia, and retardation of thermic sensibility are encountered, sometimes in the absence of all other derangement of sensibility. In one case there existed absolute analgesia and thermo-anesthesia.

A Case of Hematidrosis.—HEHIR (*Indian Medical Record*, vol. v, No. 5, p. 151) has reported the case of a girl, sixteen years old, in which the perspiration exhibited a pinkish appearence, suggestive of the presence of blood. The fluid actually oozed from the skin, and on microscopic examination was found to contain blood-corpuscles. The cuticle did not appear abnormal, and the condition seemed to arise from a rupture of the capillaries of the delicate plexus that surrounds the opening of the sweat-ducts. The affection was universal in distribution, but more marked in the axillæ and on the head than elsewhere. Here and there were petechial patches of various hue. There were no signs of hemophilia. Under treatment with iron, ergot and hamamelis internally and a lotion of tannic acid externally the condition disappeared within a week. Six months later the girl still presented petechial spots, but the hematidrosis had not reappeared.

THERAPEUTIC NOTES.

Tetra-ethyl ammonium.—It having been demonstrated in the Edison Laboratory that tetra-ethyl-ammonium is one of the best solvents of uric acid, PETERSON (*New York Medical Journal*, No. 772, p. 320) undertook to establish the dosage of the medicament, with a view to its employment in the treatment of cases of uric-acid calculi, and of gouty and rheumatic conditions. The drug answered admirably in the three cases of acute articular rheumatism in which it was employed. Doses of from 10 to 20 minims of a 10 per cent. solution may safely be administered by the mouth, and of not more than 10 minims of a 1 per cent. solution hypodermatically. Tetra-ethyl-ammonium may be obtained by decomposing its iodid by moist argentic nitrate or its sulfate by baryta. It occurs in deliquescent hair-like needles, and absorbs carbon dioxid from the air. It is strongly alkaline and saponifies fats. It is as bitter as quinine. It has a caustic action upon the epidermis, and an unctuous, alkaline feel when rubbed between the fingers. Its formula is NEt_4OH. It is not decomposed by the galvanic current. It forms numerous salts (sulfate, nitrate, phosfate, carbonate, hydrochlorate, hydrobromate, iodid, bromid), as well as beautiful double salts with gold, platinum, and mercury.

Ammonium Chlorid for Cystitis.—CORRIE (*Virginia Medical Monthly*, vol. xx, No. 6, p. 529) recommends the employment of ammonium chlorid in the treatment of cystitis, primary or secondary. Ordinarily it is directed that a capsule containing five grains of pulverized purified ammonium chlorid be taken three or four times in twenty-four hours, preferably when the stomach is empty, and followed immediately by a half gobletful or a gobletful of pure cold water. The drug has been faithfully tried in a large number of varied conditions with most satisfactory results. In the majority of cases the urine was rapidly cleared of mucus, blood-corpuscles, pus-corpuscles, urates, phosphates, and the distressing symptoms speedily disappeared. In no case did the salt occasion gastric or other disturbance when taken in the manner directed.

For Hemoptysis.—

℞.—Acid. gallic. } . . . āā gr. xx.
Ergotin. }
Aquæ destil. } . . āā ℥j.—M.
Syrup. altheæ }

S.—A teaspoonful every two hours.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 4, 1893.

THE STRAWBERRY TONGUE.

EVERYONE has heard of, and many have seen, VIRCHOW'S collection of seeds, nuts, eggs, and other natural objects, for the purpose of exhibiting standards of size. Rumor has it that when a similar case was unpacked at the Columbian Exposition it was refused a place, on the ground that it was neither instructive nor amusing. We cannot vouch for the truth of the tale, but can believe it true, because it illustrates an unmistakable and laudable tendency to substitute fixed measures and exact figures for the common comparisons formerly in vogue. It seems too early, nevertheless, to do away with the Berlin samples, for there are still some who will not express size in terms of inches or centimeters when they can do so in terms of millet-seed, hemp-seed, walnuts, tangerines, or goose-eggs. We should go even further than the founder of cellular pathology, and add to the collection some pea-soup, ocher, pipe-clay, strawberries, and other things which it is not necessary to mention now, as standards for some other comparisons frequently made. The strawberries seem especially needed, because though favorite objects for comparison, different men seem to have in their mind's eye fruit in different periods of growth or of different species. This is so true that the owner of any two of the numerous recent text-books on "Practice" runs a chance of getting two very different things compared to a third, viz., a strawberry.

For example, OSLER says of scarlet fever: "The tongue is red at the tip and edges, furred in the centre, and through the white fur are often seen the swollen papillæ, which give the so-called strawberry appearance to the tongue." LYMAN, on the contrary, speaks of a "white fur, which gradually disappears by the fourth or fifth day, leaving the organ red, swollen, and covered with prominent papillæ, somewhat resembling the surface of a strawberry, whence the term strawberry tongue that characterizes this stage of the disease." If the inquirer now thinks to find a judicial and geographic mean in WHITTAKER, he reads that: "The condition of the tongue is peculiar in scarlatina. The tongue is coated white, and studded with red spots, the protruding swollen papillæ, to constitute what is known as the strawberry or mulberry tongue." This may be consoling to the student unless some boyish memory may remind him that mulberries and strawberries are not, after all, quite alike in color or appearance, and in his bewilderment he turns to the translation of STRÜMPELL, to discover that at a certain stage of the disease "the first coating cleans off, and then the tongue usually presents a very characteristic appearance. It is diffusely reddened, and covered with little elevations corresponding to the swollen papillæ (strawberry tongue, scarlatinal tongue)." If, however, in order to complete his search, the student turns to the original, he learns that the word rendered strawberry is really raspberry. He will very probably by this time have so poor an opinion of internal medicine that in despair he will turn to special works on the diseases of childhood, but here again he finds similar divergence. GOODHART opposes ASHBY and WRIGHT, ELLIS contradicts HENOCH, and the well-known celiotomist who in his early days did STEINER into English contradicts the translator of VOGEL. SMITH is Delphic, and does not decide the matter.

If our student now looks up some ancient works on medicine he will find less difference of opinion. WATSON, TANNER, FLINT, BARTHOLOW and many others applied the term strawberry to the red tongue of scarlet fever which occurs at a later stage than the white tongue. This is similar to the usage of the French and German writers, who, however, more frequently use the term raspberry.

Although, of course, part of the confusion de-

pends on the fact that some authors describe the early and some a later stage, such a use of comparisons would less likely take place if the writers had before them a conventional strawberry. It would, of course, be still better to discard the comparisons altogether; but, as we remarked in the beginning, the time for that has not yet come.

It must also be admitted that some who use the term strawberry to describe the white and red tongue defend that use, as one who claimed the comparison arose from the resemblance of the tongue in the early stage of scarlet fever to "strawberries lying in the straw" (*sic*). Another speaks of a "strawberry and cream" tongue, a refinement worthy of severest condemnation.

It can hardly be doubted that the too-ready recourse to the comparison often coincides with a description of the tongue in scarlet fever less full than it should be. Even writers who give the briefest description usually admit that the changes on the tongue are of importance, and while differences such as we have quoted have no effect on the experienced observer, they do lead to confusion and uncertainty on the part of the beginner.

The changes that take place, it is hardly necessary to say here, are, in the first stage, in the beginning of the disease, a white or yellowish "coating" on the tongue, the tip and edges of which, however, are red, and through the coating the prominent papillæ show. This is followed after a few days by a shedding of the epithelium, whereby the tongue becomes red, and it is usually, at the same time, more or less uneven on the surface. Finally, the epithelium being gradually restored, the tongue regains its natural form and color.

In none of the stages is there anything absolutely unique, as any one of them may be observed under other conditions. In regard to comparisons, it would seem to the ordinary observer that the second stage resembles the strawberry (still more the raspberry, however) than the first; but if we must retain the term, let us at least have some uniformity of application. The tendency at present seems rather toward diversity.

In this connection the investigations of NEUMANN (*Deutsches Arch. für klin. Med.*, Bd. 47) are interesting, and should stimulate similar researches. NEUMANN found that the conventional three stages not only can be seen clinically, but that in relative time they often follow the periods given in certain text-books. It is especially interesting to know that in thirty-eight cases of a total of forty-eight the commonly accepted changes occurred. In four cases one of the stages was not strongly marked. In six the typical stages were not present. But in all of these cases there were conditions present that made even the exceptions valuable. Two of the six had severe dyspeptic conditions before the occurrence of scarlet fever. In both of these the tongue remained smooth and shining during the whole course of the disease. Another had septic symptoms from the beginning, and died on the fourth day. The tongue was dry, fissures appearing on the second day, with hemorrhage and sordes. The tip, however, showed the "raspberry" appearance. In the other two cases, both in children, and one just recovered from diphtheria, the tongue remained unaltered.

NEUMANN concludes, and in this he will be joined by all who have investigated the matter, that the so-called scarlatinal tongue is a pretty frequent phenomenon in the disease, and in the majority of the cases in which it is absent complications or previous diseases have in some way altered the epithelium of the tongue.

In regard to the dates on which the "raspberry" tongue appeared, NEUMANN found it once on the second day; 11 times on the 3d; 5 on the 4th; 9 on the 5th; 4 on the 6th; 2 on the 7th; 2 on the 8th; 3 on the 9th; 1 on the 11th—that is, in the majority of cases the tongue became clean and "raspberry"-like between the third and fifth days.

The pronounced raspberry tongue lasted one day in each of 3 cases; two days in 5 cases; three days in 6; four days in 4; and more than four days in 20 cases. In 11 cases it was not present after the seventh day, but in 12 cases it was still present on the fourteenth day, always counting from the beginning of the disease. In other words, the raspberry tongue, or the *red* strawberry tongue of some American writers, in one-third of the cases comes and goes within the first week; in another third it disappears in the second week, and in the remaining third it can be seen in the third week. In 68 per cent. of the cases the raspberry tongue appeared after the fourth day.

Like other observers, NEUMANN found no relation between the severity of the skin-lesions and those in the tongue. That the scarlatinal tongue, in its different stages, is simulated in other diseases, he, of course, admits, though holding that in most cases, by careful observation and consideration of the

sequence of the changes, one can distinguish the scarlatinal tongue from the others.

That the most characteristic stage is the second, or that in which the tongue is clean, red, and more or less like a raspberry or stawberry as to surface, and not the first, or that in which the red papillæ fungiformes show through the whitish coat, makes the tongue less useful as a guide in the early stage of scarlet fever. Careful observation of the tongue, however, is by no means to be neglected for that reason.

THE STAR-SYSTEM IN MEDICAL EDUCATION.

M. ZOLA, of France, has of late been telling us about the advantages of the French system of signed articles over the Teutonic and English methods of anonymity in journalism. The argument has its own excellent *reductio ad absurdum* in the fact of the powerlessness, triviality, and venality of the French press, as compared with the power and dignity of the great journals of English-speaking peoples. It is interesting to note in passing that in an art wherein the French undoubtedly excel not only the English, but also the whole world—the dramatic art—the absolutely opposite plan has been followed, and to this fact may be ascribed the French dramatic success. The system of signed articles in journalism is the exact analogue of the star-system in acting, and anonymity in journalism as certainly conduces to make personality subserve general tendencies, idealism, and logic, as does the method of the *Theatre Français* conduce to a harmonious and powerful presentation of a great drama.

The comparison extends itself spontaneously to the star-system as applied to politics, in which the powerful leader becomes not a spokesman, representative of the people, or legislator for them, but the boss of present-day unsavory prominence; the same trend is shown by the star-preacher whose pernicious selfishness attracts attention to himself rather to the Master or the cause he is supposed to represent.

It is not generally known that the French custom of signing articles is the direct result of a legislative act successfully designed to destroy the influence of the press. In 1850 the MARQUIS DE TINQUEY, addressing the Legislature that acknowledged LOUIS NAPOLEON as President of the Republic, said in reply to objection: "You tell me my plan will mutilate the press, destroy its influence, take from it its individuality? But that is precisely what I want." The French press opposed the measure bitterly, one writer calling it "an infernal machine placed under each newspaper to blow it up and shatter it." But the law was passed, and it was made an offense punishable by a fine of $100 to print an article on politics, philosophy, or religion, without the writer's signature. From that date French journalism declined to its present degradation.

The reason of all this is easy to see: Just as the preacher or priest exists for the cause and the truths he advocates, just as the politician proper should be the spokesman and defender of the people's cause, just as the actor should subordinate his personality and rôle to the dramatic presentation of the whole play, just so must the journalist represent a subordination of his individuality to the advocacy of the public cause or truth of which he is the spokesman.

It is all founded upon the obvious truth that human progress is every day and in every age conditioned upon the rise, the conquering, and the ascendency of one method, or principle, or idea, as opposed to another, either different or opposite, and that individuals must range themselves upon one side or the other. It is the idea or principle that is to prevail or be conquered, not individuals as such. Human genius and heroism consist in catching up the coming truth, the true truth, and being its champion and defender. Human selfishness consists in attracting attention to the individual—preacher, actor, or politician—instead of to the truth.

Precisely the same law holds as to medical journalism, but it also holds in a profounder sense as to medical teaching and medical education. The system of the past represents the plan of signed articles in journalism, or the starring method in acting. But just so fast and so far as medicine becomes a science, just so fast and so far does starring in medicine and in medical teaching become obsolete and out of touch with the times. There is always at least something of the quack about the medical star, and he is the forerunner and the first-cousin of the downright quack, with his newspaper and bulletin-board portraits, and his barnside advertisements. Like the star-actor, the quack, whether in or out of the profession, always manages to get his portrait on exhibition. As if an actor's portrait or that of a doctor could be any guarantee either of histrionic or of therapeutic ability!

In a medical college the thing to be taught is medical science and art, the work to be done is to

drill young men and train them in this science and art. The strength of the typical medical college of the past consisted in having as professors one or several famous physicians, who in didactic lectures and in the clinical amphitheater should play the part of the star-actor two, three, or more hours per week, as if any number of lectures on acting, or as if the fact of being a spectator at good theaters for a year or two, could make one a good actor! It is perfectly well recognized that this idea of medical education and this ideal of the medical teacher is utterly out of date. Indeed, the real medical teacher of the past was not the professor, but was the humble quiz-master or demonstrator. He it was who really taught the student after the star-professor had finished his hour of didactic declamation or amphitheatric pyrotechnics. Laborious laboratory drilling, actual bedside work, the training in actual diagnosis and treatment, the making of urinalyses, blood-countings, the actual management of labor, etc.—such things are to replace the hearing about them and the watching of others as they do them. The hospital must be used by the student and for him, not by and for the professor. *Experientia docet* is an old saw, but we are always forgetting that it is one's own experience that teaches and not that of others.

The star-system of medical instruction and the monopoly it engenders seems also to be arousing the indignation of our colleagues over-sea. From the recent noteworthy inaugural address of PROFESSOR BLACK, of Glasgow, we extract a few paragraphs:

> If there be one thing on earth which should be as free as the winds of heaven, it is the right to impart knowledge, no less than the inalienable right, if a man feels so inclined, to make that knowledge a marketable commodity. Nothing is more tenacious of life, nothing dies harder, than a corrupt and profitable monopoly. It is surely superfluous to argue at this time of the world's history that it should matter little to an intelligent or a discriminating public where or from whom a man receives his knowledge, providing he gives satisfactory evidence of the possession of it. It requires no argument to demonstrate that monopolies of every kind are subversive to the best and highest interests of the people, and that of all monopolies, monopolies of learning are the most wicked and the most indefensible.
>
> If the laborers are numerous then we have the usual effects of competition—industry, dexterity, and moderate wages. If, on the contrary, the laborers are few in number, then we have, as usual, carelessness, bad work, insolence, and exorbitant demands. And these evils attain their maximum when, as in the Scotch universities, there is only one laborer, and can be no more. Mental labor is, therefore, subject to the same laws as labor of every other kind, and it is surely alike entitled to the protection of the laws. There is surely no more oppression in prohibiting a man from exerting his thews and sinews in an honest calling than in prohibiting him from using the powers of his mind that he may derive an honest profit from the exercise of them. But, say the professors, the magnitude of our classes proves to a demonstration that we are the most capable teachers. "One might just as well say," remarks ANDREW BUCHANAN, "if there were but one ferry-boat between Dover and Calais, or between Portpatrick and Donaghadee, that the excellence of the boat was demonstrated by the number of the passengers, or that there is any connection between Tenterden Steeple and Goodwin Sands." For my part, I think that the price of oatmeal in Scotland and the right possessed by the universities to confer degrees are the main factors in the proliferation of these hypertrophied classes.

From a multitude of reasons, therefore, it is seen that the organized and vivified medical college is to take the place of the cluster of individual medical star-professors of the past—that personalities are to be subordinated to a system, leading rôles to be merged into a harmonious unity, men into an institution. A great work is to be done, a work requiring a large number of specialized workers, each performing his peculiar function, each the equal of the other, and all running to a unity of result that leaves no place for exaggerating one or two rôles, whilst extinguishing all others. It is clear, therefore, that the college which soonest and best meets the new ideal will be the college of the future, and the college that clings to the methods of the past, seeking a few leading actors and cruelly silencing subordinates—with necessarily resulting jealousies and self-seekings—must assuredly go down. Such a college as this last inevitably becomes ring-ruled, the financial aspect ever uppermost, never willingly lengthening the course or raising the entrance-standard.

All of this looks to the motives and methods of government of medical colleges being taken from the hands of the student and of the proprietary owners and being put into the hands of the profession as a whole. Neither student nor teacher-owner can be expected to raise standards, lengthen courses, diversify and deepen instruction, making it all practical and thorough instead of theoretic and superficial. The profession should give its opinion by resolute resolution through its associations and congresses, both local and general. It is the physician who for years has seen the deplorable results, both in himself and in others, of inexact, unpractical, and insufficient education, who is capable of speaking a true and a decisive word. It is his affair moreover, and his profession, that is at stake. His society com-

mittee of investigation, his society resolution of commendation or condemnation can give a needed word of encouragement to colleges moving in the right direction or haul up sharply those that are the real enemies of professional progress and dignity.

This new tendency, nay, this coming and pressing necessity, does not in the least extinguish individuality, but leads to its healthy development. It was the old plan that with ruthless barbarity throttled all individuality except the egregiously selfish individuality of the star, and that smothered nascent ambition and possible teaching-ability in order not to permit rivalry. The new plan, with its enormous increase in numbers of the teaching body of a college, encourages the healthy growth of individuality and of special ability. But it does one other most important thing: it reduces to useful subordination all egotistic advertisers and self-seekers, and binds individualities together for a work and a system that outlasts and is of more importance than individuals.

EDITORIAL COMMENTS.

The Care of Our Lepers.—In a paper read before the recent World's Public Health Congress, Dr. Benjamin Lee, secretary of the State Board of Health of Pennsylvania, stated that cases of leprosy are under observation in the following States and Provinces: New Brunswick, twenty-two cases; British Columbia, seven cases; New York, six cases; Pennsylvania, four cases; Illinois, two cases; Iowa, one case; Minnesota, seven cases; Wisconsin, four cases; Louisiana, forty cases; California, twenty-four cases, making in all one hundred and seventeen cases.

At the well-known Lazaretto at Tracadie, in the Province of New Brunswick, provision is made for the comfort, care, and treatment of lepers in a manner in harmony with the dictates of humanity and the requirements of modern science, while, at the same time, they cease to jeopardize the health and happiness of others. The United States has only gone so far as to make the affection quarantinable at the seacoast, and to order those on arriving vessels found suffering from it to be at once returned to the ports from which they came. In the different States of the Union the widest diversity prevails, both in theory and practice. The only place in which segregation is practised, and at the same time humane provision is made for the shelter, maintenance, medica attendance, and nursing of lepers, is the City of Philadelphia.

While the number of lepers is small, no rural community, very few States even, feels justified in going to the expense of establishing a lazar-house or colony. Dr. Lee asks: Is it wise to wait until State after State finds itself compelled by the increasing number of lepers to take this step, or is it not rather the duty of the central government to gather them all into one properly supervised community, where they can have the companionship of their fellows, the comforts of a thoroughly furnished home, and the advantages of the best medical and surgical skill?

He further adds that in determining the importance of this question and the necessity for governmental interference, the numerical method is entirely misleading. One case of leprosy outweights a hundred of any other disease. If there were but ten lepers in the land instead of more than ten times ten, it would be equally the duty of Congress to initiate measures to prevent, if possible, a single addition to the number.

"Special" Press Reports.—The venality of the ordinary newspaper is becoming more and more disgusting. When a scamp wishes to gull the community with his quack nostrum the "business" is carried out as follows: First he gets the degree of M.D.—a very easy thing. Second, he gets enough money to buy the services of the agent of one or many newspapers, and has him to supply his so-called newspapers with puffs and lies as to his "cure." Each "despatch" must be cunningly worded—a good literary hack, or street-car-sign poet can now be had for a thousand a year—and the supply kept up regularly, and from all parts of the country. There is not the least doubt about the moral newspaper publishing the highly important special despatches. Every other paper contains them. Here are two samples which the *Cincinnati Lancet-Clinic* says were printed in advance and sent to three hundred newspapers:

Special to the ———.

PHILADELPHIA, Oct. 18.—The County Medical Society's petition to the Board of Health to isolate consumptives has increased their fears, occasioned by startling head-lines in a local paper declaring the disease infectious. The State Legislature of Michigan recently indorsed this view, as did the Medical Congress in Washington, and deaths from consumption having decreased everywhere recently, Dr. Flick, with a few others, ascribes this to isolation. The majority of medical experts, however, credit it to the free, broadcast distribution through physicians of test outfits of the ——— treatment, by which authentic cures are reported daily in the medical and secular press.

MINNEAPOLIS, Oct. 18.—Recent local editorials condemning the medical code while commending ———, the ——— scientist, for withholding his consumption-cure formula, are exciting much discussion in medical circles. The *Times* said: "His discovery greatly assists the fight against this enemy of human life, and thirty or more local physicians say that the medicine accomplishes more than his claim."

The *Journal* said: "It is one of the most valuable and wonderful discoveries ever hoped for in medical science, and the formula is not given to every Tom, Dick, and Harry to monkey with, and is preserved from the tampering of fool empiricists."

Castration for Prostatic Hypertrophy.—In view of the dangers and the troublesomeness of prostatic enlargement, together with the uncertainty of the results of treatment, the surgeon would hail with delight some safe measure that would promise reasonable hope of permanent success in the treatment of an unavoidable condition. In a paper read before the last meeting of the American Surgical Association, J. WILLIAM WHITE (see THE NEWS, June 10, 1893, p. 636) pointed out the analogy between the prostate gland and the uterus, and the hyper-

trophy of the former and the fibromata of the latter. He also detailed experiments demonstrating that orchectomy in dogs is followed by a reduction in the size and weight of the prostate. The practical outcome of these observations resides in the treatment of prostatic hypertrophy by castration. The same line of thought has been followed, and similar experiments have been undertaken by an independent observer, Rocum (*Centralblatt für Chirurgie*, No. 35, 1893, p. 759), of Christiania, Norway, who has reached identical results. This observer, however, has gone a step further, for in a preliminary communication he reports two cases of prostatic hypertrophy in which he removed the testicles with most satisfactory results.

Slips of Medical Editors.—Our contemporary, the *Medical Record*, in an editorial, August 26th, criticises sharply and justly the carelessness of other medical journals in regard to prescriptions, at the same time modestly disclaiming any disposition to assume for the editor of the *Record* superiority in proof-reading. The disclaimer is as timely as the reproof; for in the next issue we find a prescription with about as many faults of style, grammar, spelling, and capitalization, as could be expected in one effort. Here it is:

℞.—Tr. ferri chlor.	. . . . .	℥ss.
Spts. minderus	. . . . .	℥jss.
Glycerine	. . . . .	℥j.
Tr. aconitia	. . . . .	℥ss.
Aq. font	. . . . q. s. ad	℥viij.

Here we have a man's name spelled wrong, and without a capital; a nominative for a genitive; an English word for a Latin one; a tincture of an alkaloid (an absurdity) with a nominative again for a genitive; and all the liquids ordered by weight, when there can be no doubt the prescriber intends fluid measure.

The modesty of our contemporary compels gentleness in pointing out these slips, and evokes the kindly wish that none more serious may ever mar its broad and fair pages.

Facilis Descensus Averno.—One of our subscribers received the following letter from an "Imitation Gold-Cure," which we reproduce *verbatim*:

Dear Sir: Enclosed please find our circular for the cure of Liquor Opium Morphin and Tobacco Habits. we are prepared to send the cure to Dr's and would like to have you handle our cure in your county we furnish the cure at $10.00 per patient with full instruction to Dr will come and help you start a branch cure if you desire to take hold of cure we have several patients from your vicinity one at Austin Lanesboro Rushford Whalen and La Crosse. you might get the services of a Keeley Cure Graduate and do a nice business this Winter hoping this will meet with your aproval I remain Resp yours —— ——

The Right of a Wife to Pay for her own Medical Treatment and Recover therefor.—It is the duty of the husband to support and maintain his wife, and to furnish medical treatment and care in the case of injury or ailment, and presumptively all such damages accrue to him when an action is brought to recover on account of a personal injury to the wife. But the Appellate Court of Indiana says, in the case of Board of Commissioners *v.* Castetter, just reported (34 N. E. Rep. 687), that this is but a naked presumption, and when it is averred and proved that the wife has expended or incurred a liability on her own account, she is entitled to recover therefor as if she were sole in a State where she can maintain in her own right an action to recover for the personal injury making such medical treatment and care necessary.

Pseudo-cerebro-spinal Sclerosis.—The vagaries of the malarial poison are admirably illustrated in a case reported by Triantaphyllides (*Archives de Neurologie*, September, 1893, p. 232), which presented many of the classic symptoms of cerebro-spinal sclerosis; slow, scanning speech; intention-tremor; nystagmus; exaggerated tendon-reflexes. There was also a tendency to epileptiform seizures. There was, however, a history of intermittent fever, and the spleen and liver were enlarged, while the blood contained hematozoa; recovery ensued upon the internal and subcutaneous administration of generous doses of quinine. The case is particularly interesting and important in view of the fact that organic disease of the central nervous system has been observed as a complication or sequel of malarial infection.

Cremation and the Use of the Cremating Furnace in France.—The thrifty Parisians are proverbially expert in money-saving devices. While cremation is slowly progressing in popularity (49 cases in 1889, 159 in 1892) they utilize the cremation-furnace of Père Lachaise to dispose of the anatomic remains of the hospitals and dissection-rooms. This is much more economic than burial. During the last four years there have been no fewer than 111,852 incinerations of anatomic remains at Père Lachaise. Each parcel represents a human body when the doctors and students have done with it. To this end 27,000 persons annually come to the city of Paris. All of them are supposed to be friendless, because their bodies are not claimed.

Keeley withdraws his Libel-suits.—The libel-suits instituted by Keeley against the *Medical Press and Circular* and the *Lancet* have been voluntarily withdrawn, the costs of the respective proceedings being paid by the plaintiff. The reason given by the solicitor was that the demands upon the plaintiff's time and attention are so great that he finds it impossible to go to England. The courage of the two English newspapers is a lesson to American publishers and editors. The mere whisper of the word libel is often enough to make them run to hole as if no principle were at stake, and as if the whole medical profession were of less value than a nostrum-vender's profits.

SELECTIONS.

"GREATER LOVE HATH NO MAN THAN THIS."

The Greeks made their gods simply themselves, with all their potentialities glorified into certitudes, as if to demonstrate what a Greek could be at his finest and best. The hero was merged into the god. The world has ever been quick to recognize valor, delights in brave exploits, exults in signal instances of moral courage, and makes haste to raise monuments to its heroes. Humanity

loves to see itself at its best. Our rich inheritance from the ages in stories of daring on the battle-field, or heroism on the quarter-deck, has, perhaps, blinded our eyes to the silent, single-handed combats where there is no enthusiasm of numbers, no excitement of banners and drums, no shout of victory. And perhaps among the glorious company of heroes unchronicled and martyrs unsung, no profession holds so large a place as that of medicine.

The physician knows that a foe as deadly as a bullet and far more insidious lurks in the micröorganism. But undaunted, high-hearted, strong in his professional loyalty, he takes the risk which personal contact involves, with no thought but wresting his patient from the grasp of death. But the world too often fails to see that thus the doctor merges into the hero.

Every physician knows many instances in which his professional comrades have fallen by his side, struck down by infectious fevers or septic absorption acquired at the bedside of a patient. Notable instances have recently brought this peril afresh to our minds. A contemporary journal, in the last issue, records the death of a practising physician who caught the infection of yellow fever from a patient whom he was attending, and also the death of a promising young doctor to whom the infection of typhoid fever was communicated from a child-patient at the New York Hospital. Last week it was our melancholy duty to report the death of a brilliant young physician, of unusual qualities of mind and heart who caught diphtheria at the Boston City Hospital.

On another page of this week's issue will be found the resolutions passed by the Visiting Staff of the hospital upon his death. In another editorial column of this week's issue also are references to several deaths from disease contracted in the discharge of duty among medical officers in the Marine-Hospital Service.

It will be observed that the personal risk is greatest to the hospital physician, not only on account of the large number of patients and variety of diseases which come under his care, but because the most malignant and extreme cases are naturally aggregated within hospital walls. It must be remembered that the physician and surgeon runs his greatest risk in that part of his calling where his skill and services are bestowed gratuitously.

Every call for medical aid in great epidemics has always brought a swift response of willing hearts and ready hands. Physicians have set aside all personal comfort, and gone to the unpleasant surroundings of loathsome disease, doing not only the work of nurse but even of household drudge, because all others had fled in terror from the dead and dying. Self-sacrifice is, after all, the real essence of heroism. The great scourges, formerly regarded as dispensations of Divine wrath, but now known to be the results of sanitary pollution, are yet full of imminent peril to the practitioner. The very scientific knowledge which helps him more intelligently to combat disease has also revealed the extreme subtlety of his invisible foe, and made clearer his hazardous calling. But increase of knowledge brings no shrinking to the physician. He puts fear under his feet, and walks serenely on in the path of his self-appointed duty. Carlyle says of the hero, "Now and always, the completeness of his victory over fear will determine how much of a man he is."

To the unthinking, the surgeon at the operating-table or the physician in the wards for infectious diseases is only a man pursuing his profession. But under the impassive exterior will be found "the stuff of which martyrs are made." He holds his life none too precious to be sacrificed, if need be, in relieving humanity's physical suffering, and surely "greater love hath no man than this, that a man lay down his life for his friend."—*Boston Medical and Surgical Journal.*

HARD TIMES AND FREE MEDICINE.

From every part of this great and rich country the news comes to us of extreme stringency in the financial position of our *confrères*, the general practitioners. Never was there a richer opportunity for the masses to play the pauper than now. The present panicky state of the money-market affords people an immense excuse for wholesale imposition on the profession. The conditions of the times will not give them free bread, free clothes, free transportation on the railroads, or rent free, but they hie away to many of our too numerous hospitals and dispensaries for free treatment—advice, medicine, and all included for nothing, or for "ten cents," the figure fixed in certain palatial infirmaries.

The consequence of all this has been most demoralizing to the profession and the public. Practitioners reduced to a state of enforced idleness and grim want are forced either to quit their profession altogether, or to "meet *steal* with steel," to open rival dispensaries, to advertise, or to drift into downright quackery.

Many cases have come to our knowledge which go to prove that the practice in vogue in many of our largest dispensaries is a species of downright robbery, and tends to work incalculable harm to the profession. Case after case is taken from among people of ample means and turned over to the hospital or to the college professor for his clinic, without a word being asked as to their mendicity or ability to pay anything at all. Cheap railroad excursion rates drain the outlying villages for miles in every direction.

This hydra-headed monster of indiscriminate free treatment must be seized and strangled, or we will soon see the profession of medicine dragged in the dust; open downright quackery will be rampant, and integrity and honor in the healing art will be things of the past.

By no means let us withhold our services to the poor and deserving, for humanity compels us to gratuitously attend those without means. Nor let us strip the field of such clinical material as legitimately belongs to the teacher, but let the teacher not forget that he has no prescriptive right to filch from the struggling practitioner what justly belongs to *him.—Medical and Surgical Reporter.*

CORRESPONDENCE.

THE HUMOR OF PHYSICIANS.

To the Editor of The Medical News,

Sir: An editorial in a recent number of The News (August 3d) noted "a certain absence of humor in medical men," and recounted some interesting instances to establish the thesis. The subject might be enlarged

upon and illustrated by some observations upon the late Pan-American Medical Congress, whereby it may appear that what at first seems to be an absence of humor is really its very quintessence, the gravity of the actors and the apparent unconsciousness of their own humor being so marked that one can scarce help interpreting them literally.

When upon the eve of the opening of the Congress, the foreign delegation was entertained at the National Theater, seeing Seabrooke in the Isle of Champagne, its sense of humor was aroused to a high pitch by the simple incongruity of a living king entombed with his departed queen, holding his sides and rolling over in convulsions of laughter at his own resurrected jokes; but at other times and in more serious places our guests were surprised by humor not only unlooked for, apparently unconscious, but tinctured with a spice of inconsistency that reminds one of a certain dominie who figured in the annals of the Mohawk Valley some years ago, and who was brought to book for his habit of exaggeration. He said: "Brethren, I confess that this is my besetting sin; it deserves condemnation, and I have shed hogsheads of tears over it."

The incident about the registration of Mr. Ernest Hart at his hotel, for which he has been criticised, ought not to be regarded too seriously. Doctors were registering by the scores, most of them not affixing any sign to their names to distinguish them from the vulgar crowd, even the president of the Congress subscribing himself as plain "Wm. Pepper, Philadelphia." To be sure some English physicians observe the same practice, but it is presumably opposed to the spirit of the British Code of Medical Ethics. It was Mr. Hart's opportunity, as the great exemplar of that venerable document, to give an object-lesson in medical ethics, while at the same time being mindful of his peculiar position as guest of the Congress. The delicate humor with which the registering officials were criticised is evident in the contrasting "formal" registration of "Ernest Hart, F.R.C.S., D.C.L., London, England, editor *British Medical Journal*, Dean of St. Mary's Hospital." It may now be considered settled that upon such occasions not only is a titular registration professional, but likewise according to the Code. It does not follow that it is proper to emblazon one's cards, letterheads, the directories and doorways with a labored enumeration of all hospital and journal connections. That is simply carrying the joke too far.

The humor sometimes assumed a fantastic type, as when the official guest appeared to ignore common parliamentary rules and jocosely directed the presiding officer in the discharge of his duties. This type of humor is frequently met with in frontier settlements where laws are lax, and is not unknown even in such a deliberative body as the House of Commons, and not easily restrained by rigid codes of procedure, as was shown during the recent debate upon the Home Rule bill, when the dignity of parliamentary law gave way to the humor of the Donnybrook Code.

In the Section of Children's Diseases, the paper of Dr. J. Lewis Smith, upon "Diphtheria," had an allusion to the use of a proprietary remedy that was suggested probably by papayotin. Dr. Jacobi, of the New York State Medical Society, that heretic organization that knows no code, stated that he did not countenance the use of a remedy the composition of which he was ignorant of; and Dr. Love, of St. Louis, secretary of the Association of Medical Editors, and a prominent member of the American Medical Association that ostracized Dr. Jacobi's State Society for its ethical heresies, defended the use of any and all remedies, from whatever source under whatsoever names. The apparent inconsistency that would indicate that a member of the Medical Society of the State of New York could under any circumstances be observant of sound principles of pharmacy, or that a member of the American Medical Association could violate its sacred Code of Ethics, disappears when viewed from the humorous standpoint. Syllogistic reasoning cuts the very soul out of humor, and a too logical mind never appreciates a joke.

In this city recently a whiskey and opium cure was started and some members of the New York State Medical Society (no code) were asked to assume its management, possibly because the Society in some quarters had been advertised as a pariah among medical associations, and was supposed to engender and monopolize all of the quacks and everything of quackery. Failing in this direction, they finally persuaded a capable and promising recent graduate to take charge of the institution. He had, however, some compunction of conscience about the matter, but was advised by a member of the New York State Medical Association (old code) to accept it, and so he did. The humor of the situation followed at the next district meeting of the Association when one of the members read a paper deploring the decadence of medical ethics, charging members with violations of the Code, and appealing to the Association to stand by its declaration of principles. The Puritan, with his profession of holy inspiration and fervid zeal, when persecuting Baptists and Quakers, never realized that there was any humor presented so grimly by his inconsistency. Truly, Mr. Editor, there *is* humor of the deepest dye among physicians, when you observe their whims and warps and wrinkles, that not all codes, human or divine, have been able to eradicate. With Touchstone, this "rumination wraps me in a most humorous sadness."

"INDIAN FIRE."

To the Editor of The Medical News,

Sir: My attention was first called to this disease late last summer, and being unable to properly classify it, I made a study of it. The older physicians call it "Indian fire," but seem unable to explain its pathology. Some confound it with varicella, and there are cases that resemble this. In the proper place I shall show the points of distinction between the two. "Indian fire" presents several distinct characteristics, but I have been unable to find a description of it in any text-book or cyclopedia.

It is best defined as a specific infectious disease of the skin, not accompanied by constitutional disturbance. It begins as a bunch of tiny vesicles thickly studded over a reddened area. There may be one, two, or more bunches, and the vesicles vary in size from that of a mustard-seed to that of a bleb from one-fourth to five-eighths of an inch in diameter. In a few cases I have seen, the vesi-

cles were widespread; but generally they are found only in a circumscribed area. The large vesicles are, probably, aggregations of small ones. There is no pain, no fever, but after the eruption appears the affected area has a peculiar burning sensation; if this be scratched, or the vesicles be broken, the itching is intense.

The diagnosis is not easy. The affection is often confounded with herpes. But the absence of pain and constitutional disturbance, the length of time the disease lasts, and its undoubted power of infection, clearly distinguish it from herpes.

It may also be mistaken for varicella, but there are three points of distinction: 1. The entire absence of fever. 2. The course and termination. 3. The location and distribution of the lesions.

The treatment is important. If seen early, the case is well in five or six days; but if neglected, as is often the case, it hangs on for weeks. I have one case that was not brought to my notice until more than six weeks had elapsed.

If seen early and a soothing ointment, ung. zinci oxidi, or an ointment of boric acid, powdered camphor, and lanolin is applied, with a mild laxative daily, the eruption quickly dries up and forms a scale, which drops off in the bath, leaving a reddened, but afterward normal skin, as in herpes. But if neglected, the blisters and vesicles are broken and the intense itching keeps the parts red, and the irritation increases the flow of serum; the parts are then found constantly bathed in a sticky, gummy fluid. In the cases that have come under my observation, the favorite location of the lesions was the face and neck, usually in both places at the same time.

Now, Mr. Editor, I would like to know more about this disease, and if it has any other name. What authors have described it, and when?

I neglected to state that it was introduced into Natchez from Louisiana, and all cases could be traced to the one source of infection.

Very truly yours,

J. C. BALLARD, M.D.,
Chief Health Officer, Adams Co., Miss.

NATCHEZ, MISS.

EPILEPTIFORM SEIZURES DUE TO OCULAR REFLEX.

To the Editor of THE MEDICAL NEWS,

SIR: M. O. C., an unmarried domestic, eighteen years of age, in good physical health, consulted me on March 28, 1892, for what she called "nervous spells," which had occurred at frequent intervals during the past three years. She had taken every remedy that many physicians and others had prescribed for her, without any influence upon the seizures, which came on whenever she looked at any object steadily for a moment or two. She could neither read nor sew, as any such work tended to bring on the "spells." The external examination of the eye was negative. Visual acuity in the right eye was 20/80; in the left 20/100, but the letters seemed to her to be continually moving. The accommodation was paralyzed with atropin, and three days later vision in each eye was found to be 20/200. Her refractive error was as follows:

R. + sph. 4.5 D. ⌒ — cyl. 1. ax. 180 = 20/20.
L. + sph. 4.00 D. = 20/20.

The retina was hyperesthetic, the ocular tension normal. No examination of the field was made.

Correcting lenses were ordered and the atropin continued for one week, during which time the nervous seizures entirely disappeared. After the effect of the mydriatic had passed away the patient had no more seizures, except when the glasses were removed. During a visit to my office I removed the glasses and at once the patient began looking fixedly at the lamp, the stare becoming more pronounced until a swaying motion began, during which breathing was for a moment imperceptible. The patient seemed about falling to the floor, but was caught and led to a seat. The skin became cold and bathed in a cold perspiration. Respiration was panting or sighing in character, and then there was a spasmodic action of the mouth and throat, as if the patient were trying to swallow something. She refused to lie down, saying that she would be "all right in a minute." In about ten minutes she was as well as ever.

Very sincerely yours,

W. F. CONNERS.

OIL CITY, PA.

THE GROWTH OF THE FINGER-NAILS.

To the Editor of THE MEDICAL NEWS,

SIR: When seventeen years, being interested in physiology, I saved the finger-nail parings for a period of seven months from January 1st. Great care was taken to save filings as well as cuttings, and the loss, except from ordinary wear, was insignificant. In regard to variations due to temperature and use of the hands, the result may be considered a fair average. After years of drying in a tin box, which was found in a garret among rubbish two or three years old, the combined parings of the ten finger-nails weigh (1.56) one gram and fifty-six centigrams. This is at the rate of about (2⅔) two and two-thirds grams per year; or, say, a quarter of a kilogram (half a pound) in a long lifetime of ninety years.

During an attack of sapremia, due to infection of the thumb at an autopsy, the swelling interfered with the circulation in the thumb for several days. After a week or two a distinct groove, one millimeter deep, was noticed in the nail, parallel to the skin-border, from beneath which it had emerged. It took almost exactly five months for this groove, which was undoubtedly formed at the time when the felon was at its height, to travel to the end of the finger, a distance of eighteen millimeters. This represents a rate of forty-three and two-tenths millimeters a year, or 3 meters, 888 millimeters (3.88) in a lifetime of ninety years.

Beau, quoted in the *Reference Handbook of the Medical Sciences*, estimates the growth of the finger-nails at a millimeter a week, slightly in excess of the rate noted in this case. The discrepancy is easily explained by the fact that for two or three months the circulation in the thumb was sluggish. Even now, four years after the infection, the interphalangeal joint is limited in motion, and the circulation is not perfect.

Very truly yours,

A. L. BENEDICT.

BUFFALO, N. Y.

THE MYSTERY OF ICE-CREAM POISONING.

To the Editor of THE MEDICAL NEWS,

SIR: Apropos of a paragraph in THE NEWS of September 2d, page 275, on "The Mystery of Ice-cream Poisoning," allow me to call your attention to the discoveries of Prof. V. C. Vaughan, which should be better known.

Dr. Vaughan obtained, in 1885, a ptomaïne from milk and cheese, which he identified as a salt of diazo-benzene, $C_6H_5N_2$. He has investigated its chemic and physiologic properties, and the conditions of its formation. It has the curious and striking property of being explosive. In the human subject it produces the usual symptoms of cheese-poisoning; in children, those of cholera infantum.

Detailed accounts of these investigations, including chemic tests and separation, practical suggestions for preventing the development of this ptomaïne (tyrotoxicon), and for destroying it when its presence is suspected, have appeared in various publications.[1] Cases of wholesale poisoning by ice-cream are, indeed, lamentably common; poisonous milk, possibly, is responsible for much infantile mortality, and much of this might be prevented, and much unjust suspicion averted, if the guardians of the public health made the facts a matter of general knowledge. Very truly yours,

CHARLES E. PARKER.

EAST ORANGE, N. J.

DR. RHOADS'S METHOD OF LENGTHENING BONES.

To the Editor of THE MEDICAL NEWS,

SIR: Since the appearance of your editorial of Nov. 28, 1891, on "Dr. Rhoads's Method of Lengthening Tendons, Nerve-trunks, and Bones," in which especial attention was called to the utility of the method in lengthening bones, I have been experimenting on bones, and have come to the conclusion that they can be both lengthened and shortened to any desired extent. I believe, however, that owing to muscular resistance, better results can be obtained by shortening the bone of a leg that is two inches longer than its fellow than by lengthening the short one (provided the patient would consent to have his stature shortened). If the lengthening should be insisted upon and the muscles should prove to be very troublesome, they could generally be lengthened in the same manner as the bone had been done.

The following description as you gave it in your editorial I deem sufficiently explicit, with the simple change of the words *cut* and *tendon* to *saw* and *bone:* "Saw transversely half through the bone, then longitudinally to any desired extent, and finally finishing the division by sawing through the remaining half of the bone on the side opposite that on which the original transverse incision was made and at a point longitudinally removed from it."

As it has now been nearly two years since I began to study and experiment as regards the extension of the method to bones, and not having had an opportunity in my small field of surgery to do the operation, I thought it better to write this than to wait longer for a proper subject. Respectfully,

J. NEELY RHOADS, M.D.

NEWS ITEMS.

Dr. Paul Ernst has been made professor extraordinary of Pathologic Anatomy at Heidelberg.

Gustave Antoine Richelot, one of the founders of *L'Union Médicale*, died recently at the age of eighty-seven years.

Dr. Ladislaus Gluzinski has been elected ordinary professor of General and Experimental Pathology in the University of Cracow.

Prof. Wagner, of Prague, is in contemplation as the occupant of a new chair of Psychiatry to be established in the University of Vienna.

Dr. George Juffinger, formerly of Vienna, has been made professor extraordinary of Laryngology and Otology at Innsbruck.

Prof. Siemerling, of Berlin, has been elected to the recently established chair of Psychiatry in the University of Tübingen.

THE INFLUENCE OF CLIMATE ON THE BREATHING-HABIT, WITH A COMPARISON OF AMERICAN CLIMATIC RESORTS.

BY SAMUEL S. WALLIAN, A.M., M.D.,
OF NEW YORK.

THERE ought to be a special text-book and a special chair in every medical school devoted to the principles and practice of respiration. No department of physiology is so vitally and universally important, and none is so universally slighted and ignored.

In all wasting and in most other chronic diseases, what is termed by physiologists *the equilibrium of metabolism* is disturbed. The patient no longer replenishes and repairs as rapidly as he wastes. This lost equilibrium can be reëstablished and preserved only by prompt and persistent recourse to all known hygienic and physiologic resources. Instigating and underlying all the vital functions, and back of all forms of tissue-change, is the unique and fundamental function of respiration. Breathing is the indispensable preliminary process and *sine qua non* of digestion. An imperfectly performed breathing-function means proportionately diminished digestive power, inadequate assimilation, retarded metabolism, insufficient hematosis, and, consequently, anemia, emaciation, and general vital decline. Many chronic invalids are more or less handicapped in the struggle for life by an inherited or acquired lack of lung-capacity; and yet, with very few exceptions, this lack can be overcome if the capacity possessed be at all times thoroughly and fully utilized. Patients are quite inclined to unthinkingly and perhaps unconsciously avoid this, unless they be placed under conditions that naturally tend to induce if not to actually compel it. Thus the total respiratory capacity of an average male adult is placed at from 200 to 230 cubic inches; but of this only an almost inconsiderable fraction is habitually brought into use, leading authorities in respect to physiologic data asserting that the quantity of tidal air inhaled at each ordinary and passive respiratory effort does not exceed from 20 to 30 cubic inches. Accepting this statement, it follows that not more than one-eighth of the total quantity of air in the lungs is subject to renewal at each ordinary act of respiration, the other portions being designated, respectively, *complemental*, *reserve*, and *residual* air. These several portions are estimated and defined as follows:

Complemental air, 110 cubic inches, is the volume that can be forcibly inspired over and above what is taken in at an ordinary normal respiration. *Reserve* or *supplemental* air, 100 cubic inches, is the volume of air that can be expelled from the chest after a normal quiet expiration. *Residual* air, 100 cubic inches, is the volume of air that remains in the chest after the most complete or forced expiratory effort.

The breathing-apparatus is therefore endowed with a remarkable and fairly disproportionate reserve fund and capacity, which can be impressed into service at any time to meet any unusual contingency of the vital necessities or physiologic demand. How far and how fully this reserve can be made to reach and remedy pathologic conditions is a subject that has hitherto received but a modicum of professional attention. Waldenburg vaguely presaged its possibilities in advocating his compressed-air chambers, and the more recent pneumatic cabinet was another somewhat cumbersome effort in the same direction. These purely mechanical and compulsory means of accomplishing the object sought—lung-expansion—bear about the same relation to normal physiologic measures that dumb-bells and Indian-clubs bear to rowing, hunting, tennis, and other forms of pleasurable exercise. They may be utilized under certain unusual conditions and in some emergencies with decided and unmistakable advantage; but they are too formal, too heroic, and not susceptible of sufficiently accurate regulation to ever become of more than limited availability.

Among the natural and universally applicable means and methods, consciously or unconsciously advised, and either empirically or intelligently adopted and used, with the result of calling into service more or less of this reserve capacity and resource, may be mentioned all the multitudinous forms of muscular exercise—pedestrianism, horse-back riding, rowing, hunting, mountain-climbing, out-door games, and old-fashioned *work*. As imitations of all of these, we have mathematico-anatomic systems of gymnastics, the health-lifts and "home developers." Resort to any of these increases the breathing-necessity, and to the same extent compels the utilization of reserve respiratory capacity. Any treatment of pulmonary and other wasting and

chronic diseases that ignores the fundamental and paramount value of an enhanced breathing-function is from the outset severely, if not hopelessly, handicapped. Forced feeding, increasing the proportion of the so-called respiratory foods, intra-pulmonary disinfection, and antisepsis, chemic antidotes, toxic inoculation, and the use of artificial oxygen, have all been resorted to, in the hope of finding some approximation to a specific *règime* or method by which to combat the annual inroads of the more prevalent and fatal forms of chronic disease. But notwithstanding the professional *éclat* with which some of them were announced, the high hopes entertained, and the painstaking accuracy and expertness with which the details of complicated experiments were carried out, all alike—hot-air inhalations, sodium and gold chlorid, beechwood creosote, tuberculin, and pyoktanin—all have professionally proved flat failures and popularly cruel delusions.

Doubtless the professional dreamers and theorizers, delusionist imitators of Ponce de Leon, who, in or out of the profession, still cherish a vague and nebulous, if not outspoken, faith in the existence of some sort of scientifically refined and modernly improved philosopher's stone, who have never admitted the impossibility of evolving a perpetual motion or self-replenishing force, and who are quite convinced that the Kochs, Pasteurs, and Brown-Séquards of the age are on the eve of announcing a direct antagonist, an autotoxic, germ-engendered antidote to pulmonary tuberculosis, impotency, rheumatism, and old age, will continue the fascinatingly hopeless search for specifics. But evidently the sooner the profession and the professors abandon all attempts to evolve or discover chemic, dynamic, organic, "kinetic," or any other real, far-fetched, or phantom form of "remedy" for the various forms of wasting and constitutional diseases, the sooner will wise physicians begin to avail themselves of the wide range of rational and strictly physiologic agencies and resources that have always been at command, that are as old as Nature, and that we are almost ready to recognize as the only forces, influences, or materials in the universe that can logically be termed "remedies," and that must, therefore, eventually become, in legal parlance, our court of final resort—the oyer and terminer of physiologic as of pathologic science. Props, aids, and temporary palliatives, it is true, abound; and some of these, from time to time, acquire transient renown as specifics. But after flourishing for a brief day, as the fad or fashion of the profession, and somewhat longer as an overdone popular craze, each is relegated to the dusty shelves of the world's already crammed museum of delusional relics, to be referred to in the future history of the healing art as the momentary phantasy of physiologic myopes, who studied pathology and therapeutics from the standpoint of the dead-house, the rabbit-pen, and the laboratory, rather than from Nature and the clinique. The dead-house and laboratory searchers and inoculators are still in the field, but already their periodic "discoveries" and "scientific" sensations are beginning to be received with incredulous apathy and cynical impatience; and a generation or two hence the whole tribe and race of them will have become extinct.

The history of medicine and surgery, as it has been exploited or developed during the past quarter of a century, will be filled with the débris of dishonored and discarded "great discoveries," the godchildren of a hundred would-be eclipsers of Harvey, Jenner, and Pasteur. In that history the "chemic" and quintessence quacks will have their share, but these have not all been without the pale of the profession proper. For years opium, quinin, and coal-tar derivatives have been the sheet-anchors of the busy physician, and surgery has leaned upon cocain and mercuric chlorid. Just now the "animal extracts" are having, or at least demanding, an inning. A little further on the surgeons will wonder how their predecessors could have dared or needed to be so careless and lavish with the temptingly delusive cocain and the insidiously dangerous bichlorid; and the "animal extract" man—if he should live so long, through the timely absorption of his wonderful organic essences and vital resuscitators—will be heralding some newer and more remunerative if not more mysterious fad.

Dropping the digression, there would at first thought seem to be no direct relation between climatology and the breathing-habit; but a little reflection will disclose a very intimate inter-dependence between the two. Climates differ greatly in regard to mean temperature, and especially as to temperature-range, relative and absolute humidity, and in regard to altitude. That is to say, climatic variations depend to a certain extent upon all of these, and to a very definite extent upon increase or decrease of the elevation above sea-level; and all of these variations directly affect and determine the character of the breathing-habit. In any climate, whatever favors and induces an habitual out-door life proportionately and normally enhances the respiratory function. Equability, topographic attractiveness and scenic beauty, preponderance of pleasant weather, and especially of sunshine, absence of soil-moisture and of excessive atmospheric humidity—these are all qualities that make a climate desirable for chronic invalids, because they render open-air life and freedom of action at all times both prudent and pleasurable, and therefore inviting. Among the various artificial and generally much better appre-

ciated aids available at any location and in any climate may be cited mechanical facilities, artistic embellishment, and the moral and social environment. All of these aid in the psychic and mind cure side of the treatment, which should never be underrated or neglected.

The question as to where the best aggregation of these essential conditions and qualities can be found cannot be answered in a sweeping way in favor of this or that particular locality or climate for all all classes of invalids, but must to a certain extent be specially considered in each individual case, or at least in each general class of cases. At the same time, certain general rules apply to all cases, barring individual idiosyncrasy and any peculiar circumstances or conditions affecting and surrounding a given case. While it cannot be questioned that our own country, with its wide stretch of both latitude and longitude, and its almost endless variety of altitudes and configuration, affords every gradation of climate and scenery that could be rationally asked for, the patriotic prejudice indulged by those who decry all resort to foreign climes is without physiologic basis, and is narrow and sectional at best, as the whole earth is for the whole race, if they can compass it; and if patient, friends or physician has an unreasonable predilection for the shores of the Mediterranean, the valleys and slopes of the Swiss Alps, or the spas of Vaterland, their incomes warranting the outlay, there is no reason why the whim should not be encouraged, as the turning-point in many an invalid's history has, to all appearances, been based on nothing more substantial.

Let us restrict the present inquiry to localities and climates embraced within the borders of our own country. Florida early acquired a reputation that has hardly been maintained. Patients, especially of the pulmonary class, were originally sent there indiscriminately and at random, solely on account of its sub-tropical and peninsular climate. At present much more discretion is being exercised, and many physicians hesitate to send any class of patients to that locality for various reasons, but chiefly on account of the marked tendency to malarial complications there present. In Florida none of the effects and advantages of varying altitudes can be obtained, the elevation at the highest point in the peninsula being not more than a few feet above sea-level. The annual rainfall is somewhat excessive, and when it does not rain the fogs and dews are heavy enough to keep vegetation perennially green, and, as a consequence, atmospheric humidity is proverbially excessive. This condition is inseparable from "the lay of the land" and the monotonous proximity and prevalence of water. The whole peninsula is practically an island, or an archipelago of islands, anchored in the Gulf. Its most ambitious rivers are little more than broad, alligator-breeding bayous, of black and almost stagnant water. Lakes abound, underground streams are not rare, water is found by digging a few feet, in some places but a few inches below the surface, and the whole region gives the impression of being "made land" over an oozy marsh, "the Everglades" still being in a transition-stage.

Notwithstanding these numerous and decided drawbacks, many cases of tuberculosis, particularly of the laryngeal type, and of imperfectly-recovered pneumonias, do remarkably well with a winter's sojourn in "The Land of Flowers."

Beyond the bare feasibility of spending the greater portion of every day in the open air, when rain or thick fogs do not prevent, there is nothing in the climatic characteristics to stimulate or in the slightest degree develop the breathing-capacity. It is inclined to be a debilitating and languor-inducing, rather than a tonic climate. On the other hand, the social amenities have been much cultivated. Palatial hostelries and inviting resorts, with ample accommodations and luxurious appointments, are plentiful, so that the fashionable, as well as invalids, flock to the St. James, the Alcazar, the Ponce de Leon, and the hundreds of less pretentious resorts, every season, rather to escape the rigors of our Northern winters, and to enjoy social sensations, with a languid *dolce far niente*, than with any definite sanatory purposes.

The mountain regions of Georgia and the Carolinas furnish a very different aggregation of climatic qualities and conditions. The various localities in this region that have thus far been developed and brought into favorable popular as well as professional repute possess many desirable features. A moderate range of altitudes is available, the temperature-range is moderate, the annual precipitation is only about forty inches, and atmospheric humidity is not excessive.

The soil is porous and absorbent, the scenery and surroundings romantic and attractive, artificial auxiliaries are in fair supply, and reported results are quite as favorable as those of any of the noted foreign resorts. The region is one of pine forests, and hence has the desired reputation for balsamic and ozonic emanations and influences, the value of which is now unquestioned, although sometimes overrated. The entire belt is, however, subject to one quite serious drawback, that of occasional sudden and trying temperature-fluctuations. For some invalids this is not necessarily disastrous. In fact, it adds zest and variety to their everyday experiences, and acts as a constitutional tonic; but it compels us to rate the climate as somewhat robust, so much so that a certain class of sensitive sufferers who seek it are disappointed, and are driven elsewhere.

The next most popular region in the eastern portion of the United States is found in Northern New York, and is known as "The Adirondack Wilderness." This locality, with its varied advantages, has been so thoroughly advertised and written up since the days of "Adirondack Murray" and poor Marc Cook that no extended description is necessary. Its elevation is similar to that of the Carolina and Georgia resorts, varying in the settled portions from 1000 to 2500 feet above sea-level. Its evergreen forests were originally so dense that the region was formerly known as the "Great North Woods," but the lumber vandals and the relentless railroads have recently been pushing their work of landscape marring and general devastation to such an extent that the country promises to become a wilderness in fact as well as in name. It posesses a remarkably porous soil, is utterly free from malarial taint, the scenery and surroundings are still surpassingly beautiful, and within the past ten years its natural advantages have been widely recognized and extensively supplemented by professional as well as non-professional enterprise and skill. The climate is uneven and unreliable, the temperature occasionally fluctuating as much as forty or fifty degrees in less than twenty-four hours. Taken one year with another, it averages decidedly bracing, in short, rather too much so for delicate constitutions or advanced cases. Game abounds, and for such as enjoy it and can give themselves over to a semi-sporting life, the Adirondacks offer an interesting and hygienically desirable field.

The White Mountain regions of New Hampshire are similar in many respects to the Adirondacks. Both are better adapted for the climatic treatment of asthmatics, dyspeptics, and sufferers from hay-fever, than for tuberculous patients or rheumatics. Both are gradually, but surely, becoming less and less desirable as invalid-retreats, and more and more popular as summer-resorts for professional sports, social adventurers, and such folk, from the larger cities. Nevertheless, many cases of pulmonary disease have been wonderfully benefited, when not permanently cured, by becoming permanent residents of "The Wilderness."

Minnesota and the Dakotas have had some repute as climatically favorable to tuberculous patients and dyspeptics, but now can hardly be compared with the numerous more desirable sections of this climatically varied and resourceful country.

Colorado has been and still is a Mecca for tuberculous patients, asthmatics, and some other classes of invalids, thousands of whom have realized gratifying relief, with a goodly number of apparently permanent cures, through a temporary or permanent residence on some of the high plateaus of the mountainous, mid-continental region. Nearly a quarter of a century ago, after several years' residence in what was then the Territory of Colorado, after studying its characteristics and resources, I said of its climatic and other advantages as a health resort:[1]

"Colorado, as a whole, occupies the topographic center, and in fact as well as figuratively, is the summit of the continent. Taken in detail its different localities present a great variety of elevation, ranging from 4000 feet, in the Arkansas valley, to 10,000 feet, and more, in the mountain parks. . . . As to what altitude, other things being equal, is most favorable for chronic invalids of the classes mentioned, this undoubtedly depends very much on the nature of the disease, the age, temperament, and habits of the patient, and the stage of advancement of the malady, whatever it may be. In some cases of asthma the higher the elevation resorted to the more speedy and perfect the relief. Occasionally, inveterate cases fail of substantial aid until they ascend to some of the mountain towns, a residence in the valley, as everything outside the mountains proper is here termed, only ameliorating the severity of the paroxysms. On the other hand, cases of advanced pulmonary disease, at the altitude of Georgetown—nearly 8000 feet—often prove speedily fatal, which at Pueblo, on the Arkansas—4500 feet—would steadily improve, or at least live in comparative comfort for some years. . . .

"Mere altitude is not, however, as a rule, the primary thing to be considered, although its influence is more or less marked in every case. . . .

"The physiologic effects of a residence in high altitudes are to hurry respiration, consequently to accelerate the pulse, and to compel a rapid and immediate augmentation of the breathing capacity, in order to provide the requisite quantity of oxygen, from the rarefied air inspired. Hence the danger to those far advanced with tubercular consumption and to such as are subject to pulmonary hemorrhage, or some forms of cardiac disease. . . . The climate varies considerably with the altitude and with the varying topography of the country. Lying as it does in that happy mean of latitude—37° to 41°—between the extreme temperature-ranges of the Northern States and the enervating heat and humidity of the Southern, the winters of this region are mild, comparatively little snow falling except on the mountain ranges, and the summers are remarkably cool and bracing. There is about a month of each season during which, in the valley country, the mercury at midday ranges as high as at New Orleans; but one needs to keep on hand, in July, about the same clothing as is required at Christmas; and there are not half a dozen nights in the whole season when a pair of blankets to sleep under are in any degree uncomfortable. In the mountain town, gloves and light overcoats are in demand, even in dog-days. . . .

"Consumptives in the first and second stages may come to this continental summit with assurance that whatever a tonic climate, natural hygienic surroundings, pure air and water, good food, grand scenery, romantic adventure, and perpetual sunshine can do for an invalid, here awaits them."

To-day this sounds florid; but the lapse of more than twenty years has not suggested any serious questioning of its enthusiasm; and at the time, at the instigation of one of the trans-continental railways, the paper from which the foregoing extracts are taken was submitted to the *Denver Medical Association*, for approval or criticism, and was by that body unanimously endorsed as a fair and not

[1] Colorado Gazetteer, Denver, 1871, p. 107, et seq.

overdrawn statement; whereupon (without my previous knowledge or consent), a million or more copies were published in pamphlet form, and distributed throughout the East and in Europe. Proprietors of sanatoria and invalid hotels have not yet ceased to use its substance as basis stock for much of their advertising matter.

But notwithstanding the general truthfulness of the picture, the same drawback referred to in connection with the climate of the Adirondacks exists in Colorado, but in a lesser degree. In other words, it is, for many patients, a decidedly heroic resort. To realize its benefits in the fullest degree the patient needs to be still sufficiently robust to live out of doors in all seasons, to camp, fish, shoot, or botanize in the mountains, or to herd cattle on the plains, and sleep on the ground, wherever night or a fit of drowsiness overtakes him. To go there to be housed in an overheated and over-upholstered hotel in Denver, Colorado Springs, or Manitou, with a hundred others similarly afflicted, is little better than would be the same fatal routine if pursued in New England or New York.

Omitting any mention of Texas, New Mexico, Arizona, and numerous other localities which have some desirable features as health-resorts, the most unique and unquestionably best "all round" American climate, that of Southern California, remains to be considered.

In these days of trans-continental railway building and sharp traffic competition, it ought not to be a fact that remoteness should in any case be synonymous with obscurity; yet the distance from the populous centers has unquestionably prevented both the laity and the profession from acquiring other than a very vague and inadequate knowledge of the most peculiar, and at the same time, in all its features, the most inviting and sanatory climate for invalids, as a class, that has yet been made known on this continent. It may be fairly questioned whether anything in Europe can boast of such a combination of favorable qualities, with so few objectionable ones.

Lieutenant Emory, who accompanied the invading army of General Kearney, in 1846, called attention to "the superb physical health of the Californians" he met, as indicated by their "white teeth, and the blood tingling in the cheeks of their orange-colored faces."

Michler was struck with "the superbly-formed native women" he saw in this region, "their bodies as straight as an arrow."

Blodgett asserts[1] that:

"The elastic atmosphere and bracing effects of the Pacific climate constitute a striking difference from those of the Eastern States. Whether due to the absence of humidity alone is not clear; but, whatever the cause, it is a notable practical feature. . . .

"The interior valleys, where the heat is excessive, are similar to the cold coast also, and there is no climate which is not the reverse of enervating in its whole extent. . .

"All residents concur in pronouncing it more favorable to physical and mental activity than any they have ever known, from whatever quarter they have come."

Standing on the shores of San Diego Bay, Professor Agassiz exclaimed: "I have seen many lands; this is one of the favored spots of the earth."

Helen Hunt Jackson, who dwelt for some time in this Pacific coast edition of Eden restored, and made one of its secluded mountain gorges the scene of one of her most interesting romances, aptly described the favored valleys of Southern California as an island on land, so completely is the region insulated from the climatologic conditions which immediately surround it. She adds:

"Climate is to a country what temperament is to a man—Fate. And the word 'climate' is simply a statement of bounds defined according to the obliquity of the sun's course relative to the horizon—in other words, the slant of the sun. The tropics are tropic because the sun shines down too straight. In the temperate zone the sun strikes the earth too much aslant. There are a few spots on the globe where the conditions of the country override these laws and do away with these lines of discrimination in favors. Florida, Italy, the south of France and of Spain, a few islands, and Southern California complete the list."

General Greely, formerly chief of the United States Weather Bureau, in an instructive article, after describing the qualities that may be said to constitute an ideal climate,[1] adds:

"There is possibly one place in the United States where such conditions obtain, a bit of country of about forty square miles at the extreme southwestern part of the United States, in which San Diego is situated; but even here, perhaps once in two or three years, the sultry blasts of the Mojave Desert pass over the low mountain range and parch this favored district."

Brown,[2] discussing the climatic resorts of three continents, after having spent the best part of a lifetime in travel and observation, commits himself to this enthusiastic opinion:

"For those who are simply delicate, or inherit a tendency to consumption, I know of no country where I should regard the chances better for fair health and a prolongation of life than a residence in Southern California."

Charles Dudley Warner, in a work entitled "*Our Italy, or the Riviera of the United States*," published by the Harpers, expresses himself with even greater enthusiasm:[3]

"Any description would fail to give the charm of existence here; restlessness disappears, but there is no languor or depression."

[1] Climatology of the United States, p. 200.

[1] Scribner's Magazine, April, 1888.

[2] Harper's Monthly, November, 1887.

[3] Our Italy, New York, 1891.

He is of the opinion that the summer climate is quite as favorable and desirable as that of winter, for both pleasure-seekers and invalids, and emphasizes the fact that the winters are so mild that one is not obliged to expend the best part of his vitality in a six months' battle with the elements, as is the case in so many parts of the East. He adds some comments which it will be well for medical men as well as invalids to make careful note of:

"It is impossible to give an Eastern man a just idea of the winter of Southern California, who while gazing on gardens laden with tropical plants clothed in their rich and luxuriant foliage, or on the date and banana ripening in the bright sun, and on the strawberries of his warm months, which here are being gathered in mid-winter, cannot understand why he needs an overcoat . . . To the Easterner coming here with the expectation of finding the proverbially warm climates of the tropics nothing but disappointment will result. Health does not demand either the summer heat of the East or the great artificial heat of the houses of those regions, which usually is raised above 75° F. . . . The temperature of winter that has been found most congenial to either well or sick has been the temperature of from 55° to 60°; and with such a temperature, fogs, mists, or rains are in no way harmful, even to the invalid. As observed, this temperature is not an agreeable one for those accustomed to extremes, and many will perpetrate the blunder of housing themselves before a hot stove in a close room; the wise will simply clothe themselves properly in warm woolen garments, protect their feet with sensible shoes, and breathe the cooler air."

Contrasting the habits of the Chinese and Americans, he continues:

". . . But in this regard—how to weather the weather—we can learn something from that (the Chinese) nation . . . Their houses are open, and like the South American, the Chinaman will never sit in an apartment with closed doors. Draughts and air-currents affect neither the Peruvian, Colombian, nor the Chinese mandarin. . . . There is one thing that the barbarian will not do, however—something our Americans are continually doing, with great persistency—cram their guests' lungs full of foul and over-respired air. People should not forget that it is all-important to keep the body warm—something that can be done with appropriate clothing—but that if we wish to be well and keep healthy we must breathe fresh air, and that air of a temperature of 55° or 60° is not too cold for breathing purposes, even if disagreeably cold to the body surface."

Lay testimony might be multiplied indefinitely, and it is often more indicative of the real characteristics of a particular climate or locality than some professional descriptions. Professional evidence, however, is not wanting.

Dr. Remondino, of San Diego, has spent nearly a quarter of a century in the region, and has written extensively of his experiences.[1]

As coming from a keen observer, eminent as a physician as well as a writer, some climatic aphorisms and brief descriptions from Dr. Remondino's work will be found to fully corroborate the enthusiastic opinions of lay observers already cited:

"Equability and ventilation, and not altitude are the real factors in affording immunity from phthisis.

"Southern California is generally sought for its balmy, aseptic air, genial atmosphere, and invigorating climate. . . . Violets and invalids require a different locality and atmosphere.

"This portion of California has its climate modified by the marine currents. . . .

"Heat is brought to the American coast by two currents—the Kuro-Siwo or Japan stream, and the great circular North Pacific drift-current. Cold is imparted from the colder waters coming from the many cold, deep ocean currents with which the Pacific abounds.

"The effect on the climate produced by this peculiar condition of the ocean water is to give it a constancy of temperature.

"The generality of the soil is of disintegrated granite, and very sandy and porous . . . Such a thing as soil moisture cannot exist. . . . Always being dry, the soil is very warm."

Referring to temperatures, he states that:

"In the ten years from 1876 to 1885, inclusive, 3653 daily observations recorded show that on no one day during the ten years did the mercury remain below 40° more than one or two hours; on not a single day did any unusual warmth continue more than a few hours, the highest minimum for any day being only 70° on five of the 3653 days.

"Out of the same 3653 days there were 3560 days on which the mercury did not fall below 40°, 3533 days on which it did not rise above 80°, 120 on which it rose above 80°, 41 above 85°, 22 above 90°, 4 above 95°, and only one day on which it rose above 100°. The lowest maximum for any day was 52° on 4 of the 3653 days.

"It is temperature that has kept civilization within certain geographic limits; it is temperature—and that alone—that allows of free ventilation, which is the real and only safeguard against phthisis. . . .

"Perfect ventilation is impossible where the rigor of the climate and sedentary occupation require that all of the cold, external air be excluded and all of the internal warmth of the rooms be retained, that the occupants may be in temporary comfort. . . .

"To fully carry out that perfect ventilation which is an imperative necessity to health and life, *the nature of the climate must be such as will allow it to be done in an automatic or self-adjusting manner, as otherwise it will not be done;* living in unventilated apartments becomes such a habit that when once established it is hard to eradicate. The stupefying and life-slowing effects of a foul and vitiated, close atmosphere seem to become, after a time, a part of the physical existence and a necessity with many; so much so that they become positively uncomfortable in fresh air.

"*In Southern California it is never necessary to close the houses, either to exclude the heat of summer or the cold of winter.* . . . . Families have lived, my own being among the number, for several years, with wide-opened windows, without awnings in summer or fires in winter, in the greatest of comfort, showing the ease, practicability, and comfort with which free and constant ventilation can be practised in this climate."

The same author in an article in the current (October, 1893) number of the *California Magazine*, adds a summary of advice:

"I am often asked what part of Southern California is best adapted to certain individual cases. This is, of

[1] The Mediterranean Shores of America. Philadelphia: The F. A. Davis Co., 1892.

course, largely a matter of personal and contitutional election. . . . . Rheumatic, neuralgic and laryngeal cases do better in the interior. . . . . Convalescing cases recovering from some long and tedious illness, and those suffering from nervous prostration, insomnia, or the debilitated stages of advanced pulmonary tuberculosis, are more benefited by the bracing air of the coast. . . . . The region offers every conceivable variety of temperature met with in either Europe, Africa, or Asia. The shores of Africa and the interior of the great Sahara; the highlands of Spain and the low hills and plains of Italy; the abrupt Apennines and the more gigantic Alps of either Switzerland or Bavaria; the heather-clad hills of Scotland and the sunny islets of the Greek Archipelago—all have here their counterparts. Yet with this strange diversity, the climatic factorial influence of the great heated desert and the vast cold ocean combine to produce a homogeneity that makes California unique among the known regions of the world."

Briefly, the climatic features of this region may be thus summarized:

1. A mild, equable, and yet bracing temperature.
2. A warm and porous soil.
3. Pure, aseptic air and freedom from miasmata.
4. Preponderance of sunshine, light rainfall.
5. Absence of high winds and storms. (Thunder and lightning are practically unknown.)
6. Ready access to a great variety of elevations, ranging from sea-level to 10,000 feet or more, as desired.
7. A varied and beautiful landscape.
8. A soil-productiveness unparalleled in any civilized quarter of the globe.
9. A combination that, as a whole, constantly and automatically tends to enhance the respiratory function and to stimulate and develop the breathing-habit.

Finally, as it is now practically admitted that nearly all chronic constitutional perversions and morbid diatheses—pulmonary tuberculosis, lithiasis, the neuroses, chronic nephritis, diabetes, and fatty and other degenerative processes—are the direct or indirect sequelæ of persistent and habitual suboxidation, and that this result depends chiefly upon a passively-induced want of normal robustness in connection with the breathing-habit, the present status of biologic and physiologic science warrants the assumption or prediction that, by increasing the quantity of tidal air habitually and ordinarily utilized to twice or three times its present average volume, thereby securing a proportionately increased degree of automatically constant oxidation throughout the entire physical organism, the race might be rendered self-protective and practically immune as regards many, if not all, of these insidious, universally prevalent, and, at present, almost hopelessly fatal forms of disease, and the expectation of life, on which mortality-tables are now based, materially and almost indefinitely increased.

WASHINGTON HEIGHTS, WEST 181ST STREET.

THE SPINAL CORD IN POTT'S DISEASE.[1]

BY CHARLES W. BURR, M.D.,
PATHOLOGIST TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA, AND TO THE STATE HOSPITAL FOR THE INSANE, NORRISTOWN.

IN considering the pathology of the nervous symptoms of caries of the spine we need pay but little attention to the morbid anatomy of the bone-disease. We may define Pott's disease pathologically as an osteitis, usually tuberculous, of the bodies of one or more vertebræ, resulting in caseous necrosis and caries. Rarely the primary cause is syphilis and not tuberculosis. The bone-disease may be secondary to inflammation in neighboring structures. Finally, sometimes in septicemia secondary abscesses occur in the vertebræ. It is a curious fact, and one for which so far as I know no satisfactory explanation has been given, that this osteitis is most likely to occur in the dorsal region. The explanation sometimes offered that this region is the most exposed to injury does not explain, for the causal relation of trauma to Pott's disease has not as yet been positively proved.

The conditions mimicking Pott's disease—malignant tumors of the vertebræ and aortic aneurism—we may dismiss without further mention.

The first question for our consideration is: Upon what do the nervous symptoms depend? Are they caused directly by the angular curvature and the consequent narrowing and angulation of the canal? In the great majority of cases, no. It is, of course, true that if a carious vertebra suddenly breaks down and fragments of bone are driven forcibly against the cord, or if the odontoid ligament gives way, we will find sudden, severe, and even fatal nervous symptoms; but ordinarily, even if the diameter of the vertebral canal be diminished by the sudden breaking down of a vertebra, the cord slips behind the projecting bone and escapes very serious compression. In by far the greater number of cases the nervous symptoms are due to inflammatory changes in the dura causing pressure upon, and later, organic changes in the cord and nerves. So soon as the osteitis has progressed far enough to cause a breaking down of the posterior surface of the body of a vertebra and ulceration of the posterior common ligament, and consequent communication with the loose tissue filling up the epidural space, inflammatory changes due to direct contiguity of tissue arise in the latter and soon appear on the external surface of the dura, ending in a pachymeningitis. When this process has progressed far enough to produce pressure upon the cord this organ, according to Hoffa,[2] becomes edematous

[1] Read at the October meeting of the Orthopedic Section of the College of Physicians, Philadelphia.

[2] Albert Hoffa: Transactions American Orthopedic Association. Fifth Session. Washington, 1891.

from the interference with the flow of lymph and a stasis of the fluids of its tissue. The retained lymph acts not only mechanically but also as a poison, producing at first softening of the cord with, at the same time, an increase of the connective tissue, which, when sufficient, causes sclerosis. The same is true of the peripheral nerves at their points of exit from the dura. Edema is of necessity present. As to the poisonous effect of retained lymph we need further investigation.

As the time at which communication is established between the diseased bone and the canal is, as one might say, accidental, or, rather, depends not so much upon the amount of bone-tissue diseased as upon the situation of disease in the body and the direction of its progress, it follows, as is well-known, that nervous symptoms, spasmodic abdominal pain, numbness or tingling in the extremities, alteration of the knee-jerk, paralysis, or indeed all of the symptoms referable to the cord, may precede deformity or, indeed, any sign of bone-disease. The reverse is also true. There may be severe bone-disease and marked angularity without nervous symptoms.

The liability to nervous symptoms varies with the region of the spine affected. Bouvier[1] found only five paraplegias among thirty-eight cases of lumbar caries; Coudroy de Lauréal only one paraplegia among fifty-nine similar cases. Among fifty-six cases of dorsal caries, on the contrary, Bouvier observed thirty-eight cases of paraplegia, and Coudroy nineteen cases among seventy-seven in the same locality. The reason of this greater frequency of paraplegia in dorsal disease is not difficult to find. The dorsal region is the most liable to severe deformity, and to abscesses with pent-up pus, and is normally the narrowest part of the spinal canal.

The inflammation of the dura may be either simple or purulent. If simple, the external surface of the dura is reddened, with here and there patches of lymph. So long as this condition persists there are few or no severe nervous symptoms. If the inflammation be purulent, there is pus, caseous material, and organized inflammatory products. The thickening varies much, sometimes amounting to half an inch, and may surround the cord, or occupy one side, or be irregularly distributed, with nodular or even fungoid growths scattered here and there. Adhesion to the bone soon takes place. Commonly, the thickening and adhesion occur first and are greatest in the anterior portion of the dura, and hence motor cord-symptoms usually precede sensory ones. The pachymeningitis is usually confined to the neighborhood of the diseased bone, but may extend far beyond its limits. Ordinarily, the inner surface of the dura and the pia-arachnoid escape inflammatory changes till late in the disease, even though the cord is seriously disabled. This being so, we are able to say that the changes in the cord are not due to a tuberculous process in it, but to the mechanical effect of pressure and possibly the irritant effect of retained lymph, as mentioned. When the pachymeningitis invades the inner surface and the pia-arachnoid, another element is added to the destructive process.

The pressure of the thickened dura affects not only the spinal cord but also the peripheral nerves at their points of passage through it, producing Gowers' "root symptoms" and "cord symptoms." Which set of symptoms predominate will, of course, depend upon whether pressure is greatest on the nerve-roots or on the cord, and also upon which part of the periphery of the cord is most involved. As a fact, "root symptoms" vary much in intensity. There may be simply pain in the course and distribution of the affected nerves or spots of anesthesia, sometimes painful areas, muscular wasting and palsy and, curiously enough, sometimes herpes zoster. The cord symptoms, as I have said, will vary with the varying portions of the transverse area affected, and of course with the variation in the longitudinal position of the disease.

These symptoms are too well known to need repetition. In disease of the three upper cervical vertebræ, however, there is at times a curiously anomalous distribution of symptoms. Instead, as might be expected, of paralysis of all four extremities, there may be palsy of the arms, without any affection of the legs. According to Brown-Séquard the explanation is that the motor tracts for the arms are more superficial than those for the legs, and hence are earlier involved in a lesion advancing from the periphery. On the other hand, Vulpian maintains that just the opposite is true, or in other words, that in the cervical region the nerve-fibers for the arms have already entered the gray matter of the cord, while those for the legs are still in the lateral columns. He claims on this very account that the arm-fibers will be more compressed, owing to the less density of the gray matter as compared with the white.

At autopsy in an advanced case the nerves are found much decreased in size, being sometimes mere threads. Under the microscope we find an increased amount of connective tissue, with an absence of many nerve-fibers, and sometimes with enlarged axis-cylinders. It is not strictly true to call this condition an inflammation. It is rather a degeneration. The cord ordinarily shows gross disfigurement at the seat of meningitis and curvature. It may be flattened, cylindrical, or indented. Angulation may be so marked as to persist after the removal of the cord from the canal, even in cases which at the time of

[1] Quoted by Mary Putnam Jacobi. Keating's Cyclopedia of the Diseases of Children, vol. iv, p. 646.

death presented no symptoms. I know of no case in which there was complete severance of the cord. Shaffer[1] refers to an autopsy in which a portion of the eighth dorsal vertebra was found impinging directly upon the cord, through which it had so nearly cut its way that only a slender thread remained.

On microscopic examination in severe cases a peculiar interstitial myelitis is found. The newly formed connective tissue, which at first contains cells, later becomes changed into a dense reticulum, which much increases the hardness of the cord. The nerve-fibers are to a greater or less extent completely degenerated, though usually some are left with narrowed myelin-sheaths, and a few may be normal. The anterior part of the cord is likely to be most affected. The gray matter cannot be distinguished from the white, and the ganglion-cells have lost their processes and are shrunken and atrophied. Scattered everywhere are found masses of myelin, granule-corpuscles, and corpora amylacea. The walls of the small vessels are often thickened by a growth of spindle-cells arranged concentrically around the lumen, making it smaller or obliterating it entirely. This cutting off of the blood-supply of course increases the damage to the cord. The changes are greatest at the point of greatest pressure, but extend for variable distances up and down the cord. Above and below the transverse myelitis are found the usual ascending degeneration in the posterior columns and descending degeneration in the lateral pyramidal tracts. But secondary cord-changes in this disease do not always follow the usual law. According to Gowers and Charcot there may be an ascending inflammation of the lateral pyramidal tracts with consequent symptoms referable to the arms. Anomalous symptoms are also produced occasionally by inflammatory foci scattered here and there through the cord or even the medulla. Again, if the nerve-roots are affected before the cord the pressure-neuritis may invade the cord, causing streaks of sclerosis in the posterior columns. In the cases in which there is a sudden paraplegia not caused by the direct pressure of a dislocated piece of bone, hemorrhage has occurred either in the inflamed membranes or, more rarely, in the cord.

The processes by which the cord regains its functions are not altogether clear. The nerve-fibers that suffer from pressure insufficient to cause organic change, and even those in which the myelin-sheaths are greatly narrowed, will of course resume their functions on removal of the pressure. But can a nerve-fiber in the spinal cord, if completely degenerated in a part of its course, be regenerated? In peripheral nerves regeneration certainly sometimes takes place. Quite as certainly it does not happen in the spinal cord if the destructive lesion is sudden. Apparently, however, if the lesion be a slowly increasing one, as ordinarily it is in Pott's disease, axis-cylinders may regenerate. It is also curious that there may be complete restoration of function in a cord the transverse area of which at the seat of former disease is half or less than half that of the normal.

THE INDICATIONS AND PREFERABLE METHODS FOR MASTOID OPERATIONS.[1]

BY SETH SCOTT BISHOP, M.D.,
OF CHICAGO, ILL.;
SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY, ETC.

WHEN and how shall we operate in mastoid disease? Among American surgeons there is a wide diversity of opinion, especially as to what symptoms constitute a positive demand for opening the mastoid process. My observations leave the impression that the majority of surgeons are too conservative, both as to the time selected for surgical interference and the extent of the operation. While conservatism is an admirable trait in a surgeon, so long as caution is not merged into timidity, so far as I have seen its influence in this class of cases it has proved detrimental to the patients. I have seen fatal results follow: (1) Refusal to allow the operation; (2) after operations too long deferred, and (3) after operations that were performed too timidly to remove all of the diseased tissue. I have never known death to occur as a direct result of the operation itself.

We all appreciate the gravity of this undertaking, but in view of the fact that the disease demanding it is far more dangerous than the surgical measures for its relief, greater freedom of action and boldness of methods will add luster to the records of our work.

When shall we operate? The weight of experience and the testimony of trustworthy authorities favor early operations. If we wait for the very grave symptoms—fever, rigors, vomiting, vertigo, widely diffused pains in the head and neck; thickly furred, tremulous, and indented tongue; delirium, etc.—the chances of success are discouragingly diminished. I do not believe it is wise to postpone an operation until these symptoms occur, unless the patient is suffering from some other affection that renders recovery hopeless, or unless the prostration is so great as to preclude the possibility of survival.

There are tentative methods of treatment that are proper and promising in incipient mastoiditis unattended by urgent or dangerous symptoms. I have

[1] Read before the Mississippi Valley Medical Association, October, 1893.

often subdued periostitis by the use of counter-irritation, compresses, and the free extraction of blood with leeches and warm, wet applications. Many cases of mastoid disease may be cut short by this early active treatment. I have seen very acute attacks with intense pain relieved permanently in this manner. If there is also acute inflammation of the middle ear, additional leeches should be applied about the tragus, and an opiate should be given. If decided relief does not occur within twenty-four or forty-eight hours we should not hesitate to make Wilde's incision, or if this does not relieve, to open the bone.

This statement, in my opinion, embodies as great conservatism as our duty to the patient justifies. Obviously, any rules that may be laid down must be more or less elastic. For example, a case recently came under my observation in which the mastoid had been opened. Another swelling appeared above the auricle, with fluctuation. I advised opening it, and pus was liberated. Subsequently the patient was brought to me with this opening almost closed, but pus could be pressed from it. There was severe periostitis involving the whole mastoid, temporal and zygomatic regions. I advised free incision extending through the two previous openings, but one of my assistants, Dr. Hollinger, desired to try the effect of pressure with antiseptic compresses. This treatment alone dispelled all the threatening symptoms in less than two days.

I have formulated the following six rules by which I have been guided in deciding the perplexing question of an operation:

The mastoid process should be opened

1. When there is acute inflammation of the bone that resists palliative treatment.
2. When repeated swellings and abscesses occur.
3. When there is bulging of the posterior and superior wall of the meatus with suppuration of the middle ear.
4. When there is a fistula.
5. When there are severe pains in the same side of the head as the diseased ear, and resisting all other treatment.
6. When a foul otorrhea cannot be cured by any other means.

These rules may be termed conservative, and whatever deviation we may indulge in ought to be at once favorable to the operation and the welfare of the patient. Too great temporizing favors sinus-thrombosis, septicemia, brain-abscess, and meningitis.

What method of operating shall we pursue? I have usually performed Schwartze's operation, but have also used Stacke's method, with gratifying results. The latter is one of the most difficult, delicate, and dangerous of operations.

As we cannot know the extent of the pathologic process before entering the bone, it does not appear to be advisable to decide in advance upon any special method of procedure save one: remove all dead and diseased tissue. Whatever method does this does best. Stacke's and Bergmann's operations have the advantage of affording the greatest accessibility to the tympanum, so that if it is necessary to remove necrosed ossicles or diseased tympanic tissue it can be done with greater facility and thoroughness, but it is best to guard against collapse of the walls of the meatus and resulting stenosis by inserting a tube in the canal. Schwartze's operation is sufficient for most cases. It is much simpler and leaves a less extensive wound. The operations of Wolf and Küster through the meatus I have never ventured upon, for fear of not possessing sufficient skill to remove all of the diseased tissue through such a narrow field of vision.

There are a few points in this connection worth mentioning, for they are closely related to a successful issue. The best illumination is gained by the use of light reflected from the mirror on the operator's forehead. This affords a decided advantage over direct light. It is more intense, can be thrown into the opening of the bone in every direction, and there are no shadows to obscure the field.

It is safer not to close the wound entirely until it has healed from the bottom. When the interior has filled with cicatricial tissue up to the surface of the outer table it is safe to allow it to close. I have had good results after closing the wound completely at the time of the operation, but it is certainly not so safe a plan.

The best dressing is one of dithymol diiodid (usually sold under the name of aristol) sprinkled over the wound-surfaces, covering them entirely. Then iodoform-gauze should be placed lightly in the mouth of that part of the wound chosen to remain open. It should not be packed down to the bottom of the wound so as to crowd any discharge inward, but it should extend just far enough inward to keep the cutaneous tissues from closing over the superficial opening in the bone until the deep wound is well. Dithymol diiodid has two excellent qualities: It is the best cicatrizant we possess, and it has the additional advantage of being to some extent an anesthetic. While iodoform is irritant and toxic and boric acid sometimes produces pain, dithymol diiodid soothes and heals without any ill effects.

After stitching that part of the wound to be closed and dressing the open mouth for drainage, the whole is covered with iodoform-gauze, absorbent cotton, and a net-bandage. This bandage is made of the common white mosquito cloth which, as used in the Northern States, is sized with a preparation

of glue. The roll of bandange is dipped in water just before applying, until it is wet through. Then the water is squeezed out and the bandage is applied as usual. When it dries, the layers adhere together firmly, so as to retain their position for many days in succession without any attention.

But the most perplexing question before us is: When shall we open the bone? My conviction is that the earlier the operation is performed the better our records will be. We should operate while the condition of the patient favors resolution instead of dissolution, and all dead and diseased tissue should be removed.

The safest and simplest rule by which I have been generally guided is this: When there is a fistula or a group of unyielding symptoms of serious sickness undoubtedly due to the ear-disease, penetrate the bone. Unlock the vault that holds our treasure and the sufferer's doom. Give vent to the pent-up furies of disease, as Æolus loosed the struggling winds. A merciless and unrelenting foe has stormed the fortress of the brain—the citadel of life. No truce is safe, and now heroic action only conquers man's great foe.

70 STATE STREET.

THE RELATION OF THE PATELLAR TENDON-REFLEX TO SOME OF THE OCULAR REFLEXES FOUND IN GENERAL PARALYSIS OF THE INSANE.[1]

BY CHARLES A. OLIVER, A.M., M.D.,
ATTENDING SURGEON TO WILLS RYE HOSPITAL; OPHTHALMIC SURGEON TO THE PRESBYTERIAN HOSPITAL; CONSULTING OPHTHALMIC SURGEON TO ST. TIMOTHY'S HOSPITAL, ETC.,
PHILADELPHIA, PA.

THE following observations are given as expressive of some of the most important and most certain of the findings that have been obtained in a clinical study of the ocular symptoms of general paralysis of the insane as observed in a large proportion of the male inmates of the State Hospital for the Insane at Norristown, Pa. Although tentative in a measure, and not to be found to equal degrees in each individual case, yet, by reason of a combination of a large series of similarly related groupings, these observations may be justly offered as showing the relationship existing between the patellar tendon-reflexes and the ocular reflexes in this disease.

With such provisions, and with the hope that these studies may serve as inducements to others for similar research, the following formulations are herewith offered:

1. In some of the cases in the second stage of the disease, especially when the patellar tendon-reflexes were unequally exaggerated, there appeared to be an irregular and unequal spastic innervation of the two irides, causing irregularities in pin-point pupil-forms.

2. In a few cases, especially in the third stage of the disorder, when the patellar-tendon reflexes were unequally diminished, and the pupil-size was small and the pupillary shape somewhat irregular, the iris seemed to be but little acted upon by any powerful mydriatic.[1]

3. In many cases, especially in comparatively young subjects in the third stage of the disease, when the patellar tendon-reflexes were unequally diminished, there appeared to be an unequal paralytic innervation of the two irides; the pupillary dilatation manifesting itself at times, though not as a rule, in the eye with the greater amount of objective optic-nerve-head degeneration and retinal change.

4. In a few cases (especially in men of middle life) in the third stage of the disorder, when the patellar tendon-reflexes were markedly diminished and when the ataxias were quite pronounced, there were marked temporary asymmetries of pupillary form, one pupil often being quite small and irregular for several examinations, whilst its fellow was large and ovoid or oval.

5. In quite a number of cases, especially in the advanced stages of the disease, when the patellar tendon-reflexes were either unequally exaggerated or diminished, there was a failure of the irides to respond to even major degrees of light-stimulus; this being true not only for those subjects exhibiting a true spastic myosis, but more especially shown in those instances in which, with partial dilatation of the pupil, mydriatics failed to act.

6. In many instances, especially in the older cases, when the patellar tendon-reflexes were, as a rule, unequally diminished or even lost, there was not only failure of iris-response to the strongest light-stimulus carefully thrown upon the retina, but when obtainable, the irides seemed to fail to react to the various coarse and rough subjective and objective procedures necessary to be used in order to evolve both separated and associated efforts for accommodation, and associated efforts for convergence.

7. In some instances in which ciliary muscle-innervation could be satisfactorily obtained, both the spastic excitation and the paralytic innervation at times found by subjective reading-tests and objective study with the retinoscope seemed to be in direct ratio to the patellar tendon-reflexes as the iridic changes.

8. In quite a number of cases in which there was

[1] Read before the American Ophthalmological Society, July, 1893.

[1] In several such cases there were marked depressant effects, with grave constitutional symptoms, produced by single instillations of $\frac{1}{40}$ and $\frac{1}{20}$ grain of neutral sulfate of atropin in the conjunctival cul-de-sacs.

marked inequality of the pupils, with more or less want of reaction of the irides to light-stimulus, the patellar tendon-reflex on the side of the larger pupil seemed to be the one the more greatly diminished.

9. In a number of instances, especially during the very earliest stages of the disease, when the patellar tendon-reflexes were beginning to lessen to unequal degrees, there often appeared momentary secondary ataxic dilatation of the pupil during exposure to strong light-stimulation.

10. In many cases, especially during the second stage of the disorder, when the patellar tendon-reflexes began to become irregular and inconstant, pupillary inequalities as expressive of unequal iris-innervation and action became more and more constant.

CLINICAL LECTURE.

RHINOPHARYNGEAL AND NASAL NEOPLASMS.[1]

BY J. SOLIS-COHEN, M.D.,
HONORARY PROFESSOR OF LARYNGOLOGY IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

I. THE CURE OF A RHINOPHARYNGEAL FIBROSARCOMA BY ELECTROLYSIS.

GENTLEMEN: It is not often that one has the pleasure of showing to a class a case of cured nasopharyngeal fibrosarcoma, as I have the opportunity of now doing. Those of you who attended my clinic last year may remember this young man, twenty-three years of age, who came here during the winter with a face much deformed. He had been suffering for ten or twelve years with a tumor in his nose and pharynx that bled on the slightest touch. It looked so terrible that I was afraid to attack it, and I referred the patient to the surgical clinic, with the suggestion that the upper maxilla be resected and the tumor be removed by direct access, because in our indirect methods through the nose and mouth it seemed impossible to circumscribe it sufficiently. The operation was refused as unjustifiable, because it did not hold out enough hope of success, and the case was returned to the throat-clinic. Here, he would have been dismissed with palliative measures, for I had not the slightest idea of curing him; and but for the reproachful language of the physician who brought him, Dr. Harweter, of Allentown, Pa., I should not have tried it.

A tumor of this kind is very peculiar. For some reason or other unknown, in young adolescents just before puberty, usually in the male sex (for the growths are more frequent in the male), a neoplasm begins to form in the periosteum in front of the basilar process of the occipital bone—that is, at the base of the skull, either to one side or the other of the median line, rarely, if ever, in the center. Thence it extends into the pharynx, sometimes along the cervical vertebra, but much more frequently along the sphenoid bone. It forms attachments around the posterior outlets of the nose and the internal pterygoid plates of the sphenoid and the nasal septum. It becomes bound to the pharyngeal outlet of the Eustachian tube, passes into the nasal passages, and forms attachments to the turbinate bones and to the ethmoid bone, passes along the petrous portion of the temporal bone, penetrates into the zygomatic and the sphenomaxillary fossæ, passes through the sutures which unite the cranial bones and the bones of the face, then through the natural fissures and foraminæ that transmit the nerves and blood-vessels, and thus it gets into the antrum, into the orbit, and into the cavity of the skull—all the time pushing soft and hard tissues aside to make room for itself. Sometimes it stops under the dura, and sometimes eventually penetrates through the membranes into the brain. These neoplasms are generally known as nasopharyngeal polypi, and they are very terrible forms of tumor. They do not always take the full course described, though usually more or less of it. They often get into the nose and the accessory cavities, the maxillary sinus and frontal sinus, and deform the face peculiarly, the distortion being known as frog-face—a characteristic feature which this man had in a marked degree, and of which, to a certain extent, he still shows the evidence.

The prognosis in these cases is very bad, except in recent and circumscribed growths. They require surgical treatment. The rule is that the patient succumbs, whatever the operation. Some terrible operations have been performed for removal of these growths—preliminary operations, serious in themselves—simply to gain direct access to the neoplasm. Sometimes the nose is detached from the superior maxilla and turned up. Sometimes the soft palate is slit; and sometimes both the soft and the hard palates are divided. Sometimes the superior maxilla is resected, or the two superior maxillæ are separated in front through the hard palate. When direct access is attained the growths are removed as thoroughly as practicable with forceps, with scissors, with the snare, with the cautery, with saws, or by whatever methods seem most effectual. Under almost every method of operation they are likely to recur, and when they do recur they grow more rapidly than they did at first.

The method pursued in the present case was as follows: First, in the clinic, our chief, Dr. Jones, and his assistants removed as much of the growth with the electric incandescent snare as they could. They passed a platinum wire through a canula, and carried the loop as near as possible to the base of the growth. Then they tightened the wire and passed the electric current through the snare, and so continued tightening the snare and passing the current until the mass seized was cut off. When they had done as much of this work as possible, the patient was referred to me, and the remainder of the work was done mostly in my office, and chiefly by electrolysis; that is to say, by passing the currents of electricity through certain portions of the mass, an electro-chemic decomposition was set up in the tumor, as near as possible to its multiple points of attachment. You can understand by your knowledge of the growth and extension of these tumors that it is hazardous simply to take hold of them with strong forceps and pull. You may pull some important structure away with them, and thus do irreparable injury; you may even enter the cranium. More than one surgeon has seen his patient die on the table in the very effort he has made to prolong that patient's life. So you must be very careful when you try to pull such a growth away with the forceps. Elec-

[1] A Clinical Lecture delivered at the Laryngological Clinic of the Jefferson Medical College Hospital, Friday October 13, 1893.

trolysis produces an electro-chemic decomposition of tissue. If you put two electrodes from the respective poles of an electric battery in any liquid, or in a tissue largely composed of liquids, the result will be a decomposition of the liquids, the oxygen and the acids going to the positive pole, and the hydrogen and the alkalies to the negative pole. This fact is sometimes utilized for medical purposes, to get remedies into certain tissues by passing a properly arranged electric current through them. The tissues of the body are largely composed of water, and the oxygen goes to the positive, and the hydrogen to the negative pole, where the gases escape in bubbles of froth.

Now what is the result of destroying the water in the animal tissue? You dry that tissue up. The tissues exposed to the current become hard. The nutrient material cannot pass through this hard layer to the body of the tumor, and so its nutrition is thus far destroyed, and that part sloughs off, just as a limb is seen to do in a case of senile gangrene. This result is physical and physico-chemic. It is not due to any occult power in the electric force. In our patient this is what we did with our electric current, sometimes using plates, and sometimes needle-points, as electrodes at the different operations, thus destroying the paths of nutrition and favoring sloughing. As the sloughing progressed we pulled the dead tissue away with forceps. When we used plates of metal on the surface of the mass, we could see the part melting under our instruments as snow melts under the sun, although not as rapidly—very slowly indeed—but we could distintly see the foam of the oxygen and hydrogen as the tissue gave way under the electric action. This method of treatment is difficult in growths of this kind, on account of the complexity of the attachments, and many times have I spent over an hour in the procedure, becoming so exhausted that it was impossible for me to do any more work during the remainder of the day. We had in all between twenty and thirty sittings. The result was, that toward the end of June there was but little growth left, and that little seemed sloughy. I told the patient to go home and report in October. He reported yesterday, and on examining the parts I was glad to find every vestige of the growth gone. Several particles sloughed out after he went home. He can now breathe freely through both sides of his nose, and he does not now speak as though he had a hot potato in his mouth. He has gained ten pounds in weight. I have had several successes of this kind, but none of them in a case as extensive and apparently hopeless as was this. I have never known a case in which the tumor was taken away by resection of the upper jaw in which there was no recurrence. This method is both much the more thorough and also much the more difficult. The knife, sometimes even when you think you are cutting through healthy tissues, leaves more or less diseased tissue, and then, of course, another tumor grows. Again, in cutting, sometimes you carry disease to healthy tissues on your knife. I have never seen any success equal electrolytic operation through the nose and mouth, provided you take the time and the trouble. Of course, a single operation of an hour would have removed a portion only; here we had thirty or forty hours of work. The result has been excellent. When you look at the man's pharynx you will see a few rugged points, and a band across the pharyngeal outlet of the left Eustachian tube, probably due to an adhesion between the soft palate and the vault of the pharynx, a result of the operative procedures. This I will remove at some later date. Finally, let me remind you that it has occasionally happened that operations from the exterior have had to be abandoned, and yet the injury done to the parts has been such that sloughing took place and the tumor sloughed out, but you hardly dare operate with such a direct object in view.

II. TUBULAR EPITHELIOMA OF THE NOSE AND MAXILLARY SINUS.

Two years ago to-day I operated upon this patient, before the class, for a tumor of her nose that was difficult of access. In order to avoid an external operation and scarring, which is not desirable in a female, I turned up the upper lip and separated the nose from the jaw, pulling the nose upward up on the forehead. As you notice, the cicatrix is barely visible. I found that the growth was not confined to the nose, but extended into the antrum or maxillary sinus. We removed all the morbid growth with the forceps and scraped the parts, and then allowed the nose to fall in place. The parts healed kindly, and for three or four months the patient was completely relieved of severe pain and great difficulty of breathing. On examination by the pathologist of the hospital the growth removed was found to be an adeno-carcinoma or tubular epithelioma, and the probability of a recurrence was explained to the patient before she left the hospital. Since that time she has been here on several occasions for removal of recurrent growths, and her health has gradually become much impaired. During the last six months she has been here four times, probably as many as in the preceding eighteen months. That is the clinical history of these growths after evulsion or exsection; a relief of several months after operation, then a recurrence, and after that relief not so long, repetition of operation, and so on, the intervals between relief getting gradually shorter. We will again try to relieve her of her troublesome growth, but in the long run it will cause her death.

I purpose to operate in this case with a device which was employed by Hippocrates, and which I recommend you to use in cases of soft tumors, especially when you are not provided with surgical instruments. It is a string on which are tied a number of swabs. Two strings are passed through the nostrils into the mouth. The two ends of one are tied in front of the lips as a reserve in case it may be required to carry a tampon behind the palate to restrain hemorrhage. The oral end of the other is tied to the kitestring of swabs, which are then pulled forward through the nose, carrying with them a lot of this soft tissue. The end of the string of the first series of swabs is tied to another series and the procedure repeated. You will have greater success with this, perhaps, than with cutting instruments or with forceps.

III. PEDUNCULATED PAPILLOMA OF THE UVULA.

This is a case of papilloma of the uvula, a few examples of which we have every year. You notice a long pedicle, more than an inch in length, hanging from the tip of the uvula and supporting a cauliflower growth. This growth originally existed on the uvula perhaps, but

in efforts at deglutition it has gradually been drawn down and down until the mucous membrane has become elongated into this long pedicle. The treatment will consist in simply snipping it off with a pair of scissors, at the tip of the uvula, as you will watch Dr. Jones, our chief of clinic, do for us. The uvula itself, you see, is somewhat elongated. Should it not retract sufficiently after being freed of its growth, say in a month or so, we will exsect a portion in your presence.

IV. MULTIPLE MYXOMA OF THE NOSE.

This is a case of myxoma of the nose. If you look in the nasal passages of this woman, you will see globular pale-reddish masses on either side, which, we judge, are nasal polypi. These are very troublesome cases. They are usually the result of what is known as catarrh. In some cases of chronic catarrh in the mucous membrane of the nose you will find on the surface polypoid thickenings which grow into tumors, varying in size from that of a grain of rice to that of a large oyster. These tumors are gelatinoid and technically termed myxomata. Usually they are pedunculated. Only rarely do you find but one; there are generally a number of them —sometimes twenty or more, and sometimes one extracts a large handful and wonders whence so many could have come. After you have removed the larger ones you will, as a rule, find a number of smaller ones in the neighborhood, and unless these, too, are removed they grow rapidly and give you an opportunity to operate again and again. The only method of curing the affection is by removal. Sometimes these growths project into the pharynx, whence they are removed by traction and torsion, after having been grasped in the bite of, forceps or caught in a snare. Occasionally they project from the nostril. It is considered barbarous to remove them with the forceps, but it is not barbarous if correctly done. The old-fashioned method was to take the forceps and put it in the nose without looking at the interior, and then to feel around with forceps until the growths are grasped. Sometimes the turbinated bone was caught. But if light is reflected into the nasal passage so that the polypi can be seen, and a pair of delicate forceps is passed upward until you get at the pedicle of the growth, after pressing and holding it tight for half a minute, a turn is given before traction is made, and the polypi will come away without causing a great deal of pain. You can bring the pain to a minimum by painting the parts to be attacked with a solution of cocain. The method to be adopted to-day will be to pass a snare through a canula, carry it up to the polyp, guide it as far as possible along the pedicle, and then tighten the snare; probably Dr. Jones. who is now operating in this manner without cocainization, will cut through the growth, but I prefer to twist the snare around just as I would the forceps, and to pull it away, a procedure that brings away a portion of the pedicle and also probably a portion of the mucous membrane from which it arises. If this is done there will be no recurrence. The parts are then to be cleansed of blood and you go on and on, so far as possible, attacking the remaining growths until you get away all that is possible. These tumors are hygroscopic and swell up during wet weather. If the pedicle from which you take the polyp is left, it is better to cauterize it so as to destroy the point of implantation. An electric cautery is the best, but if not this, silver nitrate, chromic acid, or any other cauterizing agent you are accustomed to using, will do.

There is a dirty method of destroying polypi which is often successful. I do not want you to resort to it unless you have no instruments, although it is a very simple one. It consists in the injection with a syringe, of the tincture of the chlorid of iron into the parts, as near as possible in the pedicle. The polyp drops off in a few days, and it is usually blown out of the nose by the patient. The iron makes more or less of a magma and you have some trouble getting rid of it. I find that injections of weak solutions of alcohol and distilled witch-hazel also tend to repress the disposition to reproduction of these growths.

Occasionally these polyps are found on the upper turbinated bone, occasionally on the lower turbinated, rarely upon the septum; but in the majority of cases they are found on the lower surface of the middle turbinated bone, so that you will be more likely to strike them there. Sometimes they are far back and then you have to operate through the mouth with the aid of the mirror. It is much better to perform operations in dry than in wet weather. While I have been talking Dr. Jones has removed three polypi, which I pass around; on one you see the pedicle and a portion of mucous membrane. That polyp will not recur.

V AND VI. LYMPHOID ENLARGEMENTS AT THE VAULT OF THE PHARYNX.

We have here two cases of lymphoid enlargement in the pharynx, or as they are commonly denominated, adenoid growths. When in the streets you will notice a great many children and some grown people presenting a peculiar facial expression, with the mouth open and the nose compressed. Being unable to breathe through the nose, they breathe through the mouth. This produces a dryness of the throat and more or less soreness. We find in these cases that the lymphoid tissue existing naturally in the vault of the pharynx is hypertrophied This lymphoid tissue is the same as that of the tonsils, the glands of Peyer in the intestine, and certain glands at the base of the tongue. When this structure is slightly inflamed and in a state of hypersecretion, masses of mucus trickle down over the pharynx, and we have the condition known as nasopharyngeal catarrh, which is often nothing else than chronic inflammation of the lymphoid tissue at the vault of the pharynx, the third tonsil as it is sometimes called, or Luschka's tonsil. This structure has been known for many years. The best preparations I have ever seen were made by the famous anatomist Hunter, more than one hundred and fifty years ago, and can be seen in his museum at Glasgow or Edinburgh, I forget which; but it is only recently that we have recognized the morbid condition to which I direct your attention. Sometimes the patients are unable to hear well, and have pain in the head. Sometimes they are unable to concentrate their attention on their work. Sometimes we have a general hypertrophy of this tissue and in the central portion a depression filled with mucus. There is another form in which there are vegetations, sometimes covering the posterior nares so as to interfere with breathing, or covering the orifices of the Eustachian tubes and interfer-

ing with hearing. When they are pressed upon by the fingers they feel like a mass of worms. There is no medical way of treating them. All patients with growths of this kind are much improved by giving them internally iron iodid, or hydrated calcium chlorid. At the same time these growths should be removed. This is best done with the forceps. Pass the instrument up behind the palate, open the blades, close them so as to seize the mass, turn and pull. Or you can use forceps with cutting edges and cut the growth away in mass or piecemeal, as will be done for you by Dr. Jones in another case now being etherized. In some instances, as we shall do here, the growths are felt for with the finger, and if they are soft they can be scraped away in a great measure by the finger during the examination, as it were. Sometimes these growths bleed very much when removed, and you must be careful as to the position of the patient. I am not in the habit of using a systemic anesthetic, no matter how young the children are, unless there be an extreme nervousness which cannot be overcome, and there be urgent need for hurry. In many cases I do not even have to use cocain. The patients assure me that I do not hurt them. The growths are not sensitive. The pain experienced in their removal is produced by the physician running his instrument up against the vault of the pharynx and scraping it in his movements, a procedure which is very painful. In hospital practice we cannot take the time to do things as cleverly and neatly as at home. You must remember that blood does not run up hill, and that therefore the head should be depressed lower than the shoulders. Should you operate after the method of my friend Dr. French, of Brooklyn, give ether, wrap the patient in a blanket, put him in a chair which is to be tilted backward, and have him held. Keep the mouth open with a mouth-distender. With a mirror, throw in the light, and then pass up the forceps, in the same manner as I do, without the resort to ether. Be careful that the blood does not run down the pharynx into the air-passages. If there is a great disposition to bleed, have the patient turned over sidewise, and see that the head is lower than the shoulders. In some cases we throw the head entirely back over the edge of the table, and in that way the blood runs out of the nose and mouth of the patient, and does not get into the windpipe. After-treatment is rarely required, but sometimes there is some secondary hemorrhage.

It is wonderful the amount of relief gained by these procedures. Stunted children will sometimes grow more in a year after their respiration has been relieved, than they formerly did in three or four years. I read an account a day or two ago in the *London Journal of Laryngology*, of a lad of seventeen who was but five feet three inches in height, and light in proportion, while his brothers were six feet in height and proportionately heavy. Some hypertrophied adenoid tissue was removed from the pharynx and his large tonsils excised by Mr. Jakins, who reports that two years afterward the patient was brought to him, being five feet ten inches in height and weighty in proportion. That was a marked case. I have told many times the parents of a miserable puny child that it would become so much improved in appearance in a short time that even distant members of the family would hardly recognize it if existing pharyngeal adenoids were removed, and in a few months the prediction was verified.

The causes of these growths are not known. I believe that they are usually congenital. Properly removed they never recur. The oldest cases operated on by me with cutting forceps occurred in 1870, in two sisters who have long since grown up, and when I heard from them a number of years ago there had been no recurrence. Other cases I have seen at intervals of ten and fifteen years or more after operation, and there has been no recurrence. In order to be sure that you have taken everything away you must, some time after the operation has been performed, examine the parts carefully with your finger and with the rhinoscopic mirror.

CLINICAL MEMORANDA.

A CYSTIC TUMOR OF THE BLADDER IN A STILLBORN CHILD.

BY W. L. RANSOM, M.D.,
OF ROCKFORD, ILLINOIS.

I WAS called at 4 A.M., August 24, 1893, to attend Mrs. B., in confinement at full term. She was a well-formed, healthy primipara, twenty-two years of age. Nothing had transpired to mar the normal progress of gestation as far as she knew, save a little fright produced by a flying squirrel during a visit in a neighboring city in the second month. The animal sprang upon her hand as it rested on her lap, startling her greatly. This incident, however, made no great impression on her mind and speedily passed away.

Premonitory pains began at midnight and parturition progressed favorably and rapidly, notwithstanding the absence of amniotic fluid. The birth of the child, a female, was completed at 6 A.M., two hours after my arrival.

Motion had been felt distinctly up to the last month of pregnancy, the mother said, but had become less and less noticeable during the last four weeks.

After the head had been expelled there seemed to be an obstruction of some sort preventing the exit of the remainder of the body, and considerable force was required to extract it, the perineum being considerably and unavoidably lacerated.

The funis was about the neck of the child, but when released she made no cry; nor, indeed, was there any indication of attempted respiration.

As long as the cord continued to pulsate, efforts were made to initiate the respiratory act. These were continued for about half an hour without the slightest result or impression. The child never breathed or seemed to make any effort to breathe, as though this power were absent entirely.

In the hypogastric region I noticed a tense, elastic protuberance of considerable dimensions, which must have been the cause of the difficulty experienced in the final stage of delivery, and I was forced to conclude that this tumor had to do with my failure to induce respiration.

The funis having ceased to pulsate, I separated the little one from its mother and proceeded to make a thorough examination of the body. The child seemed to be fully developed and well formed, weighing nine

pounds. There was a deformity of the right ear, the pinna having a peculiar backward-pointed form, as though a point in the upper third of its posterior margin had been forcibly drawn backward, giving rise to a lancinate appearance of this appendage.

As already mentioned, the hypogastric region was greatly distended by an elastic tumor which seemed to fill all of the abdominal space between the sternum and the pelvis, but was especially prominent and projecting in its median line near the umbilicus.

My first incision extended from the pubic region to the sternum, directly over the most prominent portion of the tumor. On opening the peritoneum I found that nearly the whole abdominal cavity was occupied by a multilocular cystic tumor. It seemed to spring from the pelvis, to which it was firmly attached by means of three large firm processes of fibrous tissue, which severally continued beyond or through the pelvis to the inner aspect of both femora and to the front of the pelvis, forming in these locations considerable tumors.

The abdominal tumor was fully as large as the child's head. By its anterior aspect it was firmly adherent to the mesial line of the abdominal wall; in all other directions it was non-adherent, save at its point of origin in the pelvis.

It consisted of one small and three large cysts in one structure, but not communicating with each other. The small cyst was about the size of a hickory-nut, had thin fragile walls, and was filled with a creamy fluid. The large cysts had thick and tough walls and were distended with liquid, a portion of which resembled clear, and the rest turbid, urine.

On further inspection the left kidney was seen to be as much as ten times larger than the normal one on the right side. The pelvis and its calices were correspondingly dilated. The ureter was at first glance mistaken for the descending colon, such was its size; passing from the kidney it terminated in the posterior wall of the most inferior of the three large cysts. From this and from the appearance of the contents of the cysts, I concluded that this interesting tumor must have been of vesical origin. The descending colon and the rectum were nowhere constricted; meconium was observed to pass shortly after delivery.

The external genitalia (those of a female) were normal in size, position, and general appearance. The external orifice of the urethra was patulous, but a short distance within the passage was occluded, apparently from the external pressure of the extraneous tissue belonging to the tumor. The urethra was not impervious, for a probe could, by gentle force, be made to insinuate its way past the constriction into the lowermost of the three compartments of which the tumor was composed. The urethra was, however, practically a closed passage, the constricting fibers of this growth being sufficiently rigid to prevent the evacuation of the contents of the tensely distended bladder.

No vestige of the internal organs of generation was found.

Passing to the liver, I found it also to be of unnatural size, pushing its way above the tumor far up into the thoracic cavity.

Extending my incision upward along the left side of the sternum to the clavicle, I found the heart also to be greatly enlarged, but there was no lung-structure to be found in the thorax, save minute strips of lung-colored tissue packed away in the uppermost recesses under the clavicles. I no longer wondered at my futile efforts to induce respiration. The tumor, liver, and heart had crowded up and prevented the development of the less resistant lung-structure.

TOXIC SYMPTOMS FROM SEIDLITZ POWDERS.

By J. S. TRIPLETT, M.D.,
of Harrisonville, Mo.

Not long ago I called upon a physician who was convalescing from an attack of malaria, and while in conversation he related an attack of severe vomiting and retching and depressing after-effects following the ingestion of a Seidlitz powder. The depression was so marked that he feared a fatal termination, and medical aid was summoned. Emesis was provoked by titillating the fauces with the finger, when severe vomiting and retching ensued for some time, after which the functions gradually but slowly became normal. The powders were not thought of as having been the cause of the trouble, although the man said that they tasted differently from any he had previously taken.

In the same house was a young man, a relative of the physician, who was also sick and was ordered a Seidlitz powder, but took only half of the powder in solution. In ten minutes violent vomiting and retching set in, with cramps in the stomach and a burning sensation in the esophagus, together with a feeling of general depression. This man was able to go about his business in a few days.

Two or three days later, at night, I was called to see A. D. R., about thirty years old. I responded at once, and found the patient in bed, vomiting and retching at intervals of eight or ten minutes, with moist skin, slow and weakened cardiac action, and as he expressed it, "so sick he did not know what to do." Nausea was very marked. The femoral adductors were cramped, and the man spoke of a repeated desire to defecate. The voice was somewhat subdued. The result of my examination did not account for his condition, and I set about getting more facts. On inquiry, I learned that the man had been feeling badly all of the afternoon, and on returning from his work got a Seidlitz powder, ate supper, and then, at about 8 P.M., took the powder, with the results related.

Remembering the other two cases, my diagnosis was now clear. The next morning I went to the drug-store from which the powder was obtained, and, on inquiry, found that the powders taken by the physician and the young man were also purchased at this store. I related the cases to the druggist; he could not account for the symptoms, as he said that he had compounded the powders according to the U. S. P.

The blue paper was obtained from a printing-office, and he thought that possibly the untoward effects were due to arsenic in the paper. I obtained one of the powders for qualitative analysis, and on passing H_2S gas, generated in Marsh's apparatus, through the contents of the blue paper, dissolved in four ounces of pure water, a heavy, orange-colored precipitate of Sb_2S_3 (antimonious sulphid) was thrown down. The presence of so much

antimony explained the alarming symptoms in the three persons who took the powders.

In all probability the mistake was made in compounding the powders, antimoni-potassic tartrate being used instead of potassium bitartrate.

MEDICAL PROGRESS.

The Importance of Early Attention to the Disability Caused by Infantile Paralysis.—At a recent meeting of the New York Academy of Medicine DR. A. B. JUDSON raised the question whether patients disabled by infantile paralysis should not be submitted more entirely and more early to orthopedic treatment. After the child has passed through the stage of onset, and ergot, electricity, and massage have produced their legitimate effects, after the lapse of perhaps eighteen months, the remaining deformity is often found upon analysis to be rather a disability. For example, in a case in which the knee cannot be completely extended there is no deformity when the patient is sitting, but when he stands up the apparent deformity is due to an inability to extend the knee. It would have been easy to have prevented contraction of the hamstrings by providing for their repeated elongation by complete extension of the knee. Cases sometimes occur in which shortening of the tendons begins, in a manner not well understood, at a very early stage, before simple desuetude can be fairly charged with being the cause of the mischief. Thus it is that the prevention of muscular and tendinous shortening should receive attention on the part of the early observer of the case. Thus if the knee is kept extended when walking is attempted, not only are the muscles and tendons kept in normal elongation, but the general welfare of the limb is assured. If the knee is stiffened mechanically the pressure of the weight of the body in standing and the repeated concussion of the limb as the foot strikes the ground in walking and running will improve the tardy circulation; but beyond this, and better than this, will be the development of unused muscular fibers and special groups of muscles, by whose action important motions will be acquired which would have been impossible if the limb had remained in suspension. In order to keep the knee firmly extended under the weight of the body in standing and walking, and to give use and development, as far as may be, to the fragmentary muscular system of the limb, suitable apparatus is required. A good general rule in the treatment of deformity in a growing child is to keep the part as nearly as possible in the desired shape as much of the time, day and night, as is practicable, so that the increment shall be on the right side of the dividing line between the normal and abnormal. Not only should the part be kept in as nearly the normal shape as possible, but it should also be given as wide play to the functions of motion and weight-bearing as the crippled condition of the limb will allow. From the very earliest attempt to walk or to make use of the muscles and joints which are imperilled by the cord-lesion, extraneous assistance should be afforded. It should not be said, off-hand, that the child is too young. The first and repeated question should be: Is the child not yet old enough, or is he not already giving sufficient evidence of a desire to make use of the questionable muscles and joints to make assistance desirable or necessary? When efficient treatment is begun it is easily continued. The process is slow and prosaic, but the benefit cannot be overestimated.

Intra-intestinal Injections of Hot Water for the Relief of Shock, Particularly from Hemorrhage.—RUTHERFORD (*Rhode Island Medical Monthly*, vol. i, No. 9, p. 458) has reported the case of a boy, nine years old, who was accidentally shot in the thigh. There was not much bleeding from the wound, but the leg soon became badly swollen and discolored. Examination showed that the swelling and discoloration arose from an extravasation of blood into the tissues, and it was decided to cut down upon and tie the bleeding vessel (the femoral artery), as the almost bloodless condition of the boy forbade the performance of amputation. In the course of the anesthetization the pulse began to grow weaker, and doubts were felt as to the possibility of proceeding with the operation. In the hope of stimulating the patient a quart of hot water containing a small quantity of salt was pumped into the rectum by means of a catheter introduced deeply and connected with a Davidson's syringe. The pulse at once grew stronger and the skin assumed a more healthy appearance. The pulse again weakening after the lapse of fifteen minutes, two quarts of hot saline solution were injected into the rectum, the tube being introduced for a distance of seventeen inches. The presence of the fluid in the bowel caused an appreciable fulness of the abdomen, which rapidly subsided as the fluid was absorbed. Toward the completion of the operation an injection of two quarts of water had again to be made, the tube being introduced for a distance of twenty-three inches. The pulse now became strong, and the patient presented a better appearance than at the beginning of the operation. He lived for fourteen days, ultimately dying from septic infection and exhaustion consequent upon gangrene.

Intra-uterine Infection of the Fetus with Enteric Fever.—JANISZEWSKI (*Münchener medicinische Wochenschrift*, 1893, No. 38, p. 706) has reported the case of a woman, thirty-five years old, who aborted in the third week of an attack of enteric fever in the eighth month of pregnancy. The child died in the course of five days, and upon post-mortem examination numerous consolidated areas about as large as hazel-nuts were found in both lungs, together with slight enlargement of the spleen. The connective tissue in the neighborhood of the esophagus presented several hemorrhagic infiltrations. The remaining organs displayed no appreciable lesion. Inoculations of culture-media with sections of tissue from lungs, spleen, kidneys, a mesenteric gland, and a portion of the ileum near the ileo-cecal valve, all resulted in the development of organisms that corresponded in size and form with the typhoid-bacillus of Ehrlich, and which presented characteristic appearances by further cultivation upon various nutrient media.

Traumatic Rupture of the Heart.—O'BRIEN (*British Medical Journal*, No. 1711, p. 843) has reported the case of a woman who fell from the side of a ship a distance of eight feet into the water, coming into contact with the propeller of the vessel, which was in motion. Removed from the

water and conveyed to a hospital, life was found extinct. The face was blanched, and the general bloodless appearance of the body suggested death from internal hemorrhage. In the left pectoral region was a patch of ecchymosis, with a transverse fracture of the sternum at a point midway between its articulation with the fourth and fifth costal cartilages. On more careful examination the gladiolus was found to be fractured, the pericardium lacerated, and the heart ruptured through both ventricles.

THERAPEUTIC NOTES.

Malakin is the name of a new synthetic product of the laboratory for which anti-rheumatic, antipyretic, and anti-neuralgic virtues are claimed, without the dangerous secondary effects that have been observed to attend the use of some of the other drugs of the same class. The product is allied to phenacetin, being the salicyl-derivative of paraphenetidin, and may be designated salicyl-phenetidin. It appears in the form of small, light-yellow, fine needles that melt at a temperature of 197.6° F. It is insoluble in water, with difficulty soluble in cold alcohol, but fairly soluble in hot alcohol. It is insoluble in alkaline carbonates, but dissolves with a yellow color in sodic hydrate, forming a sodium-combination. Dilute mineral acids decompose the body, with the formation of salicyl-aldehyde and paraphenetidin. Experiments upon animals demonstrated not only that the drug exerts no depressant effect upon the heart and the circulation, but also that it has an antipyretic action. The drug was next tried in fourteen cases of acute rheumatism, including a number of severe cases, and in every instance with good results. It was given in doses of from 60 to 90 grains daily. The drug was administered in 48 febrile cases, including 13 of enteric fever, 7 of croupous pneumonia, 19 of various types of tuberculosis, 7 of erysipelas, and 2 of scarlatina. In several cases the temperature was not notably influenced. In the majority the decline was gradual and not excessive, and unattended with sweating. The drug acted well in 12 cases of neuralgia and headache. The following conclusions have been reached: 1. Malakin is an agreeable and certain remedy in the treatment of acute articular rheumatism, and has the advantage of being free from unpleasant secondary effects; so that it may be advantageously substituted for salicyl-preparations in susceptible patients (women and children), and in cases in which there is an idiosyncrasy to salicylic acid. 2. The drug acts slowly and gently as an antipyretic, without giving rise to alarming symptoms, so that it may well be administered to debilitated patients and to those with impaired or defective circulation. 3. It may be given for a long time without injury in cases of neuralgia and habitual headache.

Parenchymatous Injections of Salicylic Acid for Inoperable Carcinoma Uteri.—Having been struck by the peculiar affinity of salicylic acid for epithelial cells, BERNHART (*Centralblatt für Gynäkologie*, 1893, No. 39, p. 900) was induced to employ the drug in cases of inoperable carcinoma of the uterus. He used a 6 per cent. solution of the acid in 60 per cent. alcohol. A special form of syringe was employed, with a curved hollow needle of small caliber. Not more than half a dram was injected at every sitting, a few drops being introduced in from seven to ten different places. The sittings were repeated at intervals of three or four days. The results were rather encouraging, notable retraction taking place at the site of injection, while after a number of injections had been made a favorable influence upon the amount and odor of the discharge, upon the pain, and upon the hemorrhage was observed. When ulceration existed cicatrization was stimulated. In some patients the injection caused a certain amount of transient pain, and in some it was followed by slight elevation of temperature.

For Gonorrheal Vaginitis.—The vagina is first cleansed with cotton, then irrigated with a 1 : 1000 solution of mercuric chlorid, and the vaginal vault is packed with tampons saturated with the following solution:

℞.—Potassic hydrate	0.20
Methylene-blue	10.
Alcohol	15.
Distilled water	200.—M.

The vagina is then filled with dry tampons. After two days the packing is removed, and the vagina is irrigated with a 1 : 1000 mercurial solution. Two glycerin tampons are now introduced, and replaced by fresh ones a day afterward. The treatment is completed by irrigations and dry tampons continued for another week.—D'AULNAY, *Bull. Gén. de Thér.*, No. 18; *Wiener med. Presse*, No. 39.

For Pernio.—

℞.—Zinci oxidi crud.	15.
tere exactissime direct. cum	
Glycerini	45.
adde	
Lanolini	40.—M.
Ft. ung.	

S.—Apply nightly. An application can be made also by day, the excess being removed with a cloth.—STERN, *Ther. Monatsh.*, No. 8; *Wiener med. Presse*, No. 36.

Large Doses of Oil for Lead-colic.—From a small series of observations, COMBEMALE (*Gaz. Méd. de Paris*, 1893, No. 38, p. 447) concludes that given in doses of about six ounces at a time, olive oil acts as a deobstruent and sedative in cases of saturnine colic. In order that such quantities be retained, the sensibility of the stomach should be obtunded by the previous administration of cocain, menthol, or other local anesthetic. Given daily in a dose of two ounces the oil causes subsidence of the nervous symptoms.

For the Night-sweats of Pulmonary Tuberculosis.—

℞.—Acid. salicylic.	ʒjss.
Glycerin.	fʒiij.
Alcohol.	fʒiv.
Aquæ destil.	fʒj.—M.

S.—Thirty drops hypodermatically at bedtime, four or five nights in succession.—BERNHEIM, *Sem. Méd.*, No. 38; *Prager med. Wochenschr.*, No. 37.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

CHILDREN OF THE STATE.

THE expense of the care of the defective classes is becoming enormous and burdensome. The criminals in the United States, while in prisons and reformatories, cost fifteen millions of dollars a year. The other defectives cost a sum not possible to calculate, though we may safely say that it is very large. From no other class of society are the defectives recruited in such large numbers as from "the children of the street." These neglected products of modern civilization are from necessity petty thieves, beggars, and sympathy-mongers. They graduate into every class of vice and crime, and, at the best, become a serious menace to the physical, mental, moral, and commercial interests of society.

Sentimentalism, religious enthusiasm, and pseudo-charity have perpetuated the monastic idea in the orphanage. Children have been and are huddled together in cities and towns, and supported, washed, fed, and drilled, doctored, and amused, with a mortality of 200 or 300 per 1000 a year, all in the name of charity. The children that have once tasted liberty prefer the drygoods box to the white-counterpaned bed and its attendant institutional life. They prefer gutter life and freedom, to clean clothes, baths, steam-heated rooms, balls, bats, and croquet, inside stone walls, even though garnished with a half-week of well-supervised and orderly maneuvers under trees, by the side of rivers and brooks, in a strange, clear light and air. The dreadful death-rate in these orphanages, the loss by runaways, and the loss of incorrigibles sent back to the street, make altogether a pitiable showing.

From this extravagant and heart-rending picture we turn to Australia for hope—a continent without an orphanage—a country without an orphan. The good work of two women, in a rational and plastic state, has found a home and parents for every orphan. Each waif is taken to a receiving home, where it is cared for until a country home is found. The local volunteer societies canvass their neighborhoods, and send to the central *Children's Committee of the Destitute Board* the names and circumstances of such families as they have found where children may be placed. The children's committee selects that home which it judges best adapted to the development and care of the child in question. The foster-parents receive a stated sum each week for the care of the child and for proper clothing. This sum averages $1.25 per week. No child is placed in a family that is too poor. In such families the child might suffer hardship. When of school age the child must be in school. The schoolmaster makes a quarterly report to the children's committee of the attendance and general condition of all children of the State. The schools of Australia have no long vacations. The police-officer visits the child at definite intervals. The local volunteer committee looks after its care and culture, and jealous neighbors often lend a hand in watching the growth and education of these happy children, and reporting their findings to the children's committee in anonymous letters. The village health-officer also reports on any sickness he is called upon to treat, and an inspector of the committee visits every child twice a year.

When the child is fourteen years old he begins to work, usually on the farm on which he has before lived. His earnings are placed in the Postal Savings Bank, and at seventeen or eighteen he goes out into the world for himself, an independent man. The State, at an expense of less than seventy dollars a year, has raised a man or woman to contribute to its aggregate wealth, and prevented the manufacture of a criminal, the subsequent ravages of his art, and the expense of court, prison, and reformatory for him and his pupils. The hysterical activities of the charity-mongeresses have incidentally been

avoided, and their energies diverted to occupations less destructive to life.

When a mother, with the help of a half-ration from the Destitute Board, can keep her child and a roof over her head, disregarding the bugbear of out-door relief so potent with us, this ration is granted. When she has two children, one ration is given, and a ration and a half for three, and so on. Babies are placed out where they are cared for by experienced country mothers, and only one or two in a place. The foster-mother is paid more for its care during the first nine months of infant life than afterward. Old people are cared for in the same humane manner, and our Southern continental civilization is not disgraced by institutions in which old people are huddled together in lifeless and childless prisons to wait for death.

It may seem strange that Australia, Tasmania, and New Zealand have so far outstripped us in this humane, charitable, and economic work of child-saving and the prevention of disease. In our cities the slaughter of children in "institutions" still goes on, the growth of our defective and criminal class still increases, the calls upon the thrifty and humane still grow importunate, but we are unwilling to learn. It were better to recognize at once that as civilization advances the functions of the State must advance into new fields. The care of the children can no longer be left to the church and the street. As society represented by the State must protect itself against enemies from without, so it must protect itself from the greater enemy that it is suckling within. It is unnecessary to point to the influence upon general morality which the daily observation of the life of the children of the street exerts upon the more fortunate. This depressed moral tone makes our political corruption possible. Hope lies not in restricting, but in extending political activity.

Two women, MISS CLARK and MISS CATHERINE SPENCE, destroyed the orphan-asylums of Australasia, robbed the continent of its orphans, and saved these colonies from a horde of criminals and dependents. Some good man or woman must raze every orphan-asylum and "home" in the United States to the ground. We have outlived them. We are too thrifty to keep them longer, pretending to perform a function they cannot fill.

The Children's Aid Society of Philadelphia has begun in the right way. Help it to extend its aid to all the waifs of Pennsylvania.

This is a proper work for the physician, and through the activity of our profession in preventing and curing the diseases of the State, we may hope that the standing, reputation, and good name of the doctor will be restored and properly honored.

MEDICINE AND STATE RIGHTS.

THE question of State rights is about as *living* to-day as ever in the history of this country. It comprehends, along with other things of divers complexions, the care of the general health. A suggestion of the complications that may arise in connection with this subject was furnished not many months ago in the East when an invasion of cholera was threatened. Within the past year there have been a number of adjudications on the authority of States to regulate the admission of articles of food. Now there comes a decision from the United States Circuit Court, W. D. Michigan, in the case of the M., St. P. and S. S. M. Ry. Co. *vs.* Milner, just reported (57 Fed. Rep., 276), of no little interest, touching upon State quarantine. The railway company brought suit to restrain the Michigan State Board of Health from enforcing the State Quarantine regulations, on the ground that the board was daily detaining and attempting to detain passengers on the Canadian Pacific Railway, with which it had a traffic arrangement, and prohibiting their entering the State until they had undergone the quarantine detention, and until the disinfection of their baggage. It was also complained of that this detention, examination, and process of disinfection of baggage was applied to all emigrants, irrespective of whether they came from an infected or healthy locality abroad, and without regard to their point of destination, and notwithstanding the fact that all of such emigrants and travellers had been, before such detention, inspected by United States officials detailed for the purpose. The rules and action of the Board of Health, it was contended, were in direct violation of the Constitution of the United States, in that they attempted to regulate and prohibit commerce with foreign nations, and were likewise in violation of an existing treaty between the United States and Norway and Sweden. The court, however, overruled the motion for a preliminary injunction, justifying its action by the application of established decisions. CHIEF-JUSTICE MARSHALL, one of the most distinguished jurists ever on the Supreme bench, recognized, it said, that the removal or destruction of infectious or

unsound articles was undoubtedly an exercise of the police power of the State, and an exception to the prohibition resulting from the exclusive power of Congress to regulate the operations of foreign and inter-State commerce, and that laws of the United States expressly sanction the health-laws of the several States. And Chief-Justice Taney expressly declared that "It must be remembered that disease, pestilence, and pauperism are not subjects of commerce, although sometimes among the attendant evils. They are not things to be regulated and trafficked in, but to be prevented as far as human foresight or human means can guard against them."

Both of these decisions have since been referred to with approval by the Supreme Court itself, in a case in which the distinction is drawn with great clearness and force between the exercise of its police power by a State and an attempt to legislate upon matters of inter-State or foreign commerce, which are exclusively within the power of the Federal Government. Moreover, attention was called to the fact that the Quarantine Act of Congress, approved February 15, 1893, expressly recognizes the validity of State laws, and in Section 3 requires the Supervising Surgeon-General of the Marine-Hospital Service to coöperate with and aid State and municipal boards of health in the execution and enforcement of their rules and regulations. Nor could the Court find anything in any existing treaty with Norway and Sweden in conflict with the institution or enforcement by any one or more of the States of this Union of quarantine-regulations. To the objection that passengers from non-infected countries and localities were detained, the answer was made that such detentions were, in the nature of the case, to a certain extent unavoidable; and passengers from such countries and localities might have become properly subject to detention by reason of having mingled with others who could communicate pestilence or disease to which they themselves had been exposed or subjected. An opportunity for examination and inspection was indispensable also. The objection that passengers who had certificates from United States inspectors were detained was also held not tenable. The States may exercise their police power according to their own discretion, and by means of their own officials and methods. The inconvenience resulting to emigrants and travellers from being halted and subjected to examination and detention at State lines is of trifling importance at a time when every effort is required, and is being put forth, to prevent the introduction and spread of pestilential and communicable diseases. Lastly, it was held that the costs and charges which were incurred in such quarantine-inspection might lawfully be imposed on the railway company as being incident to the business in which it is engaged.

SUCCESSFUL CELIOTOMY FOR PERFORATED GASTRIC ULCER.

It is evident that the possibilities of antiseptic surgery have not been exhausted. To the numerous life-saving operations born of the present surgical era is to be added that of abdominal section in the treatment of perforation of the stomach secondary to ulceration. In spite of a certain amount of indiscriminate and perhaps unnecessary operation, there can be no question that many lives have been saved and much suffering averted by reason of the comparative safety and facility with which abdominal section can be performed if aseptic and antiseptic methods are followed. There are already on record a few cases of perforation of the bowel in the course of enteric fever in which life has been saved by promptly opening the abdomen, closing the rent in the bowel, and cleansing the peritoneal cavity.[1]

Another step in the same direction has recently been made, in that Barling (*Birmingham Medical Review*, vol. xxxiv, No. 181, p. 129) reports the successful treatment by celiotomy of a case of gastric ulcer with perforation and peritonitis. The same treatment had been previously pursued in two other cases, but with an unfavorable outcome.

The first case was one of latent gastric ulcer in a girl, twenty-two years old, presenting symptoms of peritonitis, in which the abdomen was opened six hours after the onset of the acute manifestations. The source of perforation could not be found at the operation, and death took place twenty-four hours afterward. Upon post-mortem examination, a perforating gastric ulcer was found on the anterior wall of the stomach, rather nearer the cardiac than the pyloric extremity.

The second case occurred in a girl, twenty years old, with a previous history of gastric ulcer. Symptoms of peritonitis developing abruptly, the possibility of perforation was considered, and the

[1] See Weller van Hook, The Medical News, November 21, 1891, p. 591.

abdomen was opened. At about the middle of the anterior wall of the stomach an opening, with indurated margins, was found. Five Lembert sutures were introduced with a good deal of difficulty, and the abdomen was flushed and closed and drainage provided for. Death took place thirty hours after the operation. Upon post-mortem examination, well-marked peritonitis was found, especially in and around the portal fissures, and about a pint of thin purulent fluid escaped from the cavity of the abdomen and pelvis. The perforation on the anterior wall of the stomach was effectively closed by the sutures, and adhesions had formed between the opposed peritoneal margins. A second ulcer, which had almost perforated, was found on the posterior wall.

The third case occurred in a domestic, twenty-nine years old, who was seized with abdominal pains, faintness, and vomiting. She had previously suffered from epigastric pain and vomiting, though there had never been hematemesis or melena. The acute symptoms had set in a day after the ingestion of a heavy meal, with a feeling as of something having given way within the abdominal cavity. Indications of peritonitis soon appeared, and a provisional diagnosis of perforation of a gastric ulcer was made. Under appropriate treatment the girl did fairly well for a number of days until pain was complained of in the left hypochondriac and lumbar regions, soon followed by the appearance of a swelling in the left hypochondrium. Under further treatment the symptoms again receded for a time, when, the condition of the patient appearing precarious, it was decided to perform abdominal section. An incision was made over the swelling in the hypochondrium and a small abscess-cavity found behind the stomach and evacuated. The patient doing badly after the operation had been in progress for about ten minutes, a drainage-tube was introduced into the abdominal cavity and the wound was speedily closed. Rather contrary to expectation, the girl did well. The progress of the case was complicated by the successive development of phlebitis in both legs, but recovery ultimately ensued.

Such a result as this, in connection with a condition that under any other plan of treatment is almost certain to be fatal, is, to say the least, encouraging, and adds new laurels to the credit of modern surgery and modern surgical methods. The wisdom of first passing a drainage-tube into the stomach through the orifice of perforation and evacuating any fluid present is pointed out, and considerable importance is attached to the employment of two tubes for drainage, the one placed *in situ* close to the perforation, the other introduced into the abdomen just above the pubes.

EDITORIAL COMMENTS.

The "Substitutor" and the Testimonial-writer. — A widely-spread advertising circular of a proprietary drug-preparation presents a picture of the substitutor cheating the father of a dying child. The father comes asking for the advertised cure-all. The substitutor is a drug-clerk with devilish leer, satyr ears, and mephistophelean horns. The legend given therewith is as follows:

We present on the opposite page a photograph of a modern nuisance of the vampire order. The smile on his infectious and brazen face poisons the very atmosphere as does the hated lupus tree, and his presence is the *shadow* of *death*. Unfortunately for the sick and the dying, this incarnation of evil lurks in drug-stores of doubtful reputation, and practises his arts and wiles upon his innocent and unsuspecting customers. In the picture before you a father has come in haste for a special remedy for his sick child. The mother, whose soul is filled with anxiety, is impatiently waiting his return with the medicine for her precious darling. The substitutor replies that he is out of it, but has something "just as good or better."

The parent hesitates, time flies, he is over-persuaded, he grasps at the substitutor's nostrum, and the chances are that the little one is doomed. The vampire substitutor lives upon the death of his victims. Is there any abyss too deep, any punishment too severe for the miscreant who will thus trifle with human life and love for the smallest gain? Room for the leper, room.

The literary and ethical excellencies of this remarkable product of the professional advertisement-writer are on the same level. If the substitutor's face is infectious, why doesn't the poor dupe catch the disease (of scoundrelism), and in the interests of dermatology we would like some further information about the "hated lupus tree."

But the laughter excited by this execrable stupidity is quickly transformed to disgust and indignation when it is remembered that not even the mephistophelean substitutor would ply his "vampire's" trade on the poor father if the poor father had only brought a physician's prescription. Would the sensible father of a dying child go to a drug-store for a "special remedy," or would he go to a physician? The advertiser's pamphlet is equal to the emergency—but only by implication, its most prominent claim being the published "testimonials of six thousand well-known physicians." Among these we notice two presidents of the American Medical Association, surgeon-generals, professors and professors, and professors, doctors galore, and fellows with as many as thirteen alphabetic titular tin-kettles to their tails, "M.R.C.S.I., L.R.C.P.I., L.S.A.," etc., world without end. Amen!

The Doctor in Politics.—It seems that in Buffalo, N. Y., things have reached such a pass, or such an *impasse*, that indignation has broken down the confines of

"schools" of medicine, broken down party-lines, and even broken down the natural disinclination of physicians to confine themselves to professional matters so far as public action goes. A despatch reads:

Both schools of medicine were represented at a meeting of the most prominent physicians in the city at the Academy of Medicine last night in the interest of good government. After speeches denouncing machine election-methods in this city, the doctors, with one or two exceptions, agreed to do everything in their power to influence their patients in behalf of good government, and adopted emphatic anti-machine resolutions. Still more unusual was this final resolution: "*Resolved*, That in so far as is compatible with our professional obligations we offer our services as watchers at the polls."

In Ohio the physicians, led by the noble enthusiasm of Dr. Culbertson and the *Lancet-Clinic*, are aroused and have gotten pledges from many of the candidates that they will, if elected, support the attempt to get a Medical Practice act passed by the Legislature. In no civilized country has the medical profession been so insulted and outraged by the hordes of quacks as in the past years in Ohio. We hope an end has been begun.

The Medical-belt Humbug in England was doing a thriving business. Owing to the usual complete control of the newspaper press by the quacks, through the bribery of the advertising department, it is a marvel that the *Pall Mall Gazette* should have taken up the exposure of the wretched fraud. But it did so, and was, of course, promptly sued for libel. But the humbug collapsed rather than meet the exposure of its affairs in court.

The shamelessness of the manager is shown by the fact that while steps were actually being taken to wind the company up, and after he himself had resigned the managership, he wrote to the newspapers proposing a medical commission to examine the company's patents and methods. This proposal was naturally scouted as absurd, as if he did not fear medical or scientific opinion, he could find ample opportunity of proving the efficacy of his belts, etc., by suing the *Pall Mall Gazette*, which openly courted an action for libel.

If there were but a single honest newspaper in the United States, what a field would be open to it! Every one of them is bribed or intimidated.

Lathyrism is the name given by Surgeon-Captain HENDLEY (*Indian Medical Gazette*, September, 1893, p. 300) to a peculiar form of paraplegia, observed only in males, and traceable to the employment of "teòra" or "khasari dâl" (lathyrus sativus) as the sole article of diet. The essential symptoms were weakness of the lower extremities, with tremor and stiffness, exaggeration of the knee-jerks and ankle-clonus. The health was otherwise preserved. Inquiry disclosed the fact that, the ordinary food-crops having failed, the affected community was compelled to subsist almost entirely upon "teòra." It was generally known that large indulgence in the grain for long periods was likely to induce weakness of the legs, and it was said that a similar outbreak had occurred some sixteen years previously. It was also believed that cattle are sometimes affected. An additional interesting fact is that a good deal of the grain had been blackened and diseased by rain. The opinion is expressed that the disease is a form of multiple sclerosis, perhaps in some way related to the exclusive diet of teòra.

The Cost of Carelessness.—On July 31st a vessel, the *Carlo Rizii*, sailed from Naples, bound for Buenos Ayres, South America, with 1400 emigrants aboard. No care had been taken or sanitary examination made as regards the health of these people sailing from a cholera-infected port, and the disease broke out on the ship. The vessel was not allowed to land her contagion-laden cargo, and had to return to Naples again, when it was found that 240 passengers had died of cholera. Another vessel, the *Remo*, had a similar history, with 147 deaths. These 387 deaths are, therefore, to be charged to the criminal carelessness of the officials who allowed the disgraceful embarcation. The people of Buenos Ayres were not cruel. They had learned their lesson from the bitter experience of a few years previous, when the admission of one or two infected ships from the same port cost the people of South America 40,000 lives.

He Instructs the Public in the Name of Medicine.—The climax is reached when "Leslie E. Keeley, M.D." (the "LL.D." is strangely omitted!), through the columns of the New York *Sun* (*par nobile fratrum!*) reviews the history and progress of medicine, discussing seriously the cause of disease and the contributions of science to pathology. The moral of it all is that the profession has always and without exception at first denied and persistently fought every medical discovery finally forced upon it by the intellectual giants of therapeutics. One would like to ask the shrewd proprietors of the *Sun*: 1. How much they received for the two-column advertisement inserted as genuine reading-matter? 2. If not paid for as an advertisement, why they give two columns of their space gratis to one advertiser and charge such a high price for two columns to another advertiser?

Effect of Use of Liquor on Damages Recoverable for Personal Injuries.—The acts of a person suing to recover damages for personal injuries tending to enhance the injury are admissible in evidence to reduce the amount of the damages under the general issue, whether considered as in mitigation or, as a rule, of limitation of damages, says the Supreme Court of Missouri, in the case of Boggess *vs.* Metropolitan Street Railway Company just reported (23 S. W. Rep. 159), and therefore it holds it competent in such an action for the defendant to show that the injury was enhanced by the continued use of intoxicating liquors.

Professor Roswell Park.—Last week we published a selection from our excellent contemporary, the *Boston Medical and Surgical Journal*, bearing on the fatal accidents that frequently occur to physicians as a result of their unselfish devotion to professional duty. As the words were being printed an eminent member of our guild, whom we all delight to honor, Dr. Park, of Buffalo, was most dangerously ill with diphtheria, derived from a patient in the performance of the operation of intubation. We are happy to be able to state that, according to latest advices, Dr. Park is convalescent.

SELECTIONS.

STATE EXAMINATION FOR LICENSE TO PRACTISE MEDICINE.

WE have before us a copy of the law passed by the Pennsylvania Legislature, regulating the practice of medicine in that State. The act is largely modeled after our own State law, but contains some features which we fear may prove a stumbling-block, because of the non-existence of a board of educational control, such as is our State Board of Regents. A medical council, composed largely of State officers, will be the governing body, who are to supervise the examinations, both academic and professional. And just here is where the trouble is likely to arise. If the work of this council is to be rendered effective, the standing of every educational institution in this country, and the regulations governing foreign schools of learning, must become a part of its office files. The appropriation of moneys for all the purposes of the law is but one thousand dollars per year, which sum includes the salary of the secretary and treasurer. The law is to go into effect March 1, 1894, and if those interested are wise they will ask the regents at Albany to place at the disposal of the Pennsylvania Medical Council the records, accumulated during the past one hundred years, which show the institutions whose certificates indicate the completion of a "competent common school education," and also the rating of the many medical colleges in as well as out of the country.

As in this State, there are to be three boards of examiners, representing the three incorporated systems of medicine. In almost every other particular the law follows closely the lines adopted in our State, and many pitfalls will be avoided if the newly-appointed examiners were to make a practical inspection of the workings of the law in New York. If the same harmony which marks the operation of the law in this State obtains in Pennsylvania, we predict great and lasting results as the outcome of this latest step in the advancement of medical science.

Two years have rolled by since the law empowering the State *alone* to grant license for medical practice has been in operation in New York, and the promises of the advocates of the measure have been more than fulfilled. The situation, fumed at by charlatan, fretted over by frightened student, and fought against by some college professors, has now become a matter of fact, and we hear of no one other than the barnacle that fattens in the absence of restraining influences, who is willing to return to the old order of things which existed for so many years. It is safe to say that in less than ten years the distinctions, now barely understood, or for the most part very much misunderstood, by the laity, which in medicine, as in all science, recognizes only worth and relegates bluster and charlatanry to the rear, will be an open book, so that he who runs may read. The advertising quack will have his place, as does the shyster lawyer, because all *physicians* must needs by that time be on a parity, the foundation of which will be knowledge, vouched for by the State in the form of a license.

Some of the effects of the establishment of State boards of medical examiners have been improved methods of teaching, prolongation of terms of study, and the establishment of new chairs of instruction. While in New York State the entire subject of medicine is divided into seven main topics, the questions asked under these topics are so sub-divided as to comprehend almost every sub-head in medicine. Realizing the importance of having their graduates well equipped for passing these tests, the means above enumerated have been adopted for the benefit of college and profession. In consequence, teachers on hygiene, medical jurisprudence, and other subdivisions of medicine, exist now in fact as well as in name in most of our colleges, a thorough drill and review teaching is a feature of the curriculum, and some of the lecture courses extend over a period of eight months.—*Buffalo Medical and Surgical Journal*, November, 1893.

THE GENTLE TOUCH.

MR. BILTON POLLARD, in his address before the University College, London, gave a very timely and practical hint regarding the kindly treatment of hospital patients by internes. We regret to say that such a lesson is occasionally much needed in many of our public institutions, and the heeding of it will give that necessary exercise of the finer humanities which fits the graduates for the higher grades of successful practice among the so-called cultivated classes. The lecturer very properly maintains that an interne who can, by his gentle methods and appreciative sympathy, win the love and friendship of his poor and dependent patients, has gained as important an experience as any he can obtain in the hospital ward. Not that the ordinary hospital attendant intends any wrong, but there is, in some instances, a sudden inflation of his importance which invites dictatorial brusqueness, and an indisposition, in the exercise of duties supposed to be more important, to give time and thought to the exercise of the better elements of his manliness, by a compassionate consideration for the sufferings of such as are at his mercy. The cry of agony is never necessary for a diagnosis when the surgeon is the active agent of its production. The man who inflicts unnecessary pain in handling an injured limb is either a bungler or a brute.

The difference between the one who considers the feelings of his patient and the other who does not is very apparent in the examination of a wound or the manipulation of a fracture. In the former the practised delicacy of touch discovers all that it is necessary to know concerning the extent or character of the wound, without a sign of pain from the patient; while the latter, by the pressure and twist in the wrong place and at the wrong time, transforms the patient from a quiet, helpful, and submissive subject, to a shrieking and horrified sufferer. Even the most ignorant patient takes such lessons to heart. With a rich patron the question of choice could very easily be settled, but usually the sick or injured pauper must submit to the inevitable. When we consider that the highest science aims to mitigate pain, we can hardly claim superior accomplishments or greater depth of learning for the man whose very touch is signalized by a howl.

While it may not be possible for everyone to obtain this refinement of manipulation, there is no excuse for not cultivating it in every instance. Scientifically speak-

ing, a sick beggar is the same as a sick king. Their nervous systems are made alike, their reflexes are similar, and their pain-centers are equally responsive. The one who can learn early to treat them from the same standpoint of appreciation becomes the sympathizing friend of both, and will be as welcome in the palace as in the hovel. There may be a reason why all cannot be great physicians, but we all can be gentle ones. Even in our most desperate cases, when all other remedies fail, the very last to lose its influence is the kind word fitly spoken.—*Medical Record.*

THE INFLUENCE OF ALCOHOL.

The influence of alcohol on the nerves, and especially on the motor nerves, is seen in the acute stage of intoxication, and in its chronic form is exhibited in delirium tremens and various forms of neurotic disease. But, fearful as are these diseases, they are of comparatively rare occurrence, while diseases springing from the action of alcohol on the physical organs are of such far more frequent occurrence as to render their consideration of greater practical importance. Alcohol exerts its essential and most significant influence on the vital organs by being taken up in the circulation, and thus brought into direct contact with the cellular tissues of the vital organs. Cirrhosis of the liver, diseases of the heart, of the arteries, of the kidneys, and of the mucous membrane of the alimentary canal, along with gout, diabetes, and fatty degeneration, are all ascribable to it. This is a formidable list when we take into consideration their frequent occurrence, and I can only ascribe the indifference of the profession to a want of realization of the injurious consequences flowing from the pernicious habit. Alcohol is frequently prescribed under the mistaken impression that it possesses wholesome and even healing properties. The physician, as family friend and adviser, should be careful not to err in this direction; especially should alcohol never be administered to children. The prevention of the evils of alcoholism, when once realized, should appeal to us as physicians to enlist all our forces in an earnest effort to grapple with them. Prevention is, in principle, so easy. Nothing is needed but insight and good will! Shall we not, then, gladly embrace the opportunity to avert such endless misery? The ridicule with which the opponents of alcohol are assailed will lose all its force, when one is supported by the firm conviction that he is toiling for a good cause in the service of humanity.—*Dr. Adolf Strümpell.*

REVIEWS.

A Text-Book of Ophthalmology. By Wm. F. Norris, A.M., M.D., Professor of Ophthalmology in the University of Pennsylvania, etc., and Charles A. Oliver, A.M. M.D., One of the Surgeons to the Wills Eye Hospital, etc. Illustrated with five colored plates and 357 woodcuts. Philadelphia: Lea Bros. & Co., 1893.

This book cannot fail take its place as in many respects the best American, which is equivalent to saying the best English, text-book on the subject of Ophthalmology. We have long awaited this volume, in the sense that we have long wished for such a volume from somebody, and also for this special volume by these authors. It is of course true that science knows no nationality or geographic limits, but it is also true that one people, or set of men, may at times push farther than another toward perfection in some one branch or phase of a subject, and thus be better able to present certain advances or practices of it. In ophthalmology Europeon scientists and practising physicians have stamped the specialty with a certain method and tendency that, while gratefully acknowledged by us, and also followed by us quite so far and so fast as is at all desirable, is still surely but a partial and one-sided development. In pathology, inflammatory diseases of the eye, and even in the theoretic aspect of the sciences of refraction, accommodation, and muscular errors, we may have much to learn of our brethren over sea; but it is also true that in the practical aspects of these latter branches of our science we Americans may truly contend that we are also teachers, and that we have discovered much valuable truth to teach.

In these noteworthy fields of the practical application and therapeutic results of scientific optics, Drs. Norris and Oliver have, as we have said, given us the best work yet at hand. In the ordinary text-book the ordinary student either skips entirely the chapters on optics, or he is ludicrously dazed by the incomprehensible mathematic gibberish of the "explanation." But in Dr. Oliver's exquisitely beautiful illustrations and perfect-running text, the simplest (as well as the most trained mind) must find joy in the easy comprehension of the laws of catoptrics, dioptrics, and physiologic optics. When we turn to the chapters of the senior editor on the treatment of the various phases of ametropia, we find clear recognition and exposition drawn from ripe experience of the action and cure of that condition.

The treatment of the diseases of the eye and the highly important bearings of medical ophthalmology are most praiseworthy, and are what was to be expected of the trained and experienced senior editor.

Space at our disposal does not permit of detailed mention of the many excellent things to which we would like to call attention, and criticism of a few incongruities seems almost rude in return for such excellent workmanship.

We are compelled to object to the separation of the treatment of the subjects of ametropia, accommodation, etc., in two different parts of the book, and think it would have been in better literary taste to have merged these chapters into one connected narrative. Possibly also some confusion to the student would have been avoided.

We are delighted to find a rational statement of the unreliability and defects as well as of the uses of the ophthalmometer. It is abundantly clear that for accuracy and reliance the test-lenses and mydriatic are prerequisites in refraction of the young. Neither is graduated tenotomy a fetich with our authors.

We wish mention had been made of the theories of the influence of ametropia in the production of specific macular changes, and also of the method of treating functional stenosis of the mechanism of the drainage-system by means of antiseptic and astringent physiologic irrigation aided by massage, even if the authors do not believe in these theories.

Of that most important and usually most culpably neglected literary helper, the index, we regret that a word of unqualified blame must be added; and is it not, indeed, too bad to look in vain in the index of a book on ophthalmology, A. D. 1893, for such words as these: *Tenotomy*, *Epiphora*, *Epilation*, *Cryptophthalmus*, *Collyria*, *Cocain*, *Diplopia*, *Luxation of Eyeball*, *Malingering*, *Helmholtz*, etc.? In all other respects unqualified praise must be awarded the editors and publishers for this noble piece of bookmaking, as well in illustration as in typography, etc. By the way, what superb art our Philadelphia engravers and illustrators are showing nowadays!

SYSTEM OF DISEASES OF THE EAR, NOSE, AND THROAT. Edited by CHARLES H. BURNETT, A.M., M.D., Emeritus Professor of Otology in the Philadelphia Polyclinic; Clinical Professor of Otology in the Woman's Medical College of Pennsylvania, etc. Vol. II. Illustrated. 8vo, pp. 858. Philadelphia: J. B. Lippincott Co., 1893.

BURNETT'S System, like the child that has a lot of dainties, "keeps the best for the last." The final article in the concluding volume is on Tuberculosis and Syphilis of the Larynx by no less an authority than J. Solis-Cohen. With characteristically concise comprehensiveness, this chapter, of but thirty-three pages, of which much space is devoted to pictorial illustrations, leaves nothing further to be said upon the two important subjects treated. The results of an unrivalled experience and a rare erudition are given briefly, clearly, and in a judicial spirit. The volume likewise opens well. The first subject treated is Morbid Growths and Deformities of the Nasal Cavities. There are two articles, one by Seiler and one by Jarvis. Seiler's chapter on Pathology, Etiology, Physiology, and Differential Diagnosis is one of the most important contributions to literature made by its accomplished author, and exhibits careful and conscientious study. Jarvis writes of his personal methods in Surgical Procedures, and gives brief reference to the methods of others. Bosworth has an excellent article on Hay-fever, with copious references. He believes that three elements are necessary to the full development of the affection: (1) a neurotic constitution, (2) nasal abnormity, these forming the predisposition, and (3) an exciting irritant, usually pollen, the species varying with the individual. We have seen cases in which no structural abnormity could be detected; otherwise we agree with the author. Joseph A. White writes of Neuroses of the Nose and Nasopharynx, and George M. Gould well elucidates the subject of the Interdependence of Nasal and Ocular Affections. Pathologic conditions of the nose affect the eye more often than those of the eye affect the nose; yet instances of the latter group are not wanting. Skin Diseases of the Nose are treated of by Bulkley, and in his usual thorough manner. A. W. MacCoy has a good chapter on the Anatomy and Physiology of the Pharynx and Larynx. S. H. Chapman writes diffusely but well of Vocal Culture and Hygiene. Thorner's article on Acute Pharyngitis, Bean's on Acute Tonsillitis, Ingals' on Chronic Pharyngitis, and Arnold's on Chronic Laryngitis are interesting and reliable. Croup has been assigned to W. C. Glasgow, who does nothing that is not well done, and who can now write of "idiopathic membranous croup" without fear of contradiction by the parrots. J. Lewis Smith is an authority on his subject—Diphtheria, and Nancrede's article on Surgery in Croup and Diphtheria is judicious. Lupous and Leprous Laryngitis, by Ramon de la Sota, is one of the best contributions to this excellent volume, and will be a standard of reference. Shurly's well-treated subject is Chronic Laryngitis, Simple and Traumatic; Roe's is Foreign Bodies in the Air-passages and Esophagus; C. H. Knight's is Chronic Disease of the Tonsils; R. P. Lincoln has forty good pages on the Pharynx and Larynx in the Exanthemata and Other Febrile Affections; Porcher writes of Neuroses of the Pharynx and Larynx, and Dysphagia; and Lennox Browne contributes a good account of Deformities and Morbid Growths of the Pharynx and Larynx. The volume as a whole is better than the first volume. The editor is to be congratulated on the rare thoroughness of the editorial work. The indices are models.

DISEASES OF THE RECTUM AND ANUS: THEIR PATHOLOGY, DIAGNOSIS, AND TREATMENT. By CHARLES B. KELSEY, A.M., M.D., New York, Professor of Diseases of the Rectum at the New York Post-Graduate Medical School and Hospital; late Professor of Diseases of the Rectum at the University of Vermont, etc. Fourth edition, revised and enlarged. With two chromolithographs and one hundred and sixty two illustrations. Octavo, pp. 496. New York: William Wood & Co., 1893.

THIS standard text-book has been thoroughly revised and brought up to date by the author. It is a work that the general practitioner cannot afford to omit from his library. Diseases of the rectum have for a long time been a special field for quacks and nostrum-venders, for the reason that the regular practitioner failed to examine the rectum digitally in every case of trouble with the lower bowel. Consequently errors in diagnosis were common. In recent years much interest has been manifested in rectal diseases, and as the physician is frequently consulted by his patient for the treatment of these maladies, he will do well to possess some late standard work on the subject. To such we can confidently recommend Dr. Kelsey's book. It is practical, and will enable any physician to recognize and treat many of the affections of the part without occasion to refer the patient to the special surgeon.

In no field of medicine is it more incumbent for the physician to take nothing for granted than in the diagnosis and treatment of diseases of the rectum. Yet, how frequently is a diagnosis of "piles" made by the patient, and accepted by the practitioner, without question or examination. It is true that hemorrhoids constitute the bulk of rectal maladies, yet the specialist and general surgeon are well aware that often the hemorrhoids are but a symptom of some other affection, such as stricture, etc.; therefore, in reading Dr. Kelsey's book, if nothing else is impressed upon the mind of the reader, but this advice, *Never treat a case of disease of the rectum without first making a direct ocular and digital examination*, then the price of the volume will be many-fold times repaid to its owner.

Extended reviews in The News of former editions of this work render a detailed description of the present volume superfluous.

Essentials of Bacteriology. Being a concise and systematic Introduction to the Study of Microörganisms, for the use of Students and Practitioners. By M. V. Ball, M.D. Second edition, with 81 illustrations and 5 plates. Philadelphia: W. B. Saunders, 1893.

A handy little book for the medical student and general practitioner is the second edition of Dr. Ball's *Essentials of Bacteriology*. While of too small a compass to contain any satisfactory presentation or discussion of the many moot points of bacteriology, and for this very reason misleading at times, the book is a useful one—comprehensive to a marked degree for one of the size, well arranged, well printed, finely illustrated, and with a good index.

A striking indifference, however, to the unanimous opinion of systematists, as embodied in the reports of committees on nomenclature in the various scientific congresses of late years, to the effect that all specific names, without exception, should be printed with small initial letters, is shown by the author, who appears to follow no system at all; the specific names of the table of contents all possess capitals, while none of those in the index is thus favored, and a hit-and-miss plan is adopted throughout the body of the book. Aside from this, and a few errors in synonymy, Dr. Ball's little book may fairly be considered one of the very best of its kind.

A Dermatologic System. By Dr. S. Jessner, of Königsberg. Pp. 66. Hamburg: Leopold Voss, 1893.

The system which is here put forth in detail is built upon the classic work of Hebra, and is on the pathologico-anatomic basis, which we believe to be the right one for many reasons. It differs, however, in distinct particulars from that classification. Six classes are made: 1. Functional anomalies (without visible alterations). 2. Anomalies of the distribution of the blood (without inflammation). 3. Inflammations. 4. Hypertrophies. 5. New growths. 6. Regressive disturbances of nutrition. The work has been prepared with care and from the present standpoint of knowledge, and we commend it to the perusal of all who are interested in dermatology.

CORRESPONDENCE.

COMBINED METHOD OF OPERATING UPON THE BLADDER AND URETHRA.

To the Editor of The Medical News,

Sir: The accompanying report was already typewritten when your issue of October 14th reached me, containing Dr. Stewart's article on the combined method of operating in cases of ruptured urethra.

All surgeons are well aware of the great difficulty of perineal urethrotomy without a guide, its uncertainty, and the great length of time frequently required to complete it.

While I would by no means presume to say that the combined method is best for *all* operators and in *all* cases, I am nevertheless certain that for most men it is much speedier, easier, and safer than any other.

E. M., thirty-three years old, weaver in a cotton-mill, when between sixteen and seventeen years old, acquired gonorrhea which resulted in stricture. When twenty-five years old he was operated on at the Massachusetts General Hospital. Unsuccessful attempts having been made without ether to introduce a filiform bougie, he was anesthetized and some operation performed. No perineal incision was made. He was in the hospital for about two weeks. For four months after this operation he occasionally introduced a No. 22 F. sound, which had been given him while in the hospital. He never passed this sound into the bladder but only through the pendulous portion of the urethra, and ceased using it because in spite of it his stream grew smaller and smaller until it was as small as before the operation.

After a time the urine came only drop by drop, and finally, in 1889, an attack of complete retention drove him to a physician. A perineal operation was now performed. After this operation the urine came no better than before, and a sound could not be passed. The patient's history during the past four years has been one of continuous suffering, with occasional attacks of retention.

I have seen him in several such attacks, and have relieved him by aspiration, being unable to introduce even a filiform bougie. Finally, on the eighth day of June last, after complete retention for three days, he consented to an operation.

I first opened the bladder above the pubes and passed an instrument from the bladder into the urethra as far as the posterior face of the principal stricture (which was in the membranous urethra). Then I passed an instrument through the anterior urethra as far as the anterior face of the stricture, and cut from one instrument to the other. Then with an Otis urethrotome I cut two strictures in the pendulous urethra, and with a scalpel deepened the perineal wound until a No. 18 E. sound could be easily passed into the bladder. After passing a large catheter through the perineal wound into the bladder for a drain and washing out the bladder with warm boric-acid solution, the man was put to bed. The supra-pubic wound was left open. The bladder was drained until no fluid could be forced through the supra-pubic wound. The man was at work in the mill with all his wounds healed in less than a month from the day of the operation. He uses the No. 18 E. sound himself about once a week, without any trouble at all.

My reasons for preferring this combined mode of operating were: 1. No guide could be worked through the stricture. 2. An excellent surgeon had failed to find the urethra behind the stricture in 1889. 3. The perineum was one mass of scar-tissue in the neighborhood of the urethra. 4. The patient was in such a condition that I considered it of importance to operate as quickly as possible.

The operation as described is easily performed, except when, as happened in this case, the bladder is very deeply situated and the peritoneum comes further down on its anterior surface than usual. In such cases the serous membrane must be dissected up with the scapel-handle and finger-nail until enough of the bladder is

exposed, and I have found that an assistant with two fingers in the rectum can push up the bladder much better than can be done with a rectal bag, even though the latter be helped by putting the patient in the Trendelenburg position.

Respectfully,

GARRY DEN. HOUGH, A.B., M.D.

NEW BEDFORD, MASS.

NEWS ITEMS.

Congress of American Physicians and Surgeons.—At a meeting of the Executive Committee of the Congress of American Physicians and Surgeons recently held in New York, and attended by representatives of the various constituent organizations, a local committee of arrangements in Washington was appointed as follows: Drs. S. S. Adams, John S. Billings, H. C. Beyer, S. O. Ritchie, S. C. Busey, W. W. Johnston, J. Atkinson, Wm. H. Welch, I. C. Rosse, Samuel Theobald, T. Morris Murray, D. W. Prentiss, Frank Baker.

It was arranged that the following subjects should be discussed by the Congress at its next meeting in Washington in the latter part of May, 1894:

The Climatological Association: "Sewer Gas."

Genito-Urinary Association: "The Surgical Kidney in its Clinical Aspects."

Dermatological Association: "Leprosy in the United States."

Laryngological Association: "Intra-nasal Surgery."

Gynecological Association: "The Conservative Treatment of the Female Pelvic Organs."

Neurological Association: "The Effects of Infectious Processes on the Nervous System."

Dr. Wm. H. Welch was elected to fill the vacancy on the committee occasioned by the resignation of Dr. W. H. Carmalt, so that the committee now consists of Dr. A. L. Loomis, President of the Congress; Dr. Landon Carter Gray, Chairman of the Executive Committee; Dr. Newton M. Shaffer, Secretary of the Executive Committee, and Dr. Wm. H. Welch.

A Case of Distoma Hematobium in Chicago.—HILLMANTEL (*Chicago Medical Recorder*, vol. v, No. 4, p. 230) has reported a case of distomiasis in an Egyptian boy twelve years old, connected with one of the departments of the Columbian Exposition at Chicago. The only symptom complained of was hematuria, which had been present in varying degree for six years. The general health was good and there was no elevation of temperature. The urine presented a reddish-brown color and contained a considerable quantity of albumin and clotted blood. In addition ova of the distoma hematobium were found, but a fully developed worm could not be detected.

Dr. William F. Hutchinson, who was only recently elected to the chair of Electro-therapeutics in the newly organized Tufts Medical School of Boston, died on October 2d, in consequence of a cardiac lesion, at the age of fifty-five. He was a man of liberal education and served faithfully in the War of the Rebellion.

Correction.—By an inadvertence the word "inaccessible" appears instead of "*accessible*," in the last line of the quotation from Osler's *Practice of Medicine*, on the second column of page 517 of THE NEWS of November 4, 1893.

ORIGINAL ARTICLES.

PATHOLOGY AND TREATMENT OF PARALYSIS FROM POTT'S DISEASE.[1]

BY WHARTON SINKLER, M.D.,
OF PHILADELPHIA.

AT first sight one is likely to regard the paralysis that so frequently occurs in spinal caries as the result of direct pressure upon the cord by the bent and distorted spinal column. Reflection as to the history and symptoms of the disease shows that this is not generally the case, and this is also proved by the conditions found on the post-mortem table. The onset of paralysis in Pott's disease is almost always gradual, and it is a well-known fact that cases are not unusual in which an acute angular curvature has existed for many years without any symptoms of paralysis, and yet, eventually, paraplegia may develop.

In a patient who was under my care there had been a prominent antero-posterior curvature in the dorsal region for many years without interfering with the man's locomotion. One day while carrying a heavy tin box and some fishing-tackle he ran across a ploughed field to catch a train. When he reached the train he felt considerable numbness in his legs, and upon arriving home he walked up stairs with difficulty. In twenty-four hours he was unable to stand, and within a few days there was complete paraplegia that lasted several weeks. The patient ultimately entirely recovered after suspension and the application of a plaster-of-Paris jacket.

Were the paralysis the result of bony pressure there would be complete loss of motion and sensation below the point of injury, just as is met with after fracture of the vertebræ or fracture-dislocation; but it is well known that the paralysis in Pott's disease is generally limited to motion.

The relatively large caliber of the spinal canal, compared with the size of the cord, permits of a considerable amount of bending of the spinal column without materially impinging upon the cord. Of course, it does sometimes occur that in an angular curvature there is also displacement of one of the bodies of the vertebræ, followed by complete compression of the cord, but this is not often the case. The spinal cord shows extraordinary tolerance of pressure, if the pressure is gradually produced. It is not an unusual thing to find in an old case of Pott's disease that the cord has been flattened almost into a ribbon, without its functions having been impaired to a marked degree.

The papers that are to be read dealing with the surgical pathology of spinal caries render it unnecessary for me to speak in detail of the changes that occur in the bones.

The inflammation of the bodies of the vertebræ and of the inter-vertebral substance is the first step in the process. This inflammation, which is either tuberculous or scrofulous, results in the breaking down of the substance of the bone, and when this occurs the deformity of the spine follows. The effect of this inflammation is often to cause suppuration, and the pus will either find its way externally or it may penetrate into the spinal canal and there make pressure upon the cord. Frequently, however, no pus is formed. The bodies of the vertebræ soften and break down, undergoing a caseous degeneration, and absorption of the inter-vertebral discs takes place. While these changes are going on there is an extension of the inflammatory process to the dura. The connective tissue between the dura and the bone becomes thickened, with the development of a thick layer of organized lymph between the two, giving rise to what is known as external pachymeningitis. In this semi-purulent form of pachymeningitis, the layer of inflammatory products of caseous or fibrinous material and sometimes with pus in spots, often becomes extraordinarily thick; occasionally it is as much as one-half inch in thickness, and may extend vertically two or three inches.

The inner surface of the dura is usually smooth and unaffected by the inflammation, but there may be an inflammation of the inner side as well, although this is rare. However, when it does occur the internal membranes are also involved, and adhesions take place between them and the dura and the cord.

The pachymeningitis being the result of extension of the inflammation from the contiguous surface of the degenerating vertebral bodies, the inflammatory thickening takes places on the anterior surface of the cord, the result being pressure upon this region and consequently paralysis of motion. The paralysis of motion is sometimes the result of simple

[1] Read before the Section on Orthopedic Surgery of the College of Physicians, October 20, 1893.

pressure upon the cord, but there may also be a myelitis from an extension of the inflammation, and this may extend all the way through the substance of the cord, giving rise to the so-called "transverse myelitis."

On post-mortem examination the cord presents evidence of the compression to which it has been subjected and, as has been already remarked, may sometimes be flattened out like a strip of tape. It may be reduced in size, so that for an inch or two it is not larger than a lead-pencil. When the cord has been compressed, the color is grayish, and in cases of short duration its consistency is soft, while in cases of long-standing it is firmer than usual. The amount of myelitis does not depend upon the degree of pressure, for a considerable amount of myelitis may be found in cases in which the compression has been slight, extending, as has been already said, from the adjacent inflammation in the dura.

Under the microscope there is found a general increase in the interstitial connective tissue, with various changes in the cells, but late in the disease all of the cells disappear. The nerve-elements also undergo degeneration, the nerve-fibers becoming shrunken and having but a narrow sheath of myelin. When there has been extreme pressure, nothing is to be found but a narrow fibrous band at the point of division, which is sometimes difficult to discover, but there is never actual division of the cord itself. The nerve-roots also show signs of the effects of the pressure and inflammation where they pass through the membranes and inter-vertebral foramina. They are often compressed by the thickening of the dura, and they may also suffer from the narrowing of the spinal canal. On section they are sometimes red and swollen, or they may be shrivelled and gray in color.

The symptoms in caries of the spine are threefold: first, those of bone-disease; secondly, those of disease of the nerve-roots, and thirdly, those of the changes in the cord itself. These latter may be subdivided into the symptoms depending upon myelitis from extension of inflammation and those of compression of the cord. The symptoms referable to the bone-disease properly belong to the surgical aspect of the subject, but they are so important in aiding us to make a correct diagnosis that it is well to bear them in mind. In caries of the spine there are localized pain and tenderness on pressure at a certain point of the spine. This pain is increased by movements of the trunk and more particularly by the bending of the body forward. At the seat of pain there is usually some prominence or irregularity of the spinous processes, although this is not always present, and is a later symptom in the disease.

If the disease is in the cervical region, movements of the head will occasion pain, and, in order to avoid the pain caused by these movements, the patient usually carries the head stiffly or supports the chin with his hand. Should the disease be situated in the dorsal region there is a compensatory curve in the lumbar region, and any patient presenting a well-marked lordosis, in connection with symptoms of nerve-disturbance in the extremities, should excite our suspicions as to bone-disease, even if it is not possible to detect any deformity in the vertebra. We should not forget that lateral curvature may also be due to caries of the spine and give rise to pressure-symptoms.

Symptoms of disease of the nerve-roots are usually present, although it is stated by some authorities that they are not frequently conspicuous. In my experience, however, there are usually some evidences of irritation or disease of the nerve-roots. These symptoms consist in pain in the distribution of the nerves that emerge at the inter-vertebral foramina in the affected region of the cord. There may be pain in the course of the nerves in the limbs, or the symptoms may be only those of paresthesia, such as numbness and formication. There is frequently more or less girdle-pain at the level of the affected nerve-roots, and occasionally herpes zoster may be met with in the course of the irritated nerves. It is not infrequent, in spinal caries, to find pain referred to the epigastrium, and in one or two cases I have seen severe pain in the hypochondriac region, simulating renal colic.

In irritation of the motor roots we have symptoms of disordered muscular action and wasting of the muscles. Occasionally, there are active muscular contractions as the result of the irritation of the motor nerves. When the cervical spine is diseased, there may be disorder of the sympathetic nerves, with localized sweating and dilatation of the pupils.

The symptoms of the cord-disease, when dependent upon myelitis from extension of the inflammation, are like those of myelitis from any other cause, but, as has been already observed, the myelitis is rarely transverse and is usually confined to the anterior portion of the cord; hence the symptoms are principally motor in character.

The onset of the paralysis is usually gradual and often occurs as the result of some unusual exertion or exposure to cold. The rapidity of development varies and total paraplegia may result in a few days, although it is usually several weeks before it is complete.

The degree of motor paralysis also varies with the extent of the cord-disease; sometimes there is merely stiffening of the limbs, with a spastic gait, with slight impairment in the control of the bladder and rectum, while at other times motor paralysis is absolute. When the paralysis is due to compression,

it is likely to be more complete, with sensory disturbances, as well as the loss of motor power. When the pressure is confined to the anterior portion of the cord, as it usually is, there is only motor paralysis, with more or less weakness of the bladder and rectum. The pachymeningitis may, however, entirely surround the cord, and if there is much fibrinous or caseous exudation the compression will be almost total. When there is bony displacement, in addition to the pachymeningitis, it is readily seen that the compression of the cord will be still greater. Under these circumstances, the motor and sensory paralysis is entire, and there is also paralysis of the bladder and rectum. Bedsores do not generally occur, except as the result of neglect, because, as a rule, the trophic disturbances are not great.

In both forms of cord-disturbance, whether due to myelitis from extension or myelitis from compression, the reflexes are greatly exaggerated, provided the disease is above the lumbar region. The knee-jerks are grossly exaggerated, ankle-clonus is present, and the superficial reflexes are also unduly excitable. Occasionally patella-clonus is present, and the toe-reflex, to which I have called attention elsewhere, may be developed. If the disease is situated as low as the lumbar enlargement the reflexes will be entirely absent and there will be paralysis of the bladder and rectum.

The symptoms, of course, will depend upon the region of the spine in which the disease exists. If it is in the cervical region there may be paralysis of both arms and legs, or if it is in the dorsal region, which is the common seat of caries, there will be simple paraplegia. There is occasionally complete anesthesia, but sometimes this is confined to areas of varying extent over the limbs, and at times we may have associated with loss of tactile sense hyperesthesia. Generally both legs are equally paralyzed, but occasionally one is affected more than the other, and in a patient whose history I shall relate the knee-jerk was exaggerated on one side and abolished on the other side.

Among the complications that may be mentioned are bedsores, cystitis, and contractures. The symptoms may change, owing to the fact that degeneration of the cord may extend from the original focus of disease. An ascending degeneration of the posterior columns will give rise to tabetic symptoms. Gowers asserts that the inflammation may ascend in the pyramidal tracts when the disease is in the lumbar region, and thus give rise to paralysis of the arms.

The course of the disease, once the paralysis has been established, depends to a great extent upon the condition of the bone. If the bone-disease should heal, the inflammation of the cord usually subsides as the pressure becomes less, although if the myelitis exists independently of pressure this improvement does not necessarily take place. The sensory paralysis when present usually passes away early and the motor loss remains for a longer time. The motor paralysis may remain for months and even years before improvement takes place. In one of the cases that I shall report there was total paraplegia for sixteen months, and yet the patient recovered complete use of the legs. In many cases the paralysis gradually passes away, even when the compression of the cord to a considerable degree remains. Should no improvement take place in the condition of the bones the paralysis is likely to remain complete, and although life may be extended for several years, eventually death occurs as the result of bedsores, cystitis, or from the development of tuberculous disease elsewhere. Relapses may occur during the course of the disease, but they are not common. When improvement has once begun it is usually constant.

The diagnosis of compression-myelitis is easily made, provided we find symptoms of bone-disease; and in all cases of spastic paraplegia one should carefully examine the spine for irregularities and for tenderness. This is more particularly to be looked for in children, because transverse myelitis or primary lateral sclerosis is unusual at an early age, whereas spastic paraplegia from Pott's disease is comparatively common in children. A mistake frequently made is overlooking the spinal disease in children, and it is a very serious error as regards the prospects of recovery. I have on more than one occasion seen children with paraplegia made to take as much exercise as possible when there was well-marked caries of the spine present which had not been detected, and when every movement caused pain. The symptoms depending on disorder of the nerve-roots also aid us in making a diagnosis.

The diseases most likely to be mistaken for compression-myelitis are chronic myelitis, transverse myelitis, primary sclerosis of the lateral columns, and, when the disease is in the cervical region, progressive muscular atrophy. Another condition for which paralysis from Pott's disease may be mistaken is syringomyelia. In this disease, however, there is no pain, although the spinal column frequently presents a lateral curvature, and there is the well-known symptom of inability to distinguish heat and cold.

We must not forget that there are other causes of pressure than caries and pachymeningitis. There may be tumors of the cord and aneurism.

The prognosis depends upon the extent of the paralysis, and the region of the cord affected; but there is no disease that gives rise to such complete paralysis of motion and sensation in which we may hope for ultimate recovery, as in paralysis from

Pott's disease. Even after the lapse of months or even years, complete paralysis of motion may pass away and the patient become able to walk with his previous activity. Should there be complete palsy of motion and sensation, as well as paralysis of the bladder and rectum, the prognosis is bad, but even in such cases recovery may take place. If the disease is in the lumbar enlargement or in the cervical enlargement, the chances of recovery are less. We must also bear in mind that the prognosis depends upon the prospect of recovery from the constitutional trouble. The scrofulous or tuberculous tendency may be developed elsewhere and the patient die from lung-disease or disease in some other organ.

TREATMENT.—In many cases of paralysis from Pott's disease all that is necessary to restore the power of motion is to give the patient complete rest, and some cases recover even when only a small amount of rest has been taken. The healing of the bone-disease depends very largely upon rest of the part, and the deformity that results is largely dependent upon the position in which the patient has been placed during the healing of the caries. In some cases, even after the inflammation of the vertebræ has apparently entirely ceased, paralysis remains in spite of complete rest having been enforced for many months. It is these cases that come under the care of the neurologist, and it is in these cases, I am happy to say, that the most gratifying results are obtained.

While complete rest is a necessary element in treatment, it must be supplemented by other means. The most important of these is extension of the spine by suspending the body by the head. The most satisfactory way of accomplishing this is to place the patient in an arm-chair, while from the back of the chair is a bent iron rod which projects above the patient's head. To the end of this rod is attached the cord from a head-sling. It is a good plan to insert between the head-piece and the iron bar a spring balance, so that the amount of extension may be measured in pounds. The apparatus I show you is what is usually employed in these cases at the Infirmary for Nervous Diseases.

The patient begins to have extension for fifteen minutes twice a day, and the amount of traction varies from ten to twenty-five pounds, according to the weight of the patient. The degree of pull is gradually increased and may reach seventy pounds. The length of time that the patient is suspended is increased each day until he sits up with the extension on for three hours at a time. The good effects of suspension are occasionally observed immediately, but sometimes no benefit is seen until after several weeks. I have frequently seen cases that have had rest and spinal jackets, and whose paralysis has remained stationary, yet who made immediate gain after the employment of extension.

Extension is sometimes made while the patient is lying in bed by having a cord and weight passing over a pulley at the head of the bed. This is applicable in children, but in adults the weight of the body is too great to make extension in this way effective.

Suspension after the method of Motschutkowski, of Odessa, in the treatment of locomotor ataxia, is not applicable to paraplegia from caries of the spine, as the patient is usually unable to manage the apparatus as well as an ataxic, and besides, by this method the suspension can be maintained for only a few minutes.

Some assert that the good effects from suspension are due to the straightening of the spinal column, but it is doubtful if very much elongation of the spine can be effected by this means. Others declare that by suspension the spinal cord is actually stretched. Reid and Sherrington[1] have made some interesting experiments in connection with the effect of movements of the body upon the size of the spinal canal. They arrive at the following conclusions: First, that when the body hangs freely and vertically from the skull the capacity of the cranio-vertebral canal is at a maximum; secondly, that with the body in this position, when the weight of the trunk and limbs is taken off by lifting and supporting the body vertically there is a diminution in the capacity of the cranio-vertebral canal, but the diminution is a slight one. They also state that it would appear that by suspension the size of the spinal cord is increased in the adult of middle age to the extent of some 100 cubic millimeters.

Althaus thought it probable that in suspension the spinal cord is materially stretched, and by this means some of the adhesions from chronic meningitis are broken down, thus allowing the freer transmission of nerve influence. In a modified form I am disposed to accept this view. I can scarcely believe that by suspension the cord can be stretched sufficiently to break down adhesions; but I think there is probably sufficient traction made upon it to influence the adhesions between the dura and the thickened connective tissue, and that thus absorption of the exudation is promoted.

There is also another probable effect of the extension, which is to relieve pressure upon the nerve-roots.

The treatment of Pott's disease by suspension seems to have originated with Professor J. K. Mitchell, in 1826, who wrote a paper on this subject. He used this plan principally in children, and the suspension was effected by placing the child in a frame on rollers, with a curved iron bar extending over the head, from which the patient was partially suspended by the head-sling. This method

[1] Brain, 1891.

of treatment seems to have been very successful in the hands of Professor Mitchell, but it fell into disuse, until a few years ago attention was drawn to it by Dr. Benjamin Lee.

In 1889 Dr. S. Weir Mitchell published an account of the treatment of Pott's paralysis by suspension.[1] He reviewed the treatment of his father, Professor J. K. Mitchell, and related his own experience.

I had the privilege of seeing many of the cases that he treated by extension at the Infirmary for Nervous Diseases, and the admirable results that he attained have given me great confidence in this plan of treatment.

Dr. Weir Mitchell's conclusions in regard to suspension are that, by means of it, the spinal deformity is greatly lessened; that it should be used early in Pott's disease, and that no case of Pott's disease ought to be considered desperate without its employment. In regard to the mode of action of suspension he believes that the "pull probably acts more or less directly on the cord itself, and that the gain is not explicable merely by obvious effects upon the mechanical bony curve."

Dr. Leroy W. Hubbard read a paper before the New York Academy of Medicine, March, 1890, on "The Use of Suspension in Pott's Disease," and spoke very favorably of it.

Dr. Putzel, in the discussion on Dr. Hubbard's paper, said that his pathologic studies had led him to believe that the majority of cases of Pott's paralysis were not due to pressure, but to transverse myelitis, and in his experiencewith susp ension he considered it a method that was at best of only temporary relief.

Dr. Birdsall thought that the improvement in paraplegia from Pott's disease was due to the slight separation of the vertebræ and consequent improvement in circulation of the affected parts, particularly the nerve-roots.

Dr. L. C. Gray spoke favorably of suspension in the treatment of paraplegia.

Dr. R. H. Sayre said that, carried to excess, suspension failed to give relief in his experience.

Dr. Phelps considered that suspension should not be used when the vertebral disease was still active.

Dr. E. G. Brackett (*Transactions American Orthopedic Association*, 1891) reported several cases of paralysis from Pott's disease, in which suspension had given good results.

Dr. Benjamin Lee, in the discussion that followed Dr. Brackett's paper, said that he wished to claim for himself whatever honor might attach to having been the first to propose and use self-suspension in the treatment of Pott's disease, lateral curvature, spinal pressure, paralysis, and of the conditions known as spinal irritation. He says that the treatment by suspension is very old, that it was used by Ambroise Paré, and that he got the idea from Hippocrates.

Counter-irritation is useful in many cases as an adjuvant to suspension, and the best way of making this is by the actual cautery, that of Paquelin being the most convenient to use. Sometimes when, in spite of suspension and counter-irritation, the progress of the case is slow, benefit seems to follow the use of internal remedies that have the power of promoting absorption. I have found potassium iodid useful under these circumstances when given in moderate doses.

Of course, in connection with the means already used, it is of the first importance to improve the general health of the patient by the administration of iron and cod-liver oil, and by giving the best and most nutritious food that can be taken. Massage is a most valuable aid, and it should be practised daily by a person well skilled in its use. By this means the nutrition of the muscles is improved, the circulation is stimulated, and a larger amount of food can be assimilated.

The use of the plaster jacket is of value in connection with suspension, and it is best to have the apparatus cut down in front so that it may be removed at pleasure. When the patient is sufficiently convalescent to go about, the half-tanned leather jacket made by Gemrig is helpful in giving support to the spinal column and protecting it from jars and injuries.

When the paralysis remains stationary, notwithstanding the faithful employment of the means already suggested, the question of surgical interference is worthy of careful consideration. Within the past few years the operation of laminectomy has been performed in many cases for paralysis from spinal caries. The results of this operation have been so successful that, with favorable conditions as to the general health of the patient, the operation should be advised whenever the paralysis has resisted the treatment that I have described. The mortality in these operations is comparatively small, and the beneficial effects have been shown by the brilliant operations of Macewen and others.

In my opinion, however, the operation of laminectomy is not indicated in cases in which the paralysis is purely motor. The removal of the laminæ will not relieve pressure, and it is difficult, if not impossible, to remove the exudation on the anterior surface of the cord without injury to the cord itself; moreover, it is not easy to determine beforehand whether the motor paralysis is due to pressure or to myelitis. When an operation is decided upon, the neurologist can aid the surgeon by indicating the point at which the operation should be performed, and in determining this the schedule for the localization of the functions of the segments of the spinal cord, given by Starr in his book on the *Familiar Forms of Nervous Disease*, will be found useful.

The following cases illustrate the advantage of extension, combined with rest, in the treatment of paralysis from Pott's disease.

Case I.—John T., aged eighteen, a native of Ohio, was admitted to the Orthopedic Hospital and Infirmary for Nervous Diseases, February 16, 1888. He is of healthy family with no history of tuberculosis in any of the members. He had always been strong and healthy until September, 1886, when he was violently bumped against a tree by four of his schoolmates. He suffered acute pain in the spine at the time; the pain was also felt in the epigastrium and radiated thence into the legs and shoulders.

About three weeks after the injury a lump was

[1] American Journal of the Medical Sciences, May, 1889.

discovered in the dorsal region of the spine. He became progressively weaker, and by January, 1887, four months after the injury, he was unable to walk or to sit up. On admission he weighed eighty-four pounds. There was angular curvature at the seventh dorsal vertebra. He could sit up with the aid of a leather spinal jacket which he had worn for several months. He had apparently no power to move the legs. The knees and ankles were in a condition of rigidity; the knee-jerk was exaggerated; ankle-clonus, patella-clonus, and the toe-reflex were all present. The condition of trepidation of the legs, known as spinal epilepsy, was readily induced; the plantar reflexes were exaggerated, but no cremasteric or abdominal reflex could be elicited. Sensation was impaired but not lost. There was no loss of the functions of the bladder or rectum. There was a small bedsore over the sacrum.

The patient was ordered rest in bed and massage, and the Paquelin cautery was applied on either side of the angular curvature. At the end of a month suspension was made by seating the patient upright in bed and having the suspension-apparatus projected above the head of the bed. Two months later he began to sit up in a chair while suspended, and about this time he began to have slight power of motion of the toes, and soon after this the power to flex the feet and legs followed.

On July 23d, the patient was able to move his legs, drawing up the knees while lying on his back. Sensation was improved but not yet perfect. In October he began to walk about with crutches, and from this time he steadily gained in power and soon dispensed with his crutches, but still continued to wear his spinal jacket.

I had a letter from this patient a short time ago, in which he tells me that he has remained perfectly well and that he has a position of "motor-man" on an electric car in Cleveland, Ohio. He says that he works fourteen hours a day and is as active as anyone he knows, as he is able to jump off and on the car while it is in motion, and that he can run as well as he ever could.

In this case it will be observed that the paralysis became complete in January, 1887, and it was not until May, 1888, sixteen months later, that power of motion began to return.

CASE II.—Robert H., aged twenty-one, a shoemaker by occupation, was admitted to the Orthopedic Hospital and Infirmary for Nervous Diseases, December 12, 1892. He had been a patient at Dr. Goodman's clinic since March, 1888, and had been treated with a Kolbe brace for spinal caries. The disease had followed lifting a heavy weight.

On admission the patient complained of extreme stiffness in the legs, with pain in the back extending down the legs. The pain was very severe, and the rigidity of the legs almost prevented locomotion. There was no muscular wasting. The knee-jerk on the right side was exaggerated, but on the left side it could not be elicited. There was no clonus.

The patient was ordered massage, rest in bed, and extension for fifteen minutes daily in the chair, the time to be increased by five minutes daily. On December 22d it was noted that the patient was being suspended for one hour daily and that the legs were more supple. On March 25th the patient was sitting up while wearing a plaster jacket, but still complained of severe pain in the back, and for this the cautery was applied. This immediately relieved the pain in the back, but the man still complained of pain in the anterior part of the thighs. On May 7th he was discharged greatly improved. He was able to walk without trouble, had no rigidity of the limbs, and the pain in the back was only occasionally troublesome. There was now knee-jerk present on both sides; it was exaggerated on the left side, and on the right side it was slightly in excess of the normal reaction.

CASE III.—The patient is Daniel C. B., a mulatto, twenty-seven years of age, and was admitted to the Orthopedic Hospital and Infirmary for Nervous Diseases, April 10, 1893. His father, mother, and eight brothers are all living, and there is no history of tuberculous or of Pott's disease in the family. He is married and is the father of two healthy children. He never had rheumatism and denies venereal disease.

Nine years ago a curvature in the spine was noticed. He thinks it came from a strain. No abscess formed and the legs were not affected. He was in bed at this time for three months on account of weakness of the back, but the legs were not paralyzed. Since that time he has been steadily going about and doing his work as a janitor until three months ago, when he was taken down with influenza and was in bed for one week. When he got up he was able to walk on the first day; on the second day he became very weak in his legs, and on the third day he was forced to remain in bed. His legs became gradually helpless and there was marked pain, which was of a dull, aching character, in the back and on the left side. For six weeks before admission there had been spasmodic contractions of the flexors of the legs and thighs, lasting for a few minutes, and then he could extend the legs with his hands.

Condition on examination: The patient is a light mulatto, with pallid mucous membranes. He lies on his side in bed with the thighs flexed on the abdomen and the legs on the thighs. There is a marked kyphosis in the dorsal spine, but no scars of abscesses. His teeth are bad; his tongue is foul; the bowels are constipated, and he has hemorrhoids. There is no paralysis of the bladder or rectum, and, with the exception of a few uric-acid crystals, the urine is normal. There is complete loss of motion in the lower extremities, with the exception of very slight power to move the toes. The legs are in clonic spasm most of the time. Sensation is preserved, but it is slightly delayed. There are no bedsores, but there is marked wasting of the muscles of the thighs and legs. The knee-jerks are grossly exaggerated; ankle-clonus, the plantar, cremasteric, and abdominal reflexes are present; the toe-jerk on both sides is present.

The patient was placed at rest in bed and was ordered massage and the cautery to the spine; with head-extension, ten pounds for five minutes daily, and increased by five minutes each day. On May

1st, a plaster jacket was applied, to be worn continuously. This has given considerable relief and the patient is able to lift his left leg off the bed. On May 11th he was able to move the toes of the right foot much better. There were still involuntary contractions of the limbs, but these were not so painful. On May 20th, the patient complained of numbness in both legs, from the hips down, and there was impairment of sensation. The patient gradually improved until June 29th, when he again began to lose power in the legs, and from that time until July 23d the legs became almost as helpless as they were when he was admitted. On this date he was ordered potassium iodid, five grains three times a day, and the plaster jacket was reapplied. On August 8th, he was markedly better and from this time the improvement was steadily progressive until October 5th, when the following note was made:

There is no pain, no numbness, or tingling in the legs; sensation is normal. The movements of both legs are performed well in all directions, but they are weak. He can stand alone, and walks about the ward supported by the wheel-crutch. The plantar, cremasteric, and abdominal reflexes are normal; the knee jerks are exaggerated and spastic. There is no clonus. The feet and legs are still cold and sweat freely, and although there is still some muscular wasting it is much less than previously.

This case is notable: first, on account of the prominence of the nerve-root symptoms; secondly, because after improvement had set in there was a relapse; and, thirdly, on account of the apparent benefit from the use of the potassium iodid.

ACNE.

By GEORGE D. HOLSTEN, M.D.,
of Brooklyn, N. Y.;
Dermatologist to the Brooklyn E. D. Hospital and Dispensary; Physician, Department of Dermatology, Brooklyn Throat Hospital.

The following definition of acne is taken from Jackson's *Diseases of the Skin*:

"Acne is an inflammatory disease of the sebaceous glands and the hair-follicles, due to the retention of sebum; it is characterized by an eruption of papules, pustules, or tubercles, upon the face, neck, shoulders, or chest; it usually begins at puberty and tends to run a chronic course."

In considering the subject of acne, a better understanding of the disease will be obtained by first briefly reviewing the structure and functions of the portions of the skin affected.

The sebaceous glands consist of two portions, the gland proper and the duct. The glandular portion is situated in the corium; the glands are of the racemose variety; the various acini of which these are composed, from two to twenty in number, open into a common duct which empties into the hair-follicle. Each follicle has two or more glands attached.

Embryologically, the sebaceous glands are to be considered as adjuncts to the hair-follicle, even though at a later period in adult life they exceed the follicle in size.

The sebaceous glands are divided by Sappey into three classes: First, those situated on the scalp, the bearded portion of the face, the axilla, and pubes, these being connected with hair-follicles that contain thick, coarse hairs, the hair-follicles predominating over the glands; second, those of the forehead, nose, cheeks, and chest, where the hairs are smaller—of the lanugo type—and the glands are large; and, third, those opening on the free surface of the body, not connected with hair-follicles, such as the glands situated around the corona glandis, the inner surface of the prepuce, the surface of the nipple, the vestibule, and the labia minora. Those of the second class are the most usually affected in acne.

In structure, the glands have a membrana propria and are lined with cubical or cylindrical epithelial cells, of several layers in thickness, these cells being a direct continuation of the cells forming the rete. The cells of the innermost layer undergo a fatty degeneration, and this fat, mixed with fatty acids, cholesterin, fat-crystals, and the remains of the cell-bodies, forms a mass—the sebum—which, passing out through the duct, is discharged into the hair-follicle, and serves to lubricate the hairs.

There have been many terms employed to designate the various grades of severity that acne may assume, but at the present time the disease is generally divided into two varieties, acne simplex and acne indurata; the former being superficially seated and papular or pustular in character, while the latter is deeply seated and pustular or tubercular.

The first step in the development of acne is an excessive formation of sebum in the glands. This sebum, instead of being poured out on the surface of the skin, becomes inspissated, remains in the duct, the opening of which becomes more prominent as the sebum increases. Frequently the plug of sebum becomes tipped with black. This constitutes the condition of comedo, or, popularly, "black-heads." At the same time, an increase of horny epidermis takes place around the mouth of the gland, with an abnormally light, yet firm adhesion over the opening. The simplest form of acne, most frequently seen on the forehead and chin—papular or punctate acne—is then present. These papules are pin-head in size, of a white or pinkish color, and on their summits are seen the black tips of the plugs of sebum. Subjecting one of these comedones to lateral pressure, the plug of sebum can be squeezed out. The black-brown color of this comedo-tip was formerly supposed to be due to dirt. Unna considers it as produced by a

normal pigment-constituent of the secretion of the skin, which he calls ultramarine, and which, under the influence of light, turns black; that such a pigment exists is denied by Krause. Kaposi, in his fourth edition, says he thinks that horny epidermis and fat, when they remain in contact with air for a long time, will become colored, and that atmospheric dirt is probably an accessory to this coloration.

The papular form may remain as such or go on to another form. The plug of sebum acts as a foreign body, and excites an inflammation in the gland-tissue, and we then have the acne papule larger, of a more deeply red color, and frequently with a surrounding areola. The condition of the tissues now being favorable for the development of pus-cocci, some of these gain entrance into the duct, and *pustular* acne is then the result. At this time one's patient presents the acne lesions in their various stages of development—comedones, large and small papules, and pustules. All of these constitute simple acne.

The disease may now remain in this condition, entirely limited to the superficial portion of the skin, and each lesion passing with more or less rapidity through these different stages. The pustules rupture or dry up, and the lesions depending on the grade of inflammation and suppuration which has been present, leaving more or less scarring, though this is usually not strongly marked.

After a variable length of time, if the disease is left untreated, it becomes more extensive and severe. The papules and pustules increase in number, and the individual lesions are larger, extend more deeply into the tissue, and the inflammatory symptoms become more severe; the tissues surrounding the glands are also involved, and the condition of *acne indurata* is then present. The disease is now characterized by lumps or tubercles, which are reddish or purplish in color, varying in size from that of a pea to that of a bean, and quite firm to the touch. Sometimes these lumps are so deeply placed in the skin that but little is seen on the surface, and they can only be appreciated by the touch. At first but few are present, and we have usually acne simplex, with here and there an indurated tubercle. After a time the tubercles become more and more numerous and prominent; several situated close to each other will apparently become matted together by the surrounding inflammation, and rough, irregular, lumpy masses are then seen and felt, reddish or purplish in color, hard, ofttimes very painful, and at times small abscesses may be present.

The skin of persons afflicted with acne is likely to be thick, coarse, and to have an oily or shiny appearance. In some, especially the young and robust, the skin is usually red and hyperemic, but generally the complexion is of a pasty-white color.

In considering the etiology and pathology of acne, three processes must be borne in mind: the comedo-formation, the inflammation excited in the gland and surrounding tissues by this plug acting as a foreign body, and the invasion of the pyogenic cocci causing suppuration.

The disease generally first appears at puberty and continues until full development is reached, say from the sixteenth or eighteenth year until the twenty-fifth or twenty-seventh, though it is frequently met with after this age. It is generally of more frequent occurrence and begins earlier in females. At the time of puberty there is a great developmental activity of the glands and hair-follicles. It is probable that in certain persons this activity of the glands is not only greater than it should be, but also that the product of such glands, which normally is a fatty or oily secretion, becomes perverted, and in addition, that the normal extrusive power of the gland is also deranged. At the same time, a parakeratosis of the surface and of the lining of the duct is taking place.

Certain individuals are more predisposed to acne than others, such as those with a thick, pasty complexion, and in such cases the mouths of the follicles are prominent. So-called scrofulous persons, those whose health is not the best, and persons with seborrheal eczema also manifest a predisposition.

The exciting causes are generally considered to reside in disturbances of the digestive, excretory, and sexual organs.

Whether disturbances of the sexual organs *per se* will produce acne has been questioned. That such disturbances and acne are ofttimes found in the same person is true, but it has been claimed that a lowered condition of the system generally and the influence that sexual derangements have upon the digestive organs can more frequently be blamed for the acne.

The statement is ofttimes made by female patients that their acne is worse at about the time of the menstrual period. A number of observations made by me during the past several years have shown that these patients were generally extremely costive and suffered from gastric disturbances; that when laxatives were administered and the diet carefully regulated as regards quality of food, especially avoiding the easily-fermentable foods, these exacerbations of acne did not occur. This fact would seem to disprove the statement made, unless it be argued that keeping the bowels clear reduced obstructive congestion of the pelvic viscera. On the other hand, a brother practitioner, whose labors are principally in the field of gynecology, has lately informed me of three patients under his observation whose acne always improved with the advent of or during menstruation.

It may be stated in broad terms that any cause that will lower the general health of a person will contribute to the development of acne. Over-eating, or the eating of improper food, as, *e. g.*, the excessive use of sugars and starches, which easily undergo fermentation in the stomach; over-drinking of malt or spirituous liquors, or of tea; constipation; excessive mental or physical work; the conditions of the system which give rise to gout, lithemia, oxaluria, uremia, or anemia; chronic malarial poisoning—all these are factors in the production of the comedone. Seborrheal eczema, and the condition of rosacea to which it leads, should also be recognized as important factors in the production of acne. The frequency with which seborrheal eczema is met with in acne-patients leads me to regard the association as more than merely coincidental. I think that very many cases of acne have their starting-point in the seborrheal eczema. Patients having the two diseases after being cured of them so far as the face is concerned, but failing to properly carry on treatment for the seborrheal eczema still remaining in the scalp will have a return of the acne with the next exacerbation of the seborrheal down on the face, and especially is this the case in patients past forty years of age.

Seborrheal eczema we find existing as slightly yellowish, or yellowish-gray, or slightly reddish, circumscribed, scaly patches occupying the forehead, temples, or neck, at the edges of the hair, on the cheek, or in the naso-labial fold, or more frequently, as a congested condition of the forehead, nose, cheeks, immediately beside the nose, and on the chin, associated with slight scaling or with papules from the size of a mustard-seed to that of a pea, sometimes smooth, at other times covered with yellowish, fatty scales; with this condition of the face there will always be more or less dandruff of the scalp.

Bearing in mind then the conditions that predispose to acne, the exciting causes and the pathologic changes that occur, we have an index to the measures to be pursued for its relief.

The regulation of the various functions of the body are familiar to all, and must be followed on the general principles that govern the treatment of these conditions. I shall, therefore, not speak of them, but consider the means directed against the disease itself.

As the comedones are the first exciting cause of the inflammation in the gland, they should be removed as soon as possible. For this purpose their mechanical expression by means of a comedo-extractor will be found of advantage. For the excessive formation of horny epidermis over and around the mouth of the follicle, mechanical or chemic means are necessary. Of the former, scraping with a curet, frictions with some coarse substance, such as finely powdered marble-dust, corn-meal, or pumice-stone, will effect the necessary change. As these means are not always agreeable to patients in private practice it may be better to try the chemic agents, such as salicylic or acetic acid, or the alkalies, such as potash-soap, spirit of green soap, liquor potassii, made up into ointments or pastes or lotions; or reducing agents, such as resorcin, sulfur, or the mercurial salts.

For the inflammatory reaction likely to be excited by the curetting or the energetic action of chemic agents, zinc oxid, carbonate of magnesia, corn-starch, ichthyol, will be found useful. As antiseptics, corrosive sublimate, boric acid, resorcin, and sulfur are among the best, and to restrain the excessive glandular activity and stimulate the skin to healthy action nothing is superior to sulfur.

To understand better the use of these various remedies in the different stages of acne let us suppose a case of indurated acne with large, red, painful tubercles and pustules, and consider its treatment. Having given all necessary attention and direction as regards the system generally and corrected all derangements, we will, if the patient permits, with a dermal curet scrape off the tops of the pustules and express their contents; with a dermal lancet or a small scalpel incise the tubercles and let out the pus found in them, and with the comedone-extractor press out comedones.

Bleeding should be encouraged for a short time by compresses dipped in a warm saturated solution of boric acid, the bleeding lessening the congestion and the boric acid at the same time acting as an antiseptic. Then to soothe the inflamed painful face zinc oxid and magnesium carbonate, with or without ichthyol, in lotion or in Bassorin paste, may be applied several times daily. After the reactionary inflammation has subsided a lotion containing mercuric chlorid is applied during the day and a resorcin-paste at night. The bichlorid acts as an antiseptic to prevent the formation of new pustules and also stimulates the glands to more healthy action, while the resorcin acts in very much the same way as does sulfur. If the horny epidermis is abundant, salicylic acid may be added to the paste. All of the pustules, tubercles, and comedones cannot, of course, be treated at the first consultation; therefore this mechanical treatment will have to be repeated until the face is in a fairly good condition.

The face should be washed daily with warm water and soap, and if the skin be thick, a potash-soap will be useful, while upon thin, sensitive, inflamed skins an ichthyol-soap will be of service. In either case the lather should be permitted to remain on the face for several minutes—from five to fifteen—rinsed

off with cool water, the face dried, and whatever remedy is employed, then applied.

When the acute stage of pustulation has subsided, stimulating remedies will come into service, and of these sulfur in some form is the best. The sulfur may be employed as an ointment; in the "lotio alba," made by mixing together solutions of sulfuretted potassium and zinc sulfate, to which some sulfur is then added, or it may be suspended in Bassorin paste, which has the advantage over ointments of drying in a short time, making a smooth, even dressing on the skin, keeping the remedy in close contact for a length of time, and of being easily removed with warm water.

In this way the disease will soon be brought under control. Then should come a period of after-treatment, the object of which is the prevention of relapses. Here the most service will be secured from the long-continued use of a feeble resorcin, or resorcin-sulfur, or resorcin-sublimate lotion.

Internally arsenic has long been held in great esteem. It will not be of service used alone, or during the acutely inflamed stage, but at later periods or when a condition of parakeratosis, exists, then, in conjunction with external remedies, it will do good.

Ergot has also been extolled, but my results with it have been disappointing, except that it is useful at times to lessen the vascularity of the face; but it has seemed to me that this could be better obtained by the use of local sedative and antiseptic remedies in a much shorter time.

When patients will not permit such surgical measures as I have mentioned, a slower course of treatment will have to be adopted. Antiseptic applications must be employed until suppuration ceases, combined with remedies to reduce excessive horny formation and to alter the action of the sebaceous glands.

The frequent and intimate association of seborrheal eczema with acne should direct attention to this condition, and especially after the acne has been cured should treatment be continued against the still existing dandruff. The remedies that will prove of most service will be resorcin, sulfur, boric acid, salicylic acid, chrysarobin—in fact all of those belonging to the class of reducing agents.

In the discussion of Dr. Holsten's paper, Dr. James McF. Winfield said:

The thorough manner in which Dr. Holsten has gone into the subject and the treatment of acne, leaves but very little for me to add, except perhaps a word as to the part genital reflexes play in the production of acne. In writing on acne great stress is put upon disturbances of the gastro-intestinal tract, as the great exciter of this common and exceedingly annoying cutaneous disorder. While the genital organs with their reflexes are to a greater or less extent ignored, I am inclined to the belief that the sexual tract is more likely to reflect its hyperemia on the face than upon any other organ or tract of the body. It is a fact that the simple form of this disease is observed during youth—a time of life when the sexual organs are in a state of unstable equilibrium; and furthermore, rosacea is more frequently observed late in life when the sexual and procreative powers are on the decline. We have all seen an active outbreak of acne on the face of a young woman about the menstrual period, while during the interim she is perfectly free from it. The gynecologists teach us that both acne and rosacea are common accompaniments of various diseases of the female genital organs, and, also, that after the cure of these diseases the acne disappears. American authors have paid more attention to the treatment of acne by remedies directed to the relief of genital irritation than foreign writers. Piffard, Dunslow, and Sherwell have written the most on this line of treatment. Dr. Piffard, in his work on *The Materia Medica and Therapeutics of the Skin*, published in 1881, recommends that strict search be made for sexual causes of acne and the proper therapeutic measures applied. In about the same year Drs. Dunslow and Hyde published their papers on the ergot-treatment of acne. They, however, thought this drug produced its good effect by its tonic action on the non-striated muscles surrounding the sebaceous glands. I have not seen much marked benefit from ergot upon acne in the male subject; but its good effects cannot be denied in certain cases in females when the menstrual functions are irregular; but in these cases the result seems to come from its oxytocic power rather than from any tonic effect on the involuntary cutaneous muscles. I have found it well to give ergot in doses of from fifteen to twenty drops, t. i. d., beginning four days before the expected period. This is given as a supplement to hot vaginal douches.[1] In 1884, Dr. Sherwell read a paper before the American Dermatological Association on "The Treatment of Acne in the Male Subject by the Passage of the Cold Sound." This paper was followed the next year by one by Dr. Dunslow entitled "Urethral Irritation in the Male the Cause of Certain Neuroses, and also of Acne." All of Dr. Sherwell's cases had hypersensitive urethras, while Dr. Dunslow goes a step further and reports cures following the relief of urethral strictures.

I am able to indorse Dr. Sherwell's method, or in fact any other method or treatment that will relieve the genital irritation which is so common in

[1] See paper published in Journal of Cutaneous and Genito-Urinary Diseases, March, 1891.

the disease under discussion. I have had excellent results from the cold sound in the male cases, and also from the hot vaginal douche in the female.[1] And I think it would be well to add to the treatment of acne some means directed to the relief of genital irritation.

THREE SPECIMENS OF TUMORS OF THE HEART: METASTATIC CARCINOMATOUS NODULE IN THE MYOCARDIUM, IMPLANTATION-SARCOMA OF THE RIGHT VENTRICLE, PRIMARY ROUND-CELLED SARCOMA OF THE EPICARDIUM.[2]

By LUDVIG HEKTOEN, M.D.,
of Chicago.

In his recent review of the literature concerning tumors of the heart, Alessandro Tedeschi[3] estimated that about 80 cases have been described, to which number he added three of his own. Martinotti collected 60 cases in 1886, and in 1891 Pil and Bret found 77. The *Index-Catalogue* of the Library of the Surgeon-General's Office at Washington—the volume finished in June, 1884—contains references to 85 cases, and this number does not include echinococcus-cysts, gummata, or tuberculous masses, and the *Index Medicus* from 1885 to 1892 inclusive has references to 21 additional cases, so that it would seem that the grand total at the present time must be about 110 instances. Under any circumstances this will indicate sufficiently well that tumors of the heart are among the rarest of conditions.

The majority of cardiac neoplasms are secondary, consequently, as a rule, either carcinomatous or sarcomatous, the first being the more frequent. It is very seldom that the heart becomes involved by direct extension through continuity and contiguity of tissue on the part either of a sarcoma or a carcinoma of an adjacent organ. The primary cardiac neoplasms are necessarily mesoblastic in origin, and instances of almost all the forms of mesoblastic tumors are described in connection with the heart. Berthensen[4] found 28 primary heart-tumors to include 9 sarcomas, 7 myxomas, 6 fibromas, 3 carcinomas (Krebsgeschwülste, etc.), 2 fatty tumors, and 1 cyst.

I shall describe an instance of each of the following forms of cardiac tumor, namely: A metastatic carcinomatous nodule in the wall of the right ventricle secondary to a medullary carcinoma of the breast; an implantation-sarcoma of the right ventricle, secondary to an osteo-sarcoma of the tibia; and, finally, a primary round-celled sarcoma, originating in the epicardium upon the anterior surface.

All of these cases occurred in the Cook County Hospital, of Chicago, during 1892 and the beginning of 1893.

Case I. *Medullary carcinoma of the breast; general dissemination; nodule in the wall of the right ventricle.*—A woman, fifty years of age, died from an ulcerated medullary carcinoma of the right breast. The post-mortem showed metastases in the lungs, the peritoneum, the liver, the Fallopian tubes, the uterus, and the pericardium. In the wall of the right ventricle at the right border was a mass 4 x 3 x 2.5 cm. in size, situated beneath the pericardium, and projecting up into the wall of the auricle; it was surrounded by large vessels, was very firm, grayish-white, and infiltrating; and in the immediate vicinity were smaller masses. The endocardium was not changed.

Manifestly, this metastasis occurred through the coronary arteries during the process of general dissemination.

Case II. *Spindle-celled osteo-sarcoma of the tibia; implantation-sarcoma of the right ventricle; extensive pulmonary dissemination.*—The following is an extract from the clinical record: A boy, twelve years old, was sent to the hospital with the diagnosis of osteo-sarcoma of the upper end of the left tibia. Disarticulation through the knee-joint was performed in January, 1892. In February recurrence took place at the lower end of the femur, and on May 14th disarticulation at the hip was performed. The patient was discharged four weeks later in good condition, but was readmitted July 30, 1892, into the service of Dr. C. A. Earle, on account of shortness of breath, nocturnal cough, and loss of flesh and of appetite. The examination then showed: Anemia; no local recurrence; the left chest moved less than the right; there was dulness on percussion over the upper third of the right lung, and over the middle third of the left posteriorly; bronchial breathing and resistant bulging of the intercostal spaces were present. The bones and joints, as well as the abdominal organs, were apparently normal. On August 4th the area of dulness over the left lung had extended downward. There was no palpable apex-beat, but epigastric pulsation could be made out; the sounds were rough, the first sound being almost changed into a murmur. On August 8th flatness was noted over the entire left lung, the heart's dulness not being distinguishable. The intercostal spaces were bulging over the flat areas. The sputum contained large, nucleated cells, but no tubercle-bacilli (ten slides, Dr. Eastman). Weakness and dyspnea increased, and death occurred August 14th, about eight months after the appearance of the first swelling upon the left tibia. The clinical diagnosis was secondary pulmonary sarcoma.

The post-mortem examination showed no recurrence in the tissues about the hip; the sciatic nerve presented microscopically an amputation-neuroma.

[4] Virchow's Archiv, Bd. cxxxii, H. 3.

There were no growths in any of the vessels below the heart or in any of the abdominal organs. Externally the heart presented an unusual prominence along the right ventricular border, which could be felt to be due to a nodular growth in the right ventricle. The heart weighed 250 grams. It was found that from the wall of the right ventricle along the right border sprang a lobulated mass of white, hard tissue which formed an intra-ventricular, nodular growth filling very nearly the whole cavity, projecting up underneath the tricuspid valves, and leaving only the upper part of the ventricle free to transmit the blood into the pulmonary artery. This mass was grayish-white, firm, containing in some places hard bony masses; it extended in between the muscular trabeculæ and down into the myocardium of the ventricle; the free surface was smooth, nodular, free from thrombotic deposits and from evidences of surface-disintegration. Otherwise the heart was normal. In spite of the manifest stenosis of the tricuspid orifice there was no hypertrophy or dilatation of the right auricle.

The lungs were of increased volume and weight, filling the chest to distention. They contained huge masses of whitish-gray tumor-tissue, which in some places grew into the bronchi, which thus communicated with foci of mucoid degeneration; these masses crowded the pulmonary parenchyma in all directions; they were sharply defined, almost encapsulated, in places undergoing mucoid degeneration, but mostly dense and hard, containing distinct osteoid districts that nicked the knife and scratched the palpating finger. The microscopic diagnosis was: Small spindle-celled osteo-sarcoma of the heart and the lungs. The structure was so typical as to render any detailed description quite unnecessary. In some places mucoid degeneration was present. Islands of osseous tissue were present in the cardiac as well as in the pulmonary growths.

It is to be regretted that a very minute and painstaking examination of the heart was not made during life, with a positive diagnosis of its condition in view, because it does seem probable that under the circumstances an approximately correct opinion could have been reached, although it must be acknowledged that the pulmonary lesions presented overwhelmingly prominent symptoms and signs. Thus the heart's dulness could not be distinguished on account of the adjacent pulmonary tumor-masses.[1]

The absence of hypertrophy of the right auricle, which the anatomic condition seems to have rendered unavoidable, may be quite rationally explained as due to the increasing cachexia, which is in accordance with the views generally held as to the absence of cardiac hypertrophy under analogous local and general states. Then again the marked diminution in the size of the cavity of the right ventricle may in part explain the absence of the hypertrophy, as the blood was probably forced directly through the upper part of the ventricle into the pulmonary artery.

Osteo-sarcoma of the right ventricle, due to implantation, and secondary to osteo-sarcoma of left tibia. (Case II.)

Another very interesting feature in this case is the mode of formation of the metastasis in the right

[1] Berthenson's article, "Zur Frage von der Diagnose primärer Neoplasmen des Herzens," loc. cit., covers this portion of the subject thoroughly.

ventricle. The metastatic process was confined entirely within the limits of the lesser or pulmonary circulation, into which sarcomatous emboli were introduced from the primary or the recurrent tumors in the left lower extremity through the blood-current in the ascending vena cava. In reality, the metastasis in the right ventricle depended either upon implantation upon the endocardium of sarcoma-cells coming directly from the primary or recurrent tumors, or it was due to infection carried back again from the secondary pulmonary growths. Sarcomatous emboli from the lungs might under favorable circumstances reach the right ventricle along either of the two following routes:

1. Through the pulmonary veins, the left auricle and ventricle into the coronary arteries, lodging in the capillaries of the myocardium; this route brings the systemic circulation into play, and in the absence of generalization of the secondary tumors, which would seem well-nigh unavoidable under these circumstances, any further discussion upon this particular point is unnecessary.

2. Through the bronchial veins, the vena azygos major and the superior intercostal vein, the superior vena cava, into the right auricle and ventricle, endocardial implantation of the sarcoma-cells leading to the formation of the large metastatic growth. Consequently there is practically no other explanation to be offered of the mode of growth of the tumor in the right ventricle in this case than by implantation directly upon the endocardium of sarcomatous cells or a mass coming through the inferior cava from the primary or recurrent tumors, or through the superior cava from the secondary pulmonary growths. In all likelihood the implanted cells came directly from the tumors in the extremity, along with the other emboli which were carried directly into the pulmonary capillaries. Of course it is not at all impossible that the implantation-sarcoma in the right ventricle distributed cells and masses into the lungs from time to time.

The instructive observations of a number of pathologists showing free tumor-cells and particles in the blood have, of course, a very direct bearing upon the question of growth from endocardial implantation. Bozzolo found tumor-particles in cruor masses in the right ventricle; v. Recklinghausen found sarcoma-bits in the right ventricle growing upon the endocardium between the papillary muscles; and Rieder, Weber, Lücke, Paulicki, Birch-Hirschfeld, and Laveran are cited by Tedeschi[1] as having made similar observations. Tedeschi himself studied an instance of recurrent round-celled sarcoma of the thigh, during the growth of which there developed some 300 metastases, and he found in the clots in the heart-cavities numerous white particles consisting of tumor-cells; in this case the heart contained innumerable metastatic nodules, and he very properly regards the cell-masses in the blood as indicating the mode of dissemination.

In this case, then, the course of events may be outlined in this way:

1. Primary, small spindle-celled osteo-sarcoma of the tibia; recurrence in the stump after amputation through the knee-joint in January, 1892.

2. Dissemination into the pulmonary circulation before disarticulation at the hip, *i. e.*, some time before May 14, 1892.

3. Death from pulmonary and right intra-ventricular metastatic sarcoma, August 14, 1892.

4. The growth in the right ventricle came from direct implantation of sarcoma-cells upon the endocardium, and subsequent development in the direction of least resistance, *i. e.*, out into the cavity and between the muscular tabeculæ.

Case III. *Primary round-celled sarcoma of the epicardium.*—An American Indian woman came into the Cook County Hospital moribund and died without a clinical record of any kind being obtained, except that she was fifty years old. She was quite well nourished. The post-mortem examination showed a fatty liver, pulmonary emphysema, and chronic nephritis. The following is a description of the heart: There is firm and complete pericardial obliteration; after carefully removing most of the parietal pericardium and cutting off the vessels near the base of the heart, a mass including a tumor which weighs altogether 448 grams remains. Situated upon the anterior surface of the heart is a tumor, shaped something like a cone, the base being the upper, and the apex the lower limit; the long diameter from base to apex is 8 cm., and the diameter of the base itself is 7 cm.; the interventricular septum passes under the center of the mass, which considerably overlaps the commencement of the pulmonary artery. This tumor appears to spring from the epicardium, and between the posterior surface and the myocardium proper is a layer of yellow fat, while the connection with the pulmonary artery is quite intimate. Externally the mass is covered by a thin layer of fibrous tissue—the epicardium—except posteriorly, where the capsule is continuous with the rest of the epicardium. The growth is quite firm and a little lobulated. Its cut surface is grayish-yellow, smooth, glistening, and homogeneous; large blood-spaces appear in the section. Internally the heart is quite normal, there are no endocardial changes, and the ventricular cavities and walls are not larger or thicker than normal.

There were no growths in any of the other organs examined, but unfortunately the investigation as to this point was not quite thorough enough, as it did not include the intestines and the brain, bones or joints.

Microscopic appearances. At the periphery of the mass is a quite thick layer of fibrillated connective tissue, in which are many large and irregular

[1] Loc. cit.

spaces, partly or wholly filled with blood. From this capsular layer of fibrous tissues, interlacing bands of varying width pass into the tumor proper, forming spaces of different sizes. The tumor is otherwise made up of round cells, reproducing quite typically the small round-celled sarcoma. The cells are, comparatively speaking, small, with large nuclei that stain deeply. In many places the tumor consists of diffuse areas of infiltrating round cells, separated by a faint and delicate intercellular network; in such districts, small, thin-walled blood-vessels containing blood occur occasionally. In other places again the spaces alluded to are filled closely or loosely with the round cells, and here the appearances are not at all unlike those seen in sections of certain carcinomas, but there is usually an intercellular network to be made out connected with the grosser bands of fibrous tissue. There is no pigment present. In conclusion it may be said that this tumor in part presents the structure of a small round-celled sarcoma, in part that of the so-called lympho-sarcoma.

This then is without much, if any, doubt a primary sarcoma of the epicardium of the anterior surface of the ventricles, and it is interesting not so much on account of its structure as on account of its very unusual point of origin, namely, the sub-epicardial areolar tissue.

In this case it is also exceedingly regrettable that a thorough physical examination could not be made, because it would have been very instructive to have a record of the physical signs presented on the part of the heart. Here again there is noted absence of hypertrophy and dilatation of the heart, although the weight of the tumor itself, as well as the pericardial adhesions, would seem to be ample causes of increased labor for the heart. The post-mortem examination did not disclose any satisfactory explanation of the absence of hypertrophy.

COLUMBUS MEMORIAL BUILDING.

CLINICAL LECTURE.

CARCINOMA OF THE UTERUS.

A Clinical Lecture delivered at the Philadelphia Hospital, October 7, 1893.

BY E. E MONTGOMERY, M.D.,
PROFESSOR OF CLINICAL GYNECOLOGY, JEFFERSON MEDICAL COLLEGE; GYNECOLOGIST TO JEFFERSON AND ST. JOSEPH'S HOSPITALS; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL.

GENTLEMEN: The case I bring before you this morning is a woman with the following history: She is fifty-two years of age, married, and the mother of seven children. Her mother died from some uterine disease after a year's sickness. She menstruated regularly, excepting as interrupted by gestation and lactation, until forty-five years of age, when she had an attack of typhoid fever and the menses never subsequently reappeared. She had had a profuse leukorrheal discharge for a number of years; had been treated at one time for uterine disease; and after the birth of her last child, some twelve years ago, she was operated upon for a lacerated cervix. In the last two years the discharge has been more profuse and has had quite an offensive odor. Eight months ago, after lifting some heavy weight, she had an attack of flowing, and since then she has had repeated attacks of hemorrhage. She entered the hospital a few weeks ago for treatment.

Taking such a history you will, I am sure, come to the conclusion that this patient is suffering from a grave constitutional condition. Introducing my finger into the vagina it comes in contact with nodular projections, more marked on the anterior wall, and as the finger passes up I find that the whole of the anterior wall of the vagina is involved, producing marked thickening, with irregular projections. This extends up to the uterus. The uterus itself and the upper part of the vagina are one mass of diseased tissue. I am unable to show you this, because the mere introduction of the speculum to separate the parts and expose the vaginal walls, would result in a great deal of pain to the patient, probably also in a profuse hemorrhage that would require tamponing to control it, so that the slight information a few of you would derive by such exposure would not justify the discomfort to her.

I have sent the patient out, for the reason that I do not wish to discuss before her the gravity of her symptoms. You will have noticed that her face was pale, anemic, and of a dirty-straw color. She has lost flesh and strength and suffers continuously. This is a case of unquestionable epithelioma of the uterus and vagina. In such a case, having reached the development it has in this patient, there is no condition with which it could be confounded. Consequently the diagnosis is rapidly made.

This class of cases is among those in which it is extremely important that an early diagnosis should have been secured, for if the disease is permitted to continue until it has reached the stage it has in this patient, there is but one inevitable termination. Our hands are practically tied, and we can accomplish nothing more than to palliate the more unpleasant symptoms. I cannot too strongly urge upon you the importance of careful examination in every case in which there is reason to suspect malignant disease; even under the best circumstances the disease is so insidious in its onset that it may have reached a serious stage before the patient comes under our observation. Then, too, the natural modesty of the patient compels her to neglect consulting the physician as long as she possibly can; and with the belief of many patients that they must undergo certain marked phenomena at this period of life, they wait, hoping that the unusual phenomena are but the premonitory symptoms of the climacteric period. It is to be regretted, but fortunately not so frequently as formerly, that many physicians console their patients at such times with this hope, and fail to subject them as they should to a careful examination, to determine the cause of the condition. Let me impress upon you the importance of making a careful examination, if necessary, at the price of your continued attendance upon the patient, for you cannot afford to go on in attendance upon a patient when you suspect the possibility of a grave disease and do not have the permission to make the necessary examination to determine its existence. It

is far more dignified and more to your credit to absolutely decline to continue in your attendance upon a patient who will not submit to necessary examination.

What symptoms should lead us to suspect that malignant disease is present in any individual case? The symptoms that are in every case most marked and that should arouse suspicion, are hemorrhage, pain, and offensive discharge. These symptoms are not present in every case, nor do they occur in regular order. Pain may be entirely absent during the entire progress of the disease, and in some cases only marked in the later stages. In some patients the first symptom will be a smart hemorrhage; in others a profuse watery discharge will exist for a length of time. Malignant disease is most likely to occur at or near the climacteric, so that age is to be considered in eliciting the history and in leading us to suspect such disease. It is well, however, to keep in mind the fact that it is not confined to any particular age, as I have seen cases of as serious disorder in women of but twenty years of age as in the patient whom I have just shown you. It is also more likely to occur in women who have borne children, as a result of the injuries to which the cervix is subjected during the progress of parturition. It may occur in women who have borne no children, or in the unmarried. In the latter, however, it is more likely to affect the mucous membrane of the body of the organ. The site of the disease is usually the cervix; in fact, it occurs in the body of the organ in only about 2 per cent. of the cases in which the uterus is involved. We can understand why the cervix should be the part affected, for the reason that it is the portion of the uterus that is most frequently subjected to injury during parturition, and in which the injury is likely to produce the greatest amount of subsequent irritation.

Generally the earliest symptom is an increase of bleeding during menstruation; or, a patient may suffer from slight discharges of blood, or from a leukorrheal discharge streaked with blood, during the menstrual intervals; or, a patient who has ceased to menstruate may after months, or even after years, be taken after a little exertion with a smart hemorrhage. This may subsequently recur at frequent intervals, and finally there may be a continuous bloody discharge. Another early symptom is the offensive discharge. This is thin and watery in character, having the odor of decomposing tissue. Pain may occur early in the disease, and is more likely to be present in those cases in which the cervix becomes extensively infiltrated, the infiltrate causing pressure upon the terminal nerves.

Pain, hemorrhage, and profuse discharge soon lead to emaciation and loss of strength. The means that are taken to allay the pain produce interference with general nutrition, causing the patient to rapidly break down. You must keep in mind the fact that the disease in its origin is a local one, and if we are enabled to remove it before the constitutional symptoms have developed, or before the disease has passed beyond its original site, we may feel hopeful of securing a radical cure. The progress of the disease, however, is so insidious, and it is so difficult to determine when the disease-agency has been carried from the source of origin, that it is not wise in the individual case to promise certain relief. In some cases in which the disease is extensive in character, you will find that an operation results in cure, while in others with apparently but slight involvement there will be a recurrence. The occurrence of any of the symptoms mentioned, or of hemorrhage in any patient, should be an indication for most thorough physical examination.

You will ask: Is there any condition that may be mistaken for carcinoma, or with which the latter may be confounded? By physical examination we usually find that the disease has begun on one or the other lip, or near the canal of the cervix; that it has resulted in hypertrophy of the papillary layer, cellular infiltration, and the development of tissue that is extremely friable, that breaks easily under the touch, with consequent hemorrhage. When the disease has existed for a length of time, this tissue may break down, leaving an ulcerated or excavated cavity covered with a foul, disagreeable discharge, from which hemorrhage is likely to result. In other cases we may find marked hypertrophy of the tissue and the formation of cauliflower growths, which are very friable and break down under the touch, causing profuse bleeding. In the majority of these cases we must make our examination by the touch. When the uterus is extensively diseased, the introduction of the speculum is likely to result in bleeding. In the early stages of the disease, if we are in doubt as to the condition, the diagnosis may be confirmed by removing a section of the tissues and subjecting it to microscopic examination. In a case in which hemorrhage occurs, if it is found that the cervix appears healthy, but that the bleeding still continues, the uterus should be carefully dilated and its cavity explored, with the finger if necessary, to determine the cause of bleeding.

Thus we recognize that hemorrhage may result from a variety of conditions, and that it is not always necessarily an indication of the existence of malignant disease. Thus, it may take place from a hemorrhagic endometritis, from interference with the circulation, as in the uterus, from disease of the ovaries or pelvic exudation, the presence of ectopic gestation, or growths within the walls of the uterus itself. Thus a woman suffering from a fibroid growth may have the circulation interfered with to such a degree as to lead to partial sloughing, to ulceration of the mucous membrane, to sloughing of the superficial tissue, or to necrosis of the entire mass. In such cases we would necessarily have profuse offensive discharge. We shall have the patient suffering from symptoms of septic absorption. The dilatation of the cervix to permit the introduction of the finger will readily disclose the character of the condition. Sloughing fibroids will still be of sufficient resistance and tenacity to prevent breaking down under the finger, while in carcinoma or epithelioma of the uterus the surface will be infiltrated, giving the sensation of possible sloughing, the friable mass resting upon a firm, indurated base.

Having had our suspicions of malignant disease confirmed by examination, it now becomes a question of what shall be done in order to afford the patient immunity against its return. A variety of operative procedures have been suggested, some amputating the cervix by either the knife or the scissors, or by the galvano-cautery, as has been recommended by Byrne, of Brooklyn. Another operation is that devised and recommended by Baker, of Boston, which consists of high amputation of the cervix, amputating it flush with the

attachments of the vagina anteriorly. These operations, however, will remove only a portion of the cervix. We must remember that the disease extends continuously and contiguously. If the smallest portion of the tissue is left in which malignant cells have wandered, there will be a return of the disease, and the outlook is consequently bad. For this reason it has been my habit to urge that in every case in which the disease is confined to the uterus the operation shall be extirpation of that organ. I believe that this is as thoroughly indicated in carcinoma of the uterus as would be the removal of every vestige of the mammary gland if one lobe was involved in malignant disease. In studying the indications for any operation we have to consider it from different standpoints: First, with reference to the influences upon the patient, and to the unmolested continuation of the disease, and, secondly, as to the mortality of the operative procedure proposed.

As to the patient, we have in this condition a disease in which the outlook for the patient is bad. We have as yet been able to obtain no remedies that have any marked influence upon the progress of the disease; consequently constitutional measures are ineffective. The patient is absolutely doomed unless a radical operation can save her. Even this would not justify the performance of an operation of a grave character, one in which the chances for the return of the patient to health are meager. Removal of the uterus has not proved a very dangerous procedure. It has been my good fortune to operate in twenty-one cases with but a single death, and a mortality so slight as this does not indicate that the operation is an exceedingly dangerous one. The indications for the operation may then be considered to be, first, the existence of malignant disease in any portion of the uterus, however slight, providing the uterus be still movable; second, the mere existence of fixation of the uterus need not necessarily be considered a contra-indication to operation, as this fixation may be due to inflammatory rather than to malignant infiltration, and the malignant disease may be secondary to the inflammatory condition; indeed, the implantation may be upon a soil better fitted for its development by the previous inflammatory disease. We may be able to determine by careful examination whether the fixation is due to inflammatory exudate or to malignant infiltrate. This is accomplished by making a rectal examination, which should be a part of the routine in every first examination. Examining through the rectum, we may find that although the disease is extensive in character, the mucous membrane is movable from the mass of exudate. In malignant disease, however, it will be found that the mucous membrane is not movable, but is fixed. The tissue infiltrates it, giving rise to a hard, rigid surface. Then, too, in the case of infiltration, it will be found that the surfaces are uneven, not smooth and regular in outline, as will be the case with exudation.

When we come to the consideration of the operation itself, we have a variety of methods of procedure, some operators preferring, in removal of the uterus, that the broad ligaments shall be ligated in sections, others advocating ligation *en masse*, and some advocate stitching the peritoneum to the vaginal wall as the operation proceeds. Others stitch the peritoneal surfaces together, others the peritoneal surface and the vaginal surface separately; some use drainage, others none; some preferring drainage by means of tubes, others by gauze. By some the broad ligament is ligated, and each section cut off, allowing the last portion to be drawn further down; some, instead of drawing the uterus straight down, invert the fundus forward; others invert it backward; then tying off the uterine and ovarian arteries on either side, the uterus is cut away. In all the operations that I have performed I have preferred to use the clamp.

The method of procedure is as follows: First, the patient is thoroughly prepared for the operation by frequent vaginal irrigations; from several days to a week before the operation the uterus itself, with as much diseased tissue as possible, is carefully curetted, the diseased prolongations cut away, the vagina cleaned and packed with iodoform-gauze. This may be repeated at intervals of two days for a week before the operation is attempted. In beginning the operation the cervix is seized with a pair of strong volsella forceps, and for this purpose I prefer those instruments having four prongs to the blade. They are much better than the two-pronged instruments, because, in having a firm instrument like this, it is certain to seize some healthy tissue and will consequently promote this being drawn down. The cervix is then encircled by a knife, and the vaginal mucous membrane cut through as far away from the surface of the disease as the position of the bladder and orifice of the urethra will permit. Having cut through the mucous membrane, we then dissect up with the fingers, pushing the bladder until we reach the peritoneum posteriorly. We also push the tissues off until the peritoneum is reached, when the latter is grasped with hemostats and incised, the opening torn larger, and a sponge with a string attached is passed through it into the peritoneal cavity, to hold up the intestines and also to prevent them from being soiled by the bladder discharge. The peritoneum is then opened anteriorly, the uterus now remaining attached by the broad ligament on either side. With a pair of modified Greig-Smith clamps one blade is placed behind the broad ligament and the other in front, the clamps screwed down until the tissues are firmly held and are crushed in the grasp of the clamp. With the clamp applied upon one side the uterus is then cut off, leaving the clamp in place. This permits the uterus to be dragged down and delivered. The large second clamp can be applied with much less difficulty outside. Having clamped the second broad ligament, the uterus is cut away and the clamp is then replaced in the vagina, projecting into the abdominal cavity. The parts are irrigated with hot water, dried with sponges, the abdominal sponge is removed, and a piece of iodoform-gauze is carried over the end of each clamp to keep the intestines away from it, and also to prevent them from coming in contact with the denuded surfaces, which would result in improper union and in subsequent contraction, or possible obstruction of the intestine. This method of procedure has the advantage that it is expeditiously carried out; that there is no danger of the ligature slipping and hemorrhage taking place; that free drainage is afforded, and the clamps may be removed at the end of twenty-four hours without fear of hemorrhage. The drainage is free in such patients, convalescence is usually undisturbed, and if antiseptic or aseptic precautions have been observed the recovery is usually uninterrupted. In the patient we had before you to-day,

however, no such plan of treatment can be exercised. By no operative procedure can we hope to remove the entire disease. To accomplish its complete removal would necessitate the removal of the septum between the vagina and the bladder, and the removal also of the posterior wall, so that it is not worth while attempting a dangerous operation which can by no means be a radical one.

CLINICAL MEMORANDUM.

A CASE OF DEPRESSED FRACTURE OF THE SKULL IN A CHILD, WITH AN ENORMOUS CLOT; OPERATION; RECOVERY.

By WM. N. JOHNSON, M.D.,
of Germantown, Pa.

Sallie R., eleven years of age, was admitted to the Germantown Hospital on Saturday, July 29, 1893. Two days previously she had fallen from an apple-tree a distance of fifteen feet, and struck directly on her head, and immediately became unconscious. How long this primary unconsciousness continued is not definitely known, for after a time she recovered sufficiently to walk to her house, about five hundred yards distant. While there, she again became unconscious, and a physician was summoned, who did not recognize her true condition until Saturday morning, when he advised removal to the hospital. Upon admission, the following condition was present: The temperature was 97°, the pulse 135, the respiration 26. There was total unconsciousness, even to absence of the conjunctival reflex. Ptosis of the right eyelid was present, and the right pupil was widely dilated and insensible to light. The left pupil was normal. Urine and feces were passed involuntarily. I am unable to state whether there was hemiplegia or not, as owing to the precarious condition of the patient, examination in this direction was not pushed.

When the child's head was shaved, a large depression over the right side, between the frontal and parietal eminences, could be made out, although no external wound was visible.

No anesthetic being required, and with antiseptic precautions, an incision about three inches in length was made over the central portion of the depression, and a large stellate fracture, involving the lower border of the parietal bone, and the adjacent portion of the temporal bone, was revealed. With a thumb-gouge, an opening large enough to admit one blade of the rongeur forceps was made, and with this latter instrument three square inches of bone were removed, disclosing a large clot between the dura and the bone. This clot was so extensive, being fully the size of a seven months' placenta, that it was necessary to remove it piecemeal, and in order to do this, a considerably larger quantity of bone had to be chiselled away. When the clot had been entirely extracted, the space left was large enough to allow the hand to sweep downward as far as the orbital plate of the frontal bone, and upward to the longitudinal sinus. The brain-substance did not expand after the pressure was removed, and there was considerable capillary oozing from all that portion of the dura underneath the clot. To control this the cavity was thoroughly washed out with a hot solution of boric acid (gr. x : ℥j) and afterward filled with a 25 per cent. solution of boroglycerid, which was allowed to remain.

At this time the patient's condition seemed hopeless, the pulse being 178 and the heart-sounds barely perceptible. Two large drainage-tubes were introduced into the wound; the scalp was rapidly approximated by means of four or five silk sutures, a large antiseptic dressing applied, and the girl was put to bed, surrounded with hot-water bottles, and a hypodermatic injection of strychnin, gr. $\frac{1}{30}$, administered.

At 3.30 P.M., half an hour after the completion of the operation, the pulse was 130, the respiration 34, and the temperature 101.4°. One hour later the girl opened her eyes, recognized her father, and complained of pain. At midnight she was perfectly conscious, and passed her discharges voluntarily. She was given calomel in one-tenth-grain doses every half-hour, and strychnin sulfate hypodermatically, gr. $\frac{1}{30}$, every third hour, with milk-diet, and whiskey in moderate quantities.

The following day she complained of "seeing everything double." The right pupil was still widely dilated, but responded slightly to light. Ptosis of the right lid continued. At the end of the second week diplopia had disappeared, and the ptosis was markedly improved, although the dilatation of the pupil still continued.

The greater portion of the wound healed by granulation. The temperature never exceeded 101.4°, and this was immediately after operation, and the pulse dropped from its highest point—178, during the operation—to 81, on the third day, and remained there.

Then followed an excellent and uninterrupted recovery, and the child was discharged cured on September 9th, six weeks after operation. On September 15th there was still a slight dilatation of the right pupil. The wound was entirely healed, with the exception of one small sinus, and considerable regeneration of bone had taken place. On October 30th the wound had entirely healed, pulsation of the brain being distinctly visible over the scalp. There are no symptoms at present, except possibly a little slowness of mental activity.

5346 Main Street.

MEDICAL PROGRESS.

Transient Bilateral Amaurosis following Concussion.—Sealy (*British Medical Journal*, No. 1711, p. 843) has reported the case of a boy who, while working in a coal-pit, was struck on the back of the head by a lump of coal and was insensible for about ten minutes. On regaining consciousness he noticed that vision was poor in the left eye and a half-hour later the eye was completely blind. When seen, some two hours after the accident, vision was also lost in the right eye, although light-perception remained. The eyes appeared normal and the pupils reacted to stimulation. No fracture of the skull could be detected. A purgative was ordered and it was directed that the boy be put to bed. Several hours later, the right eye, like the left, had become completely blind. Small doses of potassium iodid were prescribed. On the following day the condition was unchanged, but on the next day light-perception had returned to the left eye. A day later objects became distinguishable to the left eye, and the right was capable of recognizing light. On the fourth day vision was per-

fect in the left eye and almost so in the right. On the sixth day the boy was in quite as good a condition as he had been before the accident, and so continued.

Anuria from Compression of the Ureters by a Uterine Fibroid Relieved by Operation.—TUFFIER (*La Semaine Médicale*, 1893, No. 59, p. 468) has reported the case of a woman, forty-eight years old, who came under observation on account of retention of urine of three days' standing, together with a history of having had a subperitoneal uterine fibroid removed two years previously. There was also constipation. The introduction of a catheter showed the bladder to be empty. Vaginal examination disclosed the presence of a tumor wedged in the pelvis and obviously compressing the ureters and the intestines. In view of the gravity of the situation and of all of the circumstances, abdominal hysterectomy was undertaken and successfully carried out. Urine began to flow on the following day, and by the fifth day the state of the urinary secretion had become normal. Barring the temporary persistence of a small fistula the post-operative course of the case was uncomplicated.

Spontaneous Rupture of the Heart.—DEANE (*Australian Medical Journal*, No. 9, vol. xv, p. 471) has reported the case of a woman, seventy years old, who, in ordinary health on retiring at night, was found dead in bed in the morning. She had had an attack of influenza more than a year previously, and had never afterward felt well. For some time there had been attacks of faintness on slight exertion. Upon post-mortem examination the left pleura was found filled with serum and presenting extensive adhesions. The base of the left lung was congested. The pericardium contained a large clot, on removal of which a ragged rent was found at the apex of the left ventricle, large enough to admit the tip of the little finger. The muscular structure of the entire heart was of a putty-like color and exceedingly friable. The valves were normal. Around the rent and extending for a distance of one inch from it, there was a tumefied, dark-red infiltration of the muscular tissue.

A Hitherto Undescribed Symptom of Complete Facial Palsy.—At a recent meeting of the Ophthalmologic Society of Heidelberg, GOLDZIEHER (*Centralbl. f. Nervenheilk. u. Psychiatrie*, October, 1893, p. 478) expressed the opinion that the teaching that the trigeminus is the secretory nerve of the lacrymal gland is not to be depended upon, as this function belongs to the facial nerve. The fibers that transmit the necessary impulses enter the spheno-palatine ganglion with the nervus petrosus superficialis and pass hence in the temporo malar nerve. In case of a lesion seated in the bony canal and at the level of the geniculate ganglion, and attended with complete palsy of the seventh nerve, including the veil of the palate, there follows a suppression of the lacrymal secretion and a cessation of the reflex flow of tears.

Angina due to Oidium Albicans.—BRANDENBURG (*Corr.-bl. f. Schw. Aerzte*, 1893, No. 20, p. 709) has succeeded in demonstrating the presence of oïdium albicans in the whitish deposits in two cases of angina in adults. Both cases presented mild fever and dysphagia, as well as gastric derangement. The small punctate deposits presented on microscopic examination a large number of bright spores and long mycelial threads. In one case the morbid process remained confined to the vault of the palate and the uvula; in the other the deposits extended to the gums. The covering of the tongue and the lining of the cheek escaped. Therapeutically, potassium chlorate was employed as a gargle, and topical applications of dilute tincture of iodin were made.

THERAPEUTIC NOTES.

For Parenchymatous Metritis.—CHERON (*Medical Press and Circular*, No. 2840, p. 375) recommends the following line of treatment: The nourishment should consist of two quarts of milk in small quantities, frequently repeated. For the relief of pain and the reduction of temperature five grains of phenacetin may be given every six hours, and hot antiseptic fomentations applied to the abdomen as follows: A large layer of cotton is plunged into hot water, wrung out, sprinkled with from forty to fifty drops of tincture of opium, placed upon the abdomen and covered with a layer of oiled silk. This application is to be frequently renewed night and day. The following ointment is rubbed into the lumbar region:

℞.—Salicylic acid . . . . . ʒj.
Lanolin . . . . . ʒj.
Essence of peppermint . . . ♏iv.
Lard . . . . . ʒjss.—M.

As soon as the patient can bear it, a hip-bath of warm starch-water is given twice a day, and also a vaginal injection of a 3 per cent. solution of boric acid. Subsequently antiseptic vaginal suppositories are used to complete the cure.

Spleen-feeding in the Treatment of Lymphadenoma.—BLOMFIELD (*British Medical Journal*, No. 1712, p. 889) has reported the case of a boy, twelve years old, with lymphadenoma, in which during the last month of life a spleen, grilled slightly, over which fresh marrow was melted in lieu of butter, was daily administered with the food. The general feelings were much improved, the chief difficulty being to find a comfortable position, in consequence of the great size of the spleen and the lateral displacement of the head from the mass of glands in the neck. The spleens were generally those of sheep, and were obtained as freshly as possible. It is not suggested that life was prolonged in consequence of the treatment, but it is believed that the general condition was ameliorated and death made easier.

For Psoriasis.—JAMES (*British Medical Journal*, No. 1712, p. 889) recommends the employment of a solution of chrysarobin in chloroform (1 to 7), to which a suitable amount of oleum deelinæ (an equal amount or less) is added, the whole being stirred with a hog's-bristle shaving-brush. With this mixture the diseased area is well scrubbed.

For Undue Sweating.—OLSZEWSKI (*Centrabl. f. d. ges. Ther.*, ix; *Corr.-bl. f. Schw. Aerzte*, No. 20) recommends fluid extract of hydrastis canadensis. In mild cases a single dose of from 20 to 30 drops at night suffices; in more aggravated, from 25 to 30 drops, three times a day, for several successive days will be required.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 18, 1893.

FOOT-BALL.

To one who is not bereft of reason and moderation by the "rush-line" of a popular craze or fad, it is simply astonishing to witness the excesses permitted—nay, encouraged—in the name of athletics and education, by the foot-ball enthusiasts.

Note, first, the clear trend of the whole affair toward professionalism, including betting and gambling. It is simply absurd to longer shut one's eyes to this fact. Pseudo-educators and wild enthusiasts may deny or seek to ignore it, but it is fast becoming an open secret that men are making a livelihood by the game, that sometimes their expenses in college are paid for the purpose of winning match-games and that betting on the results of the matches is growing more and more common. Now, a frank, out-and-out professionalism in athletics is not so bad a thing, if the game be truly an athletic and hygienic one, and not brutalizing to mind or body. But one who to any small extent is aware of the way collegiate politics are becoming bound up with semi-professional foot-ball politics must deplore the malevolent influence of the game upon modern educational tendencies.

And, in the name of education—what a farce! Can any sane man deny that in founding, endowing, and encouraging institutions of learning, the object is to fit men for the intellectual battles of life? Can he deny that the training and development of the muscular system, desirable as it is or may be—and there is only one thing that is more desirable—should be subordinated, as a feeder and supporter to mental athletics? Finally, can it for a moment be denied that the student who is a foot-ball enthusiast, whether player or "howler," is nowadays giving a disproportionate amount of his time and interest to the game rather than to his studies? Does the collegiate foot-ballist desire rather to stand at the head of his class, school, or country, as the best-educated man, or to win the applause of 20,000 spectators, and to have his hideous picture and his biography spread before the readers of every daily paper as one of the winning team in a match-game?

What do professors and educators mean who encourage such a tendency? It is either an undignified renunciation of their proper office and function in favor of the professor of athletics and physical training (would it were even so good a thing as that!), or it is a concession to a low type of collegiate politics, and to an irrational fashionable fad.

Do they not suspect that they are raising a ghost that they cannot "lay" again? Wise educators are to-day frightened at the influence of the foot-ball problem, and are seeking earnestly to check the fatal tendency to rowdyishness and coarseness following necessarily and closely upon such practices and abuses of the game-instinct.

We are well aware of the favorable statistics the enthusiasts offer as to the influence of athletics on education. There are two fallacies in them: 1. Foot-ball is not athletics, and the influence of this game will soon reduce the good average as shown by and due to athletics proper. 2. The statistics are gathered and offered by the enthusiasts of the game.

In the name of universal and of university gymnastics—what a farce! Instead of carefully training each and every student physiologically and systematically, so that his bodily defects shall be corrected, and so that his body shall be a supple, strong, and beautiful servant of the mind, there is a concentration of all training upon one man out of a hundred, for a special and not by any means beautiful purpose. Ninety-nine let one do their exercising (excepting the vocal part!) for them, and we have the noteworthy result—vicarious athletics, or gymnastics by proxy. Athletics by proxy can only be compared to religion by proxy—the plan of some religious sects that hire a few professionals to do

their worship for them—they, the passive audience, watching the performance. The aim of educators, so far as it relates to athletics, should be to give every student a rounded harmonious physical organization, not to train a dozen or two dozen semi-professionals (sometimes wholly professional except in name), hired, bribed, or wheedled to attend the institution, to be a show-team, and win matches in order to attract students to the institution. The college that has not a splendid gymnasium, large enough for every one of its students and a compulsory system of physical training for each has little just claim upon parents or the public. The wise father, other things being equal, will send his son to the college that has the best general gymnasium and the poorest record in winning public athletic games.

In the name of esthetics—what a farce! What a remarkable spectacle is that of a quilted, bepadded, dishevelled, long-haired, begrimed, scarred foot-ball hero who finds glory in a savage's scrimmage in the mud! A sane and healthy enthusiasm and love for athletic excellence must have some artistic touch to it. How would the hero of the games of classic Greece at the height of that nation's splendid athletic development compare with our bruised and dirty hero of the foot-ball field?

In the name of hygiene, physical and mental—what a farce! Last week near New York, a young man's neck was broken on the foot-ball field. The enthusiast sneers when the game is called brutal, but in sober earnest is prize fighting less brutal? Doubtless foot-ball has killed more persons than fisticuffs. The papers teem with accounts of the physical injuries of the players after every game. These young men are getting to be proud of their injuries, their sprains, their battered faces, and wrenched limbs. Is this not topsy-turvy? Is this gymnastics? If so, it is inverted gymnastics—on its head in the mud! We laugh at the outrageously perverted pride of the German student who exhibits his chopped and mangled face as a proof of glory instead of shame—and we are going the same road. Wise fathers are beginning to refuse their sons permission to play a game that relies for its charm upon a distinct reversion to a barbaric type of sport, in which savagery, danger, and the lowest kind of physical prowess are the alluring elements.

In the name of example to the young—what a farce! A game must be translated into the vernacular of the street-urchin to illustrate clearly its possibility for evil. The beautiful games of cricket and base-ball have, on the whole, been a blessing to the country; they are not brutal; they have large elements of skill and intellectuality in them; they encourage suppleness and all-round development of the body, of the senses, and of the mind. A "scrub-game" by suburban boys, or even by street gamins, does not make the players worse than they naturally are, does not arouse all the fierce and brutal passions of the savage nature, none too easily held in control even by the best. But compare this with a foot-ball game by the same half-civilized or quarter-civilized little savages, and one sees quickly the influence for evil of apparently so simple and small a thing as a game. If, governed by rigid rules and umpires, the presence of a vast refined audience and the possession by the players of good home-training, education, and all that, the game results in charges and the facts of "slugging," and in passionate enmities and rivalries, what then is to be expected from its translation into the conditions of the alley, the vacant-lot of the city-outskirts, and "played" by the most unregenerate types of human nature? Imitation is flattery—usually—but in this instance the flattery is nauseating even to the flattered.

It is a cause of deep regret that we should approach the ideal of Rome in our national sports, rather than that of Greece, and it is especially significant when educators and universities show this tendency. One would not expect them to encourage gladiatorial rather than intellectual and truly athletic contests.

Have we not more patriotism and originality than to accept this worn-out brutal old game second-hand from England? Have we not enough intellect to put some true "play," some ingenuity, and spontaneity into our national sport? Have we not enough mind to introduce something into play except "a secret code of signs," "undergraduate rules," and a coarse scrimmage of a dozen bleeding, bunched, and scuffling fellows sprawling in the mud?

If not in the name of general education, then in the name of medical education; if not in the name of morality, then in the name of medicine; if not in the name of esthetics, then in the name of physiology; if not in the name of social progress, then in the name of hygienic progress—it is time that we should command, Halt! The game is un-American and absolutely opposed to the spirit of true education, whether of the mind or of the body.

MUSCULAR DEVELOPMENT AND USE THE CONDITIONS OF HEALTH.

It was, we believe, a saying of Pascal that the evils that afflict mankind arise from our inability to sit still in a room—meaning thereby that in useless and ill-considered action is to be found the origin of much tribulation, and that calmly thinking out the best methods of action in advance would obviate it. But the modern physician and hygienist must often feel like reversing Pascal's *mot*, and saying that the evils that afflict mankind—or more truly, womankind (the same thing, however!)—come mainly from sitting still in a room. We mean by this that the great and the increasing prevalence of sedentary and indoor occupations inflicted on human bodies is already ripening a wretched source of physical (and hence psychic and moral) suffering. If there is any truth at all in evolution it is that animal and human life and progress have always been conditioned upon the exercise of the muscular system, that function precedes and begets structure, and that disuse leads to atrophy and death.

The disuse of the muscular system that is a result of civilization is the prolific source of much of the disease of modern life and an illustration of the biologic law. All the discoveries of modern medicine and science, every bacteriologic truth, every known etiology of disease, simply confirms the truth that, together with cleanliness, muscular health and development are the necessary conditions of freedom from disease, and that there is no health of the muscles without use of the muscles. The bacillus of tuberculosis has no power of harm to a person with proper thoracic and pulmonary expansion and development. All "consumption cures" except this one are useless, and this with some exceptions is effective in prophylaxis or cure. There is hardly a disease that does not equally well illustrate this truth.

What is civilization doing with this law? It is crowding people into huge cities, where every means of artifical locomotion, every labor-saving apparatus, and every necessity of business are all working to the same end of inactive muscles. From the weak, half-atrophied muscles naturally follow the defective digestion and assimilation of food, and the overwrought hyperesthetic morbid nervous system, ever vainly seeking to undo and to right the evils of denutrition, hyper-nutrition, and muscular inactivity. Our food is pre-masticated and we are becoming edentulous, and from the advertisements of predigested foods it would appear that we shall soon have no need of a private stomach, liver, or pancreas, because we can and should buy these products from the slaughter-house and laboratory, and thus save personal wear and tear. It is in the line of the much expounded physiologic division of labor. But that line logically and inevitably ends in the condition of some slave-holding ants that cannot move, and unless fed by their slaves die of starvation even when food is before them. Of course, we already have analogues of these little organisms in the increasing horde of urban hysterics, neurasthenics, roués, and tramps of various sorts, both aristocratic and ragged.

And lastly, comes the sham-science that would supply the want of healthy vital powers of all kinds, cerebral, muscular, testicular, and what-not, burned out by abuse or atrophied by disuse, by means of squirting into the veins or under the skin some of the supposed vital, but really dead and inert, juices of animals.

And even our frantic attempts to remedy the evil of muscular inactivity, with its spawn of varied disease, are themselves morbid, and sometimes serve to increase the evil. This fact becomes plain in our rage for athletics by proxy, and in the steady trend of athletic games toward professionalism and newspaper notoriety, sensationalism, to the encouragement of betting, and to the more brutal sorts of arena combats.

So far as cities are concerned, one of the most crying of evils is over-pressure of school-children. Every physician has daily before his eyes the sad results, and he knows that instead of medicine the poor little body needs play and exercise, and out-of-door air and sunshine. All of the book-cramming that can be jammed into them will never compensate for the pallor, the pipe-stem legs, the narrow chests, and the stunted or abnormal growth.

The city child needs what it cannot have, country life. Failing in this it should be supplied with abundant, healthful gymnasium exercise, under the careful eye of expert and discriminating teachers of hygiene and physiologic development.

All of this is doubly true as regards girls and women. Fashion and house-incarceration and wealth are reducing our women to sad specimens of bodily and muscular ill-health, flabbiness, and undevelopment. Either publicly, or in private to parents, every physician can point out the truth,

and by his advice may help to avert the crop of coming disease or, in some degree, to cure the pathetic instances that fall under his care.

TOLERANCE TO SUPPRESSION OF VITAL FUNCTIONS AND RETENTION OF NOXIOUS EXCRETIONS.

NOT less remarkable than the idiosyncratic susceptibility of some persons to external influences is the tolerance of other persons to influences of the same class. We view with curiosity the individual who is excited by ordinary medicinal doses of opium or morphin, the other who is rendered vertiginous by the taking of a hundredth of a grain or less of nitroglycerin, the third who develops symptoms of coryza after the ingestion of almost inert amounts of potassium iodid, and so on; but not less curious are the instances in which massive doses of opium or morphin are well borne, as much as five grains of nitroglycerin are taken at a dose with advantage, and an ounce of potassium iodid is ingested daily without discomfort. Not less remarkable than these instances of tolerance to drugs are those cases in which life may be continued for long period after the suppression of certain functions or the retention of the products of these functions, the performance and the elimination of which, respectively, are thought essential to the continuance of life. For instance, constipation for a week is common, while constipation for a month at a time is far from unknown. Again, in some cases of jaundice, due to obstructive disease of the gall-ducts, bile does not enter the intestine for months, and even years.

Recently (THE MEDICAL NEWS, August 12, 1893, p. 176), we recorded a case of gout and renal colic in which there was total suppression of urine for eleven days. CABOT (*Boston Medical and Surgical Journal*, vol. cxxix, No. 9, p. 213) reports a similar case, in which the suppression continued for almost eight days. The case was that of a man, aged sixty, who, during a period of seven years, had had a number of attacks of renal colic upon one or the other side, and who, on several occasions, had passed renal calculi. In the attack in question, after the continuance of intermittent pain in either loin for about a month, there was a cessation of the flow of urine, and for nearly eight days none was passed, only a dram of turbid fluid being obtained by catheterization on the third day. During most of the time there were no special symptoms. On palpation a little more resistance was appreciated in the right loin than in the left, and there was slight tenderness. The prostate was of moderate size, but no tenderness or hardness could be detected above it. As the evidence indicated that the function of the kidneys had been interfered with by some mechanical obstruction, probably a stone, a median incision was made into the abdomen, between the umbilicus and the pubes. The right kidney was found to be irregular and lobulated, and enlarged to perhaps three times the normal size. Careful palpation of the ureter was difficult on account of the abundance of retroperitoneal fat, but nothing suggestive of a stone could be detected in the pelvis or ureter. The left kidney was of normal size, and its pelvis was not distended with fluid. Its ureter was traced with great care from kidney to bladder, but no stone could be detected. The bladder was contracted in the pelvis. To facilitate careful palpation of the left kidney an additional incision was made in the loin, but no stone was found. Further interference was now abandoned, the median wound being closed, the lumbar wound drained and only partly closed. The patient reacted well, and three hours after the operation there was a slight escape of urine from the urethra, and on passing a catheter thirty-seven ounces of light-colored urine were evacuated. The discharge continued, so that, partly by natural efforts and partly by catheter, two gallons of urine were obtained in the first twenty-four hours. In the second twenty-four hours five quarts were passed, the amount gradually diminishing until a daily excretion of seventy ounces was reached. Convalescence was satisfactory, and about a fortnight after the operation the bladder was washed out with a litholapaxy-pump, a few grains of calcareous matter being brought away. Some time later another attack of colic occurred, from which relief was afforded by massage in the course of the left ureter, and a calculus was passed a week afterward. It is believed that the function of the left kidney was suppressed by an inhibitory influence due to the irritation of a calculus in the left ureter, and not wholly as a result of the presence of the obstruction, while the function of the right kidney was entirely lost.

From the experience gained in this case, and from a study of the literature, the conclusion is reached (1) that in a calculous patient, or in a patient with a distinct attack of renal colic, suppression of urine should be regarded as directly due to

the obstruction. In the majority of cases both kidneys will be found to be disabled. (2) Such a case should be treated by operation as soon as it is evident that the function of the kidneys has come to a standstill, as there is little chance of the stone being pushed along the ureter when the kidney is no longer secreting urine behind it. (3) In the absence of evidence as to the location of the stone, the first step in such an operation should be median celiotomy, with the hope of discovering the whereabouts of the calculus, in order to proceed intelligently for its removal. (4) If by this examination no calculus can be found, steady massage of the pelves of the kidneys and of the ureters, from above downward, should be practised, in the hope of dislodging or breaking up a small calculus if present.

EDITORIAL COMMENTS.

The Annual Report of the Supervising Surgeon-General of the Marine-Hospital Service of the United States for the fiscal year 1892, issued by the Treasury Department, emanates from the chief officer of a very important but too little known branch of the public service. Perhaps very few persons, even among those generally well-informed, are aware of this great system of medical relief for sick or injured seamen, which had its origin nearly one hundred years ago.

In 1798 Congress imposed a monthly tax of twenty cents upon every seaman's wages, to go toward a relief fund for those in need of medical or surgical treatment. These collections, in 1802, were constituted a general fund, and provision was made for like care for foreign sailors at the rate of seventy-five cents per day. In 1811 the moneys raised from the navy were made a separate fund for the benefit of that branch of the service. A reorganization took place in 1870, and the business was placed in charge of a supervising surgeon-general; the hospital-tax on each seaman's wages was also increased to forty cents per month. Besides the revenue derived from this tax, appropriations have from time to time been made by Congress for the maintenance of the work.

Without going into detail, it may be stated that the care of the seamen is provided for by contract with general hospitals or with private parties, except where the Government has established its own hospitals through this bureau. Of these latter there appear to be at present nineteen.

Besides this prime object of its existence, aid is extended by this department to other branches of the Government service: to the life-saving service on the seacoast and on the great lakes; to the inspection service of steamboats, and to the revenue-marine service, as well as in examination of immigrants. Another very important matter, as to which interesting details are given in the report, is that of national quarantine. This subject occupies forty-nine pages, and is well illustrated.

Some idea of the magnitude of the work of the department may be obtained from the fact that at the commencement of the fiscal year there was a balance available of $75,528.01, and that the receipts from all sources were $650,510.39; the expenditures were $586,-839.06; leaving a balance at the close of the year of $139,199.34.

One hundred and nineteen pages of the report are filled with histories of fatal cases, with necropsies; many of them are of little or no scientific value, and all are simply buried. Following these there are sixty pages of tabulated statistics, of which the same may be said. We think it would have been better had the medical officers given their observations to the profession through the usual channels, and the Government issued a merely business document setting forth the workings of the office.

The Aims and Incompetencies of Opticians.—Every optician in the United States (except perhaps as many as can be counted by the fingers of one hand) is cocksure of his ability to prescribe for ametropia as well as any physician. Not only this, but the opticians (with but few exceptions) attempt to do so whenever opportunity presents. Further, their single trade-journal is encouraging this delusion, and enthusiastically urges the establishment of optic schools wherein the non-medical optician shall learn to relieve the medical profession of all care of the eyes, except as to diseases and surgery. As the treatment of ametropia and heterophoria constitutes about nine-tenths of the oculist's work, this has bearings worthy of consideration. As absolutely every pair of spectacles worn has a medical, and possibly a most *serious* medical significance to the wearer, and as (with few exceptions) no non-medical optician ever prescribed a proper pair of lenses (the writer has in thousands never seen a single instance), the fact becomes quite significant. It is exactly as if the truss-makers and instrument-makers should combine to take out of the hands of the surgeons all cases of hernia and spinal disease, and should urge that to them should be left the decision as to whether a case of rupture or of Pott's disease needed a surgeon or not. Just as every case of spinal curvature needs the surgeon's attention, so does every case of ametropia or heterophoria, and it is downright and criminal quackery to permit the present method. If the opticians only knew how to do their own proper work their pretensions would be less exasperating, but (with few exceptions) one cannot find, from any American optician, a spectacle bridge and frame sufficiently rigid and heavy to do its medical work; never a temple-piece or ear-curve having the remotest likeness to the shape of the back of the human ear; never an adjustment such as corresponds to the wearer's peculiarity of face and labor. Of the spectacles worn by the American people (and Heaven knows our opticians are better than those of foreigners) $\frac{999}{1000}$ show about the same mechanical and artistic skill and intelligence that is shown by a five-year old school-boy's first slate-picture of "a horse."

Society Transactions and Libraries.—Having occasion recently to look up a certain subject on which we hoped to obtain information from the Transactions of one of the medical societies of America, we were surprised to learn

not only that the volume desired was not in the great collection of the Library of the College of Physicians of Philadelphia, but that with a few exceptions it was only with the utmost difficulty that the librarian could obtain copies of the Transactions of American societies in general. The one place where society Transactions should be is in a great public library. That is where men go to consult such books, for few have space upon the shelves of their private libraries for the enormous number of volumes required for a complete collection of society proceedings, and incomplete collections are of little value. Every society should instruct its secretary or its editor to send the annual volumes to all the medical libraries, and even to some selected general libraries —such as those of the historical societies of the respective States and counties.

We trust that if this comment comes to the eyes of the officials of any society that has hitherto neglected to send its publications to the libraries, they will immediately take steps to remedy that neglect. The Library of the College of Physicians of Philadelphia (which is a scientific society and not a diploma-granting body) is the greatest in America, with the exception of that of the Surgeon-General of the United States Army at Washington. The address of the College is Thirteenth and Locust Streets, Philadelphia. We hope that our cotemporaries will speak of the matter, so as to attract the attention of all societies all over the land.

Non-Experts can Testify as to Value of Services in Caring for the Sick.—In many instances, before a witness can give an opinion, he must be shown to have some special aptitude, skill, or knowledge of the subject; but there are some things coming ordinarily within the observation of all men, as to which any man will be entitled to give his opinion. Thus, opinions as to time, speed of ordinary moving objects, and distances, are received without any proof of special knowledge or skill on the part of witnesses. And it is not necessary, says the Appellate Court of Indiana in the case of Storms *vs.* Lemon (24 N. E. Rep. 644), that one should be an expert, and have special experience, to enable him to be competent as a witness to testify to the value of services rendered in taking care of the sick by a person not a trained nurse. Every man who has arrived at years of maturity must, in the course of Nature, have had more or less experience in caring for the sick, or seeing it done; and when one has seen such services, as they are being rendered, he is competent to give the facts, and then his opinion as to the value of such services, the weight to be given to the opinion being determined by the jury. Besides it would be hard to conceive of a case in which one who has himself rendered a service to another will not himself be competent to give evidence as to its value. Knowing the precise nature of the service rendered, he must have some knowledge of its value, and he is thus competent to give his opinion. It may not be worth much. Its weight, however, is for the jury to decide.

The Curative Influence of Erysipelas.—Though we are yet without the explanation, it is a well-recognized clinical fact that the development of erysipelas in the course of certain other morbid conditions, such as pulmonary tuberculosis and malignant neoplasms, is sometimes followed by the disappearance of the previously existing disease. Future investigation may show that as a result of the presence and activity of the streptococcus erysipelatis certain bodies or substances are generated that exert an antidotal or antagonistic influence upon associated disease-conditions or their products. The uncertainty of the result, both favorable and unfavorable, from the artificial induction or inoculation of erysipelas renders doubtful the justifiability of the universal application of this principle for therapeutic purposes. Our clinical knowledge upon this interesting subject has been increased by the recent report of a case (SCHMIDT, *Centralblatt für Gynäkologie*, 1893, No. 39, p. 900) in which, during the progress of an aggravated attack of gonorrhea, the development of erysipelas was so immediately followed by a permanent disappearance of the urethral symptoms, that the relation could not be looked upon as other than direct and not merely accidental.

SPECIAL MEMORANDUM.

AN ADDITIONAL WORD AS TO THE TREATMENT OF EXOPHORIA.

BY GEORGE M. GOULD, A.M., M.D.,
OF PHILADELPHIA.

I HAVE received such a large number of letters of inquiry as regards the little suggestion *in rê* the treatment of exophoria made in THE MEDICAL NEWS of October 14th, that it has become almost impossible to answer each inquiry individually. I should like to add a word or two in order to classify and explain several points that seem to have been left in some doubt:

1. The treatment of insufficiencies by means of weak prisms "to strengthen the muscles," seems to have been devised and recommended by Dr. Dyer so far back as 1865, and in this field of work that veteran clinician and honored teacher, Dr. Noyes, of New York (and possibly many others), has long carried out this plan, and other excellent modifications of the plan, in his practice. When I wrote my article, as explained at the time, I had had no opportunity to look up the literature of the subject, and did not know of the work of Drs. Dyer and Noyes, nor was I aware of the excellent studies and methods suggested by my friend Dr. Savage, of Nashville, Tenn. To these and any other workers in "prism-gymnastics" I would gladly acknowledge all precedence and give all honor so far as pertains to muscular gymnastic exercises of the eye. This in answer to two correspondents who thought I had not sufficiently done so. But that even these methods of treatment have proved unsatisfactory is evident from the fact that they have not become routine with the general profession, and that in several of the best and most recent books on ophthalmology the method is not even mentioned. (I was, however, in error when I said that the fine treatise of my friend Dr. de Schweinitz had also omitted mention of it, my error being due only to its omission from the index.)

So much for my sins of omission!

2. But it remains to emphasize my contention that I do not aim to "strengthen the muscles," and that with "muscular gymnastics," as such, my plan has nothing in common except the mere use of prisms—very strong

prisms, however, instead of weak ones. If the trouble lay in the peripheral mechanism, then tenotomy or gymnastic exercises with weak prisms would be the proper treatment, and the use of such strong prisms as I advise would be the height of dangerous folly. It seems to me that all previous treatments of heterophoria have looked solely to the muscles, the peripheral condition, as the *fons et origo mali*. Surely all tenotomization proceeds on that assumption, and I as certainly judge that all previous suggestions of "prism-gymnastics" likewise are founded upon the same conception.

3. But it appears to me beyond question that in the vast majority of cases of exophoria, if not in all, the seat of the abnormality is purely, at least primarily, and always principally, central, and innervational. It is not at all a question of tendon-insertions or of muscular strengths. A few of many reasons for so thinking are these:

a. In convergence-adduction, the "muscles" overcoming the maximum of prisms, bases out, that is possible, either internal rectus may be made to greatly increase its contractile power by simply carrying the object to the left or to the right side of the field.

b. Extreme adduction (twenty feet) of exophoric eyes may be doubled, often trebled, in a minute or two by the device of carrying slowly the object gazed at, with weighted convergence-stimulus from the near to the distant point. If, as I said, one can lift with his arms only 200 pounds, one cannot lift 400 or 600 pounds in a minute by any analogous change of the method of lifting.

c. The extreme of primary adduction-power, and even the double of this extreme, may be held continuously for several minutes, even a half-hour or more—I don't know how much longer. The extreme lift of other bodily muscles can only be held an instant, and not only this, but constant and uninterrupted tension or contraction of such muscles in lifting even very small weights is impossible.

d. Besides all this, such constant tension, when solely muscular, is painful, even agonizing, if demanded by the will or by necessity. In the case of exophoria, the extreme of prisms, and even the double of the extreme, bases out, that can at first be held without diplopia, is in a minute or two continuously held without the faintest suggestion of pain or even of discomfort.

e. Muscular tissue, as such, cannot be made to double or treble its volume or its strength in a few hours or days, or even in a few weeks, but such increase of ocular adduction-power I see many times every day.

There are many other such considerations, too numerous to mention, all running to prove the same conclusions.

4. If, therefore, the seat of the difficulty lies in the innervational centers and coördinations, the treatment by tenotomy, or by gymnastic exercises (with weak prisms), seems to fall to the ground. We must instead seek to normalize innervation, leaving the muscles and tendons entirely out of the count. In accordance with this I have sought to break up the bad habit of exophorial innervation, to reëstablish normality in an erroneous nervous coördination, to heighten convergence-stimulus, and to carry this increased stimulus as well as the naturally heightened stimulus of convergence at near range, into distant and all-around seeing.

5. The method I suggest for effecting this normalization of innervation and coördination in exophoria is by what I have called "the weighted convergence-stimulus carried from the near-point to the distant-point." In the great majority of cases of subnormal adducting power, I find that the "weighting" or "handicapping" by prisms, bases out, is at first about double the primary twenty-foot adduction-power. That is, if the patient has only 10° of such adduction-power, we may at first safely give 20° prisms (total) as the handicap, then slowly carry the object gazed at fixedly and continuously from the near-point to the distant-point. This is to be repeated until the eyes with 20° prisms can hold objects all about the room easily. The repetition is to continue several times daily until this increased adduction-power *is habitual*, and until no diplopia is produced on first adjusting the prism-fronts, (or, better, prism-spectacles) and looking at distant objects immediately, and without the device of carrying the object from the near-point to the distant-point. When this condition has been reached, the strength of the "handicap-prisms" is to be increased say, to 25° or to 30°, and the method resumed as before. Before an adduction-power of 30° has been reached the symptoms of asthenopia will long have vanished, but the manifest, or the latent exophoria, will still usually, and to some degree, be present. The treatment with 30° to 40° prisms should be continued until all manifest and latent exophoria has disappeared, and 2° of esophoria have become manifest.

These, of course, are rough and indefinite rules, drawn from my short experience with the method, and they will require adaptation to the peculiarities of each case. Some patients have far greater reaction-power than others, both as to the amount of the "weighting" of the convergence-stimulus permissible or required, and as to the rapidity of the return of normalization of innervation. But in all cases, so soon as increase of adduction-power has become stronger and habitual, we should weight the convergence-stimulus with still stronger prisms, so that effort and the device of slow recession of the object gazed at are (at first) required to avoid diplopia on looking at distant objects.

Since writing my first hurried article, my experience with the method has doubled. In no case has there been anything but the most gratifying success.

Many inquiries about the "battery of prisms" for testing adduction and abduction have been sent me. I have now given an optical firm a plan of a "double battery" that will, I am sure, be far superior to the old model. So soon as the instrument is completed I shall publish the design.

REVIEWS.

A Manual of Medical Treatment or Clinical Therapeutics. By I. Burney Yeo, M.D., F.R.C.P., Professor of Clinical Therapeutics in King's College, London, etc. With illustrations. Two volumes. 12mo, pp. xv, 631, 774. Philadelphia: Lea Bros. & Co., 1893.

At the present day, when the subject of medicine is so large and the lines of division of its various departments so ill-defined, it is a matter of exceeding difficulty in

writing a practical work to determine what should be included and what excluded.

In a work on "clinical therapeutics" it is a matter of delicate judgment to decide in how far special subjects, not strictly medical, such as dermatologic, laryngologic, neurologic, surgical, and the rest, should receive consideration.

We must, however, confess to a sense of disappointment with this work of Dr. Yeo, for we have learned to repose a good deal of confidence in his writings. Our complaint is not of what is contained in these two volumes, but of what has, intentionally or otherwise, been omitted. We might, perhaps, condone the omission of any consideration of such conditions as akromegaly, syringomyelia, lateral, postero-lateral, and cerebro-spinal sclerosis, progressive muscular atrophy, general paralysis of the insane, paralysis agitans, leprosy, foot-and-mouth disease, glanders, anthrax, actinomycosis, because of their relative incurability; but the same excuse scarcely applies to the absence of any reference to such subjects as syphilis, erysipelas, insolation, yellow fever, epidemic cerebro-spinal fever, relapsing fever, trichiniasis, hydrophobia, purpura, scurvy, rhachitis, alcoholism, and not a few other conditions.

The various subjects are taken up under nine main heads: the organs of digestion; the heart and bloodvessels and the blood and ductless glands; the organs of respiration; pulmonary tuberculosis; the liver; urinary and renal affections; the nervous system; constitutional diseases; specific infective diseases.

The recommendations made include not only strictly medicinal measures, but surgical procedures as well, and a number of good illustrations aid in the elucidation of the text. The subject-matter of these volumes is, on the whole, excellent and reliable, a conservative tendency predominating. The article on pulmonary tuberculosis is conspicuously full and valuable. We are a little dubious, however, as to the wisdom of publishing the "formulæ of well-known physicians," without a willingness to accept the responsibility of recommending them. We have also to regret that Dr. Yeo found it impossible to enter fully into a discussion of the value of cold baths in the treatment of enteric fever, for an abundant clinical experience has demonstrated that in this measure we have the most powerful means at our command for reducing the mortality in this disease. Neither does it seem justifiable to say of a method of treatment, that of tetanus with the tetanotoxin, which has now been employed in some sixteen cases with success, that "it can hardly be said that any very conclusive results have as yet been established."

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By ROBERTS BARTHOLOW, M.A., M.D., LL.D., Emeritus Professor of Materia Medica, General Therapeutics, and Hygiene, in Jefferson Medical College, etc. Eighth edition, revised and enlarged. 8vo, pp. 820. New York: D. Appleton & Co., 1893.

OF all the works on materia medica and therapeutics in the market, Bartholow's most nearly meets the needs of the physician in his daily practice. Hence its great popularity, from the first edition, and hence too the confidence with which we predict an extensive sale for the new edition. In conformity with the new (1890) Pharmacopeia, many new remedies have been introduced, and the metric system of weights and measures has been measurably adopted. Tables of comparison of the old and new systems are given for reference. Of the new remedies excluded from the Pharmacopeia because of their being called by trade-marked names or made by patented process, a number have been discussed—those, namely, that are in the author's opinion of sufficient importance. No secret remedy or nostrum has, however, been discussed. The author's position is the correct one, for, as he points out, his treatise is not an official work like the Pharmacopeia, and he may justly give such information as is needed in the cases of drugs to which the Pharmacopeia could not properly give official recognition.

The book is characterized by the clearness and accuracy of statement, and the fulness with conciseness of treatment, avoiding both prolixity on the one hand and incompleteness on the other, which have made all of Dr. Bartholow's works so valuable to the profession. All that is of importance in regard to the pharmaceutic relations, physiologic action, or clinical utility of the agents discussed is told; and a sufficiency of space is devoted to remedial agents and agencies other than drugs. We conclude, as we began, by affirming our belief that while excelled by such a book as Brunton's for special investigations, yet for the daily use of the physician, Bartholow's *Materia Medica* and *Therapeutics* has no rival.

A HANDBOOK OF OPHTHALMIC SCIENCE AND PRACTICE. By HENRY E. JULER, F.R.C.S., Ophthalmic Surgeon to St. Mary's Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital, London. New (second) edition, revised and enlarged. In one handsome octavo volume of 562 pages, with 201 engravings, 17 colored plates, test-types, and color-blindness tests. Philadelphia: Lea Bros. & Co., 1893.

THIS second edition of Juler's *Handbook* is a great improvement upon the first. It has been found necessary to add about a hundred pages to the text and nearly as many new illustrations, the latter, especially the beautiful photomicrographs, being very excellent, attractive, and praiseworthy. Thus revised, enlarged, and outfitted, this good book is one of the most profusely illustrated works offered, and generally speaking, the best book on the subject that our English confrères have sent us. It has over Berry's more scholarly work the great advantage of simplicity and practicality in the presentation of the subject. There is a clearness and compactness that is rarely attained by English writers and that reminds one of the best French workmanship. The strength of the work lies in its excellent exposition of the clinical aspects of diseases of the eye, and in this department it is usually a safe and reliable guide to the student and general physician. We object, however, to the customary rash haste with which slitting the canaliculus and probing are advised in cases of functional stenoses of the lacrymal drainage-system of the eye.

The parts pertaining to the treatment of ametropia and insufficiency are often in conflict with American practice.

Most American oculists can only smile dissent when advised that mydriatics are unnecessary in the estimation of (seeming) myopia, in patients over thirty years of age, and that adults with three dioptries of hyperopia need to wear correcing glasses only for near work.

Appendices containing formulæ and Snellen's reading types, and a better index than is usual, are commendable features.

It is, of course, an excellent piece of printing and bookmaking.

A Synopsis of Clinical Surgery during the Service of Samuel H. Pinkerton, M.D., Surgeon to the Holy Cross Hospital. By Franklin A. Meacham, A.B., M.D., Assistant Surgeon to the Holy Cross Hospital, Salt Lake City, Utah. Illustrated. 12mo, pp. 145. Salt Lake City Tribune Job Printing Company, 1893.

This little brochure is a compilation of 632 miscellaneous operations performed for the most part during the past year, some of which are of considerable surgical interest. The total number of deaths is seventeen, or 2.6 per cent., eleven of which, it is stated, were *in extremis* at the time of operation.

The celiotomies are interesting on account of the high mortality, which was 24.3 per cent., six of the cases being *in extremis* at the time of operation. These include ligation (fatal) of the common iliac artery by the new intra-peritoneal method of Treves, and successful operations for a large cyst of the pancreas, an echinococcus-cyst of the gall-bladder, nephrorrhaphy, and nephrolithotomy. The most fatal cases seem to have been those strictly belonging to gynecology, in which success has been so uniformly achieved by the operators of Philadelphia in particular.

The operations for tuberculous disease merit criticism, as amputation for ankle-joint disease and amputation for ankylosis are seldom performed. Modern ideas upon articular disease have been revolutionized by antiseptic methods, iodoform-injections, and the American method of extension in the treatment of joint-disease. Of twelve operations for tuberculous joint-disease six were amputations, three through the lower third of the thigh, one at the hip, two at the lower third of the leg. When we consider that excision was introduced by MacCormick as a substitute for amputation, and that modern surgeons reserve amputation as a life-saving measure, the importance and force of these criticisms will be appreciated. In justice, however, it must be stated that all of the patients ultimately recovered from the excisions and amputations.

An Account of Bellevue Hospital. With a Catalogue of the Medical and Surgical Staff from 1736 to 1894. Edited by Robert J. Carlisle, M.D. Published by the Society of the Alumni of Bellevue Hospital. 8vo, pp. 381. New York, 1893.

We find in this handsome and attractive volume a very well written and interesting sketch of the development of a vast and thoroughly-equipped hospital, having in connection with it a medical school of high repute. And besides its purely historic interest, the work contains much material of value to all who are concerned in the management of like institutions.

On the first page it is claimed that Bellevue is the oldest hospital in this country. But this claim does not seem to us to be substantiated. There was a poorhouse in New Amsterdam, and a hospital was established in 1658. Of the latter it is merely said: "This institution still remained in 1680, for in that year what was known as the 'Old Hospital' or 'Five Houses' was sold, and a better building provided." But the poorhouse, which was not only a home for paupers, but also a Bridewell or house of correction, existed as such until 1811; "when," says the editor, "the third almshouse was about to be built, and the hospital thenceforward gradually to become the most important part of the establishment." This seems to have been the true beginning of Bellevue Hospital.

Upon the later pages of this history are to be found many names of men eminent in medicine and in surgery. Nor are there wanting accounts of those—of whom our profession may be as justly proud—who gave up their lives in the discharge of their duty to the sick.

Three Introductory Lectures on the Science of Thought. By F. Max Mueller. With an Appendix of Correspondence. Chicago: Open Court Publishing Co., 1893.

These lectures were delivered in 1887. In his strenuous contention that thought and language are identical, Professor Mueller makes the common mistake of analyzing his own thought-processes, and reasoning from them back to the beginning. If he would study children he would soon see that thought precedes language, and is carried on without the aid of words or signs. Naturally such thought is limited. After one learns to speak he finds his thought increased in definiteness and his thinking rendered easier by the use of words; yet even in the most advanced brain some thinking goes on automatically without words, suddenly forcing itself into consciousness in the form of words.

In the letters collected in the appendix, Mr. Galton and Mr. Romanes have given other examples fatal to Professor Mueller's theory. Indeed, Mr. Galton's letters are the best things in the volume.

Notwithstanding his fundamental error, the author's work is interesting and, in many collateral relations, instructive.

NEWS ITEMS.

Virchow celebrated, on October 21st, the fiftieth anniversary of his accession to the doctorate.

Twelfth International Medical Congress.—It is announced that the Russian Government contemplates inviting the Twelfth International Medical Congress to be held in Russia, probably at St. Petersburg.

Sir Andrew Clark, the distinguished English physician, was stricken with apoplexy on October 19th, right hemiplegia and aphasia developing, and death taking place on November 6th, at the age of sixty-seven years. Sir Andrew was the President of the College of Physicians of London, and the foremost medical man in England.

The Medical Society of the University of Maryland has been organized, with the following officers: President,

Dr. J. J. Chisolm: Vice-President, Dr. C. W. Mitchell; Secretary, Dr. W. B. Canfield; Executive Committee, Drs. J. E. Michael, W. B. Platt, and J. M. Hundley. The society will meet on the first Tuesday of each month and will be composed of the faculty, adjunct faculty, members of the teaching and hospital staffs, and graduates of the University.

SPASMODIC AND ORGANIC STRICTURE OF THE ESOPHAGUS: A REPORT OF TWO CASES.

BY WILLIAM PEPPER, M.D.,
OF PHILADELPHIA;
PROVOST OF THE UNIVERSITY OF PENNSYLVANIA; PROFESSOR OF THE PRACTICE OF MEDICINE, ETC.

CASE I.—C. W. J., a paper-maker, aged forty-five years, was admitted to the University Hospital on April 8, 1893, suffering with difficulty in swallowing. The history, family and personal, was as follows: His father and mother both died in advanced life, the one with dropsy, the other from pulmonary tuberculosis. Three sisters died of scarlet fever and four were living, of whom one had been abed for two years with "nervous prostration." There was no other neurotic history. The patient himself had had scarlet fever severely when seven years old, with especially severe angina, and spotted fever at seventeen. After the latter age he had been uniformly well, excepting that he suffered from time to time with choking sensations, which he thought began after the attack of scarlet fever. He was never able to swallow a bolus of large size, and during the spells of choking he would be wholly unable to swallow. These paroxysms were frequent, and scarcely a week passed without more or less difficulty in swallowing. The duration of the paroxysms varied from an hour or two to a few days. The patient had been married twice and had had seven children, three of which had died in infancy. He was an immoderate smoker, but did not use alcohol excessively. His work had been very exacting, frequently occupying eighteen hours of the day.

The illness that brought him to the hospital had begun three weeks before, with difficulty in swallowing like that which he had so frequently experienced, but instead of relief after a few hours or days, the dysphagia grew worse until he declared that there was inability to swallow even water. Meantime he had been rapidly losing in flesh and strength, his weight being 122 pounds, as against his normal weight of 142 pounds.

I was called to see him at his home, and found that a diagnosis of incurable organic stricture had been made, and that his death was confidently expected at an early day. His appearance certainly did not make the prognosis seem improbable. He was advised to go to the hospital immediately.

On admission the patient was greatly emaciated and extremely weak, and his appearance was not unlike that of a man in the last stages of a chronic wasting disease. The skin was dry and wrinkled and the mucous surfaces pale. He was offered a glass of water, but on repeated effort was unable to swallow the least part of it. His temperature, as might be inferred from his general state, was subnormal, but the rate of the pulse and that of the respiration were increased. The urine was scanty and high-colored, but normal in other respects. The patient was in a somewhat excitable condition and disposed to be dramatic in the description of his sufferings. During the first twelve hours in the hospital he took no food at all, but on attempting to swallow milk promptly regurgitated the whole of it.

The diagnosis in such a case as this is a most important matter. In any case in which there is a history such as this man gives, of paroxysmal dysphagia, attacks coming and going at short intervals and with great suddenness, our first thought naturally suggests spasmodic contraction; but we must never be guided too strictly by a history received from the patient himself. Still, in this case, we had also the confirmatory story of the patient's friends, who are intelligent and judicious people, that he had for a long time suffered paroxysms such as he described; that his present disease had begun just three weeks before his entrance into the hospital, and that the loss of flesh had been as great as he stated.

With this history it could not be doubted that the man had formerly suffered from spasmodic stricture, though his sex and age and character as a steady, hard-working man were against this diagnosis. Still it is by no means unknown to find the disease among males even of somewhat advanced years. Another question, however, presented itself, and the decision of this would have required special investigation—that is, whether there was not secondary organic stricture to account for the present and persistent dysphagia and the great emaciation. Certainly no one looking at the patient and knowing only the history of his disease during the three preceding weeks could have believed this to be a case of spasmodic stricture, for, though the complaints of patients with esophagismus are often more loud and the attempts at swallowing apparently more futile than in organic stricture, there is usually fair preservation of the weight, and there may be no emaciation at all. Certainly the rapid and extreme loss in weight in our case was an unpleasantly suggestive symptom, especially when taken in relation with the age of the patient. In this aspect of the case it is interesting to recall that a neoplasm or other lesion of the esophagus or surrounding parts may, by reflex action, give rise to paroxysms of dysphagia long before the lumen of the esophagus is sufficiently encroached upon to occasion continuous obstruction. In such a case, however, the complete occlusion would have come on gradually, and there would have been a slow transformation of paroxysmal into continuous dysphagia, whereas in our patient the final attack was quite as sudden in onset as any of the previous lesser ones. It is also possible that repeated spasm of the esophagus may eventually lead to fibroid overgrowth and stricture of the walls, much as the

spasmodic contractions of the pylorus from hyperacidity are believed to sometimes occasion fibroid thickening in that situation; but here again a gradual increase of dysphagia would occur, and not a sudden obstruction; and, besides, it has not been definitely proved that fibroid stricture does so occur.

The sudden onset, the previous history, the suspicion of neurotic character imparted by the somewhat dramatic tone and manner of the patient, and the nature of his efforts at swallowing, all inclined us to view the case as one of purely spasmodic stenosis, and encouraged the hope that we could relieve the apparently desperate condition in spite of the fact that the man had suffered such extreme emaciation and presented other appearances of a serious organic disease.

On the morning following his admission to the hospital, he was, with considerable formality, taken before the medical class in order that the attempt to pass an esophageal bougie might be made. He was warned solemnly that even if it were found that no organic stricture existed, it would be necessary to repeat the operation frequently unless the power of swallowing returned. The result was that in spite of considerable pain and difficulty the largest size was at once introduced into the stomach. There could now be little doubt of the nature of the case, for, had there been even a slight obstruction of organic nature, it would have been impossible to pass a sound of the dimensions of that used. For some hours after the passage of the instrument the patient complained of pain in the chest and of persistent inability to swallow. Galvanism of the neck was then resorted to, one pole being placed posteriorly, the other anteriorly, and at the same time chloral was administered in peptonized milk by the rectum. Two hours later the patient asked for a glass of milk, which he drank without the slightest difficulty; and during the succeeding night, and for several days, he ate and drank all forms of food ravenously and without the least sign of dysphagia. The improvement in the patient's appearance was remarkable. Almost at once his features assumed a healthier appearance, and in a single week he had gained seventeen pounds, when he was discharged from the hospital apparently well; and in the seven months which have elapsed there has been no recurrence.

Much interest attached to this case in the first place on account of the extreme and rapid emaciation and the appearance of serious organic disease in a man whose age would at once suggest the possibility of esophageal carcinoma; so that the diagnosis was of the greatest importance. Cases of this kind have been reported before, and, indeed, there have been a few in which death has occurred; but they are exceedingly rare, and the latter are not free from suspicion of some underlying affection which has been overlooked.

In the further treatment of our patient it was necessary first of all to determine, if possible, the cause of the spasms, and to institute such measures as would obviate a recurrence. There was no question but that the hereditary neurotic element, which was so marked in the case of the sister, who was confined to her bed for two years, played a most important part, and it was necessary to reduce to the minimum all depressing conditions that might call this neurosis into active operation. Overwork, doubtless, was one of these exciting causes which would require careful regulation. Another was the immoderate use of tobacco. Perhaps a proper restriction of both of these factors, aided by the powerful moral impression produced by the passage of the bougie, would alone have sufficed to prevent recurrence; but to still further guard against relapse we ordered for him a mixture containing elixir of ammonium valerianate, with the purpose of tranquillizing nervous excitement. The fact that there has been no relapse is conclusive that these measures have struck at the root of the trouble, and it may be hoped that with this treatment and with the use of suitable tonics recurrences may be entirely obviated. It is always interesting to inquire what subtle anatomic or physiologic influence may exist to determine the localization of affections evidently originating from constitutional tendencies and general predisposing causes. I incline to think that in this case the peculiar and rare expression of the neurotic diathesis and of the depressing influence of overwork and tobacco excess is to be further explained by the anatomic datum of a narrow esophagus at the cricoid level and by the lasting impairment of physiologic tone left by the severe scarlatinal angina.

Quite different from the first case is one that occurred in the wards at the same time, and which is useful to contrast with the other. The history is as follows:

CASE II.—J. S., aged fifty-five years, a laborer, was admitted to the University Hospital, complaining of great weakness and difficulty in swallowing, and vomiting. There was nothing in the family history bearing on his condition. He had been a very hard drinker, and had lived an exposed life. There was no evidence or history of syphilis. He had never been ill excepting after injuries. He had dislocated his shoulder, and had suffered necrosis of the jaw from injury in the extraction of a tooth. Some years previously he had suffered considerably with hemorrhoids. A year before his entrance into the hospital he began to lose in flesh and strength, and found that he would easily grow faint. He never fell, but frequently became very dizzy. At the same time he had difficulty in retaining food, and gradually abandoned solid diet entirely. It was impossible for him to continue at work, and he was admitted to a hospital, where esophageal bougies were passed.

On admission to the University Hospital, he was greatly emaciated, the ribs standing out prominently and the belly being scaphoid. The skin was dry and harsh, and of an icteroid hue. On physical examination it was found that the percussion-note over the lungs was hyper-resonant and the breath-sounds were feeble, with prolongation of expiration. Posteriorly there were snoring and subcrepitant râles near the bases. The cardiac dulness was difficult to determine, but was apparently much decreased. The heart-sounds over the apex, as well as over the aortic region, were extremely feeble, and sometimes almost inaudible. The apex-beat was quite

invisible and impalpable. The hepatic dulness extended from the seventh rib to the costal margin in the nipple line. Over the abdomen there were numerous greatly distended veins, especially at the sides; and on palpation the aorta could be distinctly grasped. The patient was so weak that he was confined to bed, and there was evidently considerable anemia. Examination of the blood showed 3,950,000 red blood-corpuscles to the cubic millimeter and 65 per cent. of hemoglobin. The urine was normal.

At every effort to take solid food there was extreme distress, and very soon regurgitation of the food mixed with considerable mucus. Evidently the food did not reach the stomach. The man was, however, able to swallow milk, though even this was often regurgitated.

There was evidently in this man esophageal obstruction of high grade and organic in nature. The history and the actions of the patient were in sharp contrast with those in the other man, though each was emaciated and sallow. In the present case, however, the esophageal bougie was resorted to with some hesitation for the reason that certain features in his case made aneurism of the aorta not improbable. The radial and temporal arteries were rigid; there was marked arcus senilis and evidence of arterial degeneration also in the reduced size of the liver. Careful physical examination, however, failed to reveal any evidence of aneurismal dilatation of the aorta, either by the existence of dulness or abnormal pulsation or by alteration in the heart-sounds or pulses. The question of aneurism was therefore dismissed. The smallest esophageal bougie was finally introduced into the esophagus. Six inches below the incisor teeth this met with some resistance, to overcome which pressure was required, but the instrument finally slipped on as if over a ridge. This was doubtless the projection of the cricoid cartilage. Eleven inches from the teeth there was a second and decided obstruction, through which the instrument could not be pressed without the use of unwarrantable force. After some manipulation it was determined that a little pressure sufficed to insinuate the bougie into the upper part of the narrowed portion, below which a greater narrowing prevented further penetration. There was no doubt, therefore, but that there was decided organic constriction, and it remained only to determine the nature of the stenosis.

Practically the three important causes of organic stenosis, apart from compression of the tube from without, are strictures following chemical irritants, syphilitic stricture, and carcinoma. The first of these was easily disposed of, for it would scarcely be possible for the patient to have forgotten the swallowing of a substance corrosive enough to occasion a subsequent stricture. Syphilis, however, must not too readily be set aside, for the patient may be ignorant of the infection or may wilfully conceal its existence. We must look to the physical examination to reveal other evidences of syphilis, such as enlarged post-cervical, epitrochlear, and inguinal glands, scars about the legs or elsewhere, periosteal nodes, old iritis and the like. The most careful examination and the most cautious questioning of our patient, however, made it certain that he had never acquired syphilis, and we were forced to conclude that the stenosis was due to carcinoma. This diagnosis accorded very well with the manner of onset of the disease, with the age, and with his general condition. Sometimes it is possible to obtain definitely conclusive evidence by the discovery of secondary nodes in the liver or in the lymphatic glands of the neck, but metastasis is present in only a minority of instances, and was wanting in this case.

The question of treatment in cases of esophageal carcinoma is in all respects similar to that of other forms of stenosis. The passage of bougies at regular intervals seems to keep the lumen of the esophagus open, by dilatation and possibly by repressing the exuberant growths upon the surface. Sometimes in the course of esophageal carcinoma with almost complete obstruction, there is sudden cessation of the symptoms, so that the case may simulate spasmodic stenosis, until the subsequent recurrence and course prove conclusively the nature of the case. In these instances there has been more or less ulceration on the surface of the growth, which leads to the sudden detachment of a slough and the consequent disappearance of the obstruction and the attendant symptoms. By passing bougies systematically we favor this tendency and may maintain the opening for a considerable length of time. It is always to be remembered, however, that the passage of the instrument is attended with the danger of perforation through the softened and ulcerating tissues. When the stenosis is considerable, therefore, no amount of force should be used, but by successive gentle efforts it may be possible to overcome the stricture. In any case, and no matter how well the lumen of the esophagus is maintained, the strength of the patient gradually declines, cachexia becomes more profound, and death finally occurs from exhaustion. The fatal issue may be somewhat postponed by rectal alimentation, and morphin promotes euthanasia. The operation to establish a gastric fistula has been performed repeatedly, but there is little hope of prolonging life in this way, for the esophageal growth tends to extend to the mediastinum and lungs, and to involve other organs by metastasis.

The Communicability of Tuberculosis.—The Michigan State Board of Health has decided to include all diseases dependent upon the presence of the bacillus tuberculosis in the official list of "diseases dangerous to the public health," of which notice is required to be given by householders and physicians to the local health officer as soon as such a disease is recognized.

TROPICAL DIARRHEA.[1]

BY SURGEON-GENERAL SIR JOSEPH FAYRER,
K.C.S.I., LL.D., M.D., F.R.S., HONORARY PHYSICIAN TO THE QUEEN; HONORARY VICE-PRESIDENT OF THE INTERNATIONAL CONGRESS OF PUBLIC HEALTH, CHICAGO; PRESIDENT OF THE MEDICAL BOARD AT THE INDIA OFFICE, LONDON.

TROPICAL diarrhea, diarrhea alba, white flux, sprue, psilosis, etc., are synonyms applied to a form of disease that occurs as the result of residence in China, Cochin China, Batavia, Java, the Indian and Malayan peninsulas, Ceylon, and probably in other tropical and sub-tropical countries, and occasionally in extra-tropical regions.

This is a form of disease that, if not always, is generally the result of tropical and climatic influences, and the debility and cachexia thereby induced. It is now not infrequently observed in Europe, owing to the ever-increasing means of communication with foreign countries. It is apparently generally confined to adults, is insidious in onset, slow in progress, and, owing to irreparable degenerative changes, when not arrested sufficiently soon, is often fatal.

It has been described by many observers, both English and foreign, in India, China, and Batavia. Most of the cases seen in this country come from China, India, or Ceylon. In India it is frequently met with, where a form of it is known as "hill diarrhea," from its proneness to affect dwellers in hill stations, especially those who have previously lived on the plains. Atmospheric changes, vicissitudes of temperature, greater altitude, rarefied atmosphere, and possibly water, are concerned in its causation. Some authors consider it a disease distinct from the white flux, which may be seen in any part of the country, but they are so much alike as, for practical purposes, to justify the belief in their identity. Occasionally there is a resemblance to certain forms of chronic dysentery. The two conditions may be associated, or one may merge into the other.

Tropical diarrhea occasionally makes its appearance years after the subject of it has returned from the tropics. It not unfrequently begins without any previous apparent derangement of health, though it is sometimes preceded by dysentery, diarrhea, some indication of malarial infection, or functional derangement of the liver, or other abdominal viscus, and is not noticed until excessive soreness of the tongue, and loss of strength and wasting, reveal the gravity of the condition.

People in India, suffering from malarial cachexia, are likely to be troubled with diarrhea of an irregular character, which, if not promptly dealt with, may be the precursor of the chronic form, and is often obstinate enough, especially if there be hepatic or splenic complications, or any vestige of previous dysentery, but it is not so grave in character as the white diarrhea. This latter, however, in all its forms, if carefully and promptly treated at the outset, and unattended by structural changes in the viscera, is comparatively amenable to control.

SEMEIOLOGY.—This form of diarrhea, as I have said, may begin with simple looseness of the bowels. or may supervene upon an ordinary diarrhea or chronic dysentery. The action produces a sense of relief. The dejecta at first may be natural and bilious, but gradually become light-colored, frothy, pultaceous, and copious. As the disease advances they are occasionally tinged with blood, and the sufferer becomes more attenuated, exhausted, and incapable of any prolonged exertion. The appetite may be good, but rawness and tenderness of the mouth and tongue, frequently accompanied by aphthous spots and ulcerations, interfere with its gratification. Deficiency of bile is suggested by the appearance of the dejecta, whilst the microscope detects vegetable and fibrous tissue, or other portions of the ingesta passing unaltered, as well as certain forms of microorganisms. This light color, which is irrespective of the nature of the diet, is not due to any specific disease of the liver, which only shares with other organs the shrinking due to general wasting.

Diarrhea is not always a prominent symptom of this disease, and, according to my experience, cases occur more frequently in patients from Ceylon, where general wasting and soreness of the tongue are the chief characteristics, though, at the same time, the excreta are of normal color.

The subjects of tropical diarrhea are pale and emaciated, with the skin dry, flaccid, sallow, and sometimes pigmented in patches. The abdomen is soft and flaccid, the eyes become pearly and sunken, the gums pale and shrunken, the lips and conjunctivæ blanched and anemic. The tongue, at first pale and flabby, becomes shrunken, red, and glazed; the papillæ are obliterated; it is raw, smooth, and tender, often affected, as is the buccal mucous membrane, by aphthous ulceration, and in some cases covered with a black coating of white epithelial scales. The state of the tongue is generally significant of the stage of the disease, return to the normal condition being a hopeful sign, while increased smoothness and tenderness, with aphthæ, are of evil augury.

Evidences of malarial influences are shown at the outset, and sometimes in the course of the disease, by recurrences of fever, by vague conditions of malaise, or by myalgic or neuralgic disorder.

The symptoms described may be mitigated by treatment, but the improvement is often more apparent than real. The disease slowly and surely

[1] Read before the International Congress of Public Health, Chicago, 1893.

progresses until the patient is compelled to seek change of climate. Should this be of no avail, the symptoms increase in gravity; the breathing becomes feeble and accelerated; the temperature subnormal; the extremities edematous; anemia is profound, and the urine often albuminous; the catamenia are suspended or diminished. If this evil condition be not arrested, and it seldom is checked when it has gone so far, fatal exhaustion or pulmonary embolism or thrombosis soon closes the scene.

This condition appears to be the consequence of general degeneracy rather than specific disease of any one organ, though the intestinal tract seems to be the seat of the most marked change.

Morbid Anatomy.—When death has occurred at an early period the intestines have been found contracted, with the mucous lining thickened, congested, and even ulcerated; but when death takes place at a later period, the coats of the bowel are found to be attenuated, diaphanous, and the seat of fatty and lardaceous degeneration, with occasional ulceration in the ileum or colon. The intestinal and mesenteric glands are atrophied and degenerated, the latter sometimes enlarged. The mesentery itself is wasted, the liver shrunken, pale, and contracted, so as in life to have given rise to the belief that it was specially atrophied. The spleen, pancreas, and kidneys are in a similar condition. Occasionally, though not in ordinary cases, there may be chronic enlargement of the liver, or of the spleen, or of both. There is not so much surface-change as thinning of all the coats of the small intestine, so that they become translucent; when dysenteric symptoms have appeared, ulceration of portions of the colon has been found. According to the experience of Dr. McConnell, professor of pathology in Calcutta, amyloid degeneration of the bowel is rare among natives of India, but he confirms the accuracy of the account given by Dr. D. D. Cunningham, of the morbid anatomy of the intestines of the sufferer from chronic diarrhea and dysentery in famine seasons. The valuable report of Dr. Cunningham on the famine diarrhea—of which the condition is probably analogous to that now under consideration—shows how the degenerative changes involve the intestines, as well as the other viscera, and the general result of the entire series of observations on the morbid anatomy is to show that the diseased conditions were specially characterized by extreme general anemia and destructive processes affecting the mucous membrane of the intestinal canal. This latter characteristic is also pointed out by Aitken and Virchow. The absence of epithelium and the obliteration of villi are very remarkable in the tongue, and besides these characteristics an absence of fat and a general wasting of the tissues are conspicuous.

With regard to the bacteriology of the diseased conditions due to tropical diarrhea, Professor Macfadyen points out that in the normal bacteriology of the digestive tract there are a large number of bacterial species, and that this is the case also in the normal small intestine, no one kind predominating. Its contents have a faintly acid reaction, which has inimical effects on the growth of organisms. The bacteria normally present in the small intestine ferment carbohydrates, but do not decompose albumins.

Dr. Macfadyen found the stools from a case of tropical diarrhea to be crowded with microörganisms, of which one kind, a bacillus, predominated; it was like the anthrax-bacillus, somewhat thickened, with flattened ends, and motile. He found no ameboid organisms, but, as he remarks, that does not prove that they were not there. It has, he maintains, undoubtedly been proved that in some diseases of the digestive tract, occurring in hot climates, large numbers of ameboid organisms are to be found in the large intestine. Many interesting investigations into this subject have been made by Kartulis, Osler, of Baltimore, Councilman and Lafleur, and others, but we are not yet in a position to assign them a definite *rôle* in the causation of intestinal disease.

Dr. Thin describes the cultivation of thirteen distinct forms of organisms that he obtained from a case of this disease, and their different effects on gelatin. In a more recent communication (April, 1892), he brings forward reasons to show that in the so-called sprue the reactions of the intestine are abnormal, and he argues that this must induce abnormalities in the development of the bacteria normally present in the bowel, which in its turn might account for the abnormal coloring of the stools.

Treatment.—From the insidious character of the disease, tropical diarrhea not infrequently gains ground before radical measures for its relief are resorted to. Successful issue depends much on the patient's resolution and perseverance in carrying out instructions. Alternations of temperature, errors of diet, fatigue or excitement, exertion, mental or physical, should be avoided. Physiologic rest should be insisted on.

There is a tendency in the earlier stages to get well. The object is to favor this tendency, and not thwart it by neglect of precautions. Diet is the most important consideration, and must be strictly regulated and adhered to; and scarcely less important is the question of clothing, habits, and mode of life.

Milk should be the sole and only diet, and it must be given in small quantities, often repeated, say from four to six ounces every hour, day and night. Larger

quantities at longer intervals will not do. When in the twenty-four hours an adult is able to take from three to four quarts of cow's milk in this way, ample nourishment is afforded to support his strength and to enable him to recover.

This method of treatment was begun by me before leaving India in 1872. After prolonged experience and trial of all other forms of remedies, I have found it more effective than anything else. It seldom fails, except in the very advanced and chronic cases, or in very aged persons. In ordinary cases it must be adhered to for three weeks, a month, or six weeks, when changes or additions may be tentatively and gradually made. Occasionally it may be expedient to add a little water, lime-water, or soda-water, but it is seldom necessary to dilute the milk. Tea, coffee, or cocoa, as a general rule, disagree. Alcoholic stimulants for those who have long been accustomed to them may be necessary, but should be cautiously administered in limited quantities (from two to six ounces a day). The best are old brandy or whiskey given with the milk or some alkaline water. As a rule, all wines are unsuitable. Regularity in times of administration, and the quantity of milk given, is most essential. It is generally well to begin with two or three ounces per hour, increasing to six. In very aggravated cases it may be expedient to give one or two ounces every half-hour. If, after three weeks or a month the diarrhea has entirely ceased, and for some time, if the tongue be less red and sensitive, and if the papillæ have reappeared, a slight addition may be made, but not unless this is the case. After taking the milk for some days the tongue becomes coated with white fur, but is less red at the tip and edges; the aphthæ often present disappear, as well as the abnormal sensitiveness. The diarrhea probably gives place to constipation, and the patient feels better in all respects. When this condition has been attained a change in diet may begin.

At first bread, not recently baked, and thoroughly incorporated as crumbs in the milk, may be added in small, gradually increasing quantities. After a week or more, a little finely minced mutton or chicken, not previously cooked, may be given. If the improved condition continues, a little light pudding or other farinaceous food should be given, followed by a very tentative and gradual return to meat and vegetables and other light food, but if any sign of irritation recurs, milk-diet should be at once resumed, and continued until all disturbance has ceased. It is very difficult for the patient to realize the danger of indiscretion, the need for care and caution, but these difficulties are often surmounted and complete recovery takes place.

In addition to these precautions in diet, others must be observed. These are warmth, complete rest, and, if possible, residence in some mild and sheltered locality. The latter, however, is not to be insisted on if it involves the loss of the care, comfort, and attention of home-nursing. The greater part of the twenty-four hours should be passed in a recumbent position, at any rate in the earlier stages. As the condition improves—of which the state of the tongue, as well as a diminution of the diarrhea, is the best indication—the patient may take moderate exercise, but all fatigue should be avoided. Long after recovery is apparently complete, vicissitudes of temperature, over-fatigue, and errors in diet must be carefully avoided. It may be necessary to delay return to a tropical climate for a year, if not indefinitely.

The careful use, in the early morning, of saline laxatives, combined with some bitter infusion, may be beneficial to relieve abdominal plethora and portal congestion, but care must be taken not to produce overaction. To allay irritability and to give tone, small doses, from three to five drops, of liquor arsenicalis, twice a day, continued over a period of weeks, with occasional breaks of three or four days, may be beneficial. When the bowel is very irritable, with pain and a tendency to watery discharges, doses of from five to ten minims of tincture of opium, or a few grains of Dover's powder, may be useful. Later on, as recovery progresses, mild preparations of iron, especially the potasso-tartrate, may be beneficial. Experience, however, has shown that with the exceptions already alluded to, drugs are of little use.

The hygienic and dietetic precautions mentioned are generally successful, unless visceral complications of a structural nature have occurred, or the patient be exhausted by age or debility, or the disease be in a very advanced stage. Unhappily, many who fall in the latter category succumb, whilst some suffer frequent relapses from neglect of rules laid down, and die from inanition and exhaustion; hence the necessity for early treatment and rigid adherence to the simple though irksome regimen which experience has shown to be the best. When the milk has failed, it has frequently been because it had been mixed with other food, or has been taken at irregular intervals and in too large quantities at a time.

The conclusion is that, though drugs are generally of little avail, if milk, taken as prescribed, does not succeed, there is but small chance that any other form of treatment will do so.

De Renzi has succeeded the late Professor Cantani at the first medical clinic at Naples, while Carderelli succeeds De Renzi at the second medical clinic.

REPORT OF A FIFTH SERIES OF CASES OF ENTERIC OR TYPHOID FEVER TREATED BY SYSTEMATIC COLD BATHING IN THE GERMAN HOSPITAL, PHILADELPHIA.

BY JAMES C. WILSON, M.D.,
PHYSICIAN TO THE HOSPITAL, AND PROFESSOR OF THE PRACTICE OF MEDICINE IN JEFFERSON MEDICAL COLLEGE.

FROM the introduction of the treatment of enteric fever by systematic cold bathing according to the method of Brand, in the German Hospital, February, 1890, until June 1, 1892, 226 cases were treated, of which number twelve terminated fatally, giving a death-rate of 5.3 per cent. The hospital statistics relating to the subject were published in detail in this journal last year.[1]

During the year terminating June 1, 1893, 74 additional cases have been treated by this method, bringing the total number up to 300.

The following table, compiled from the records of the hospital by Dr. Hand, resident physician, shows in detail the date of admission, the sex, age, the day of the disease as nearly as could be ascertained upon which the patient entered the hospital, the highest recorded temperature, the first day of the attack upon which the temperature fell to normal, the number of days in the house, and the number of baths administered in each case:

CASES OF ENTERIC FEVER TREATED BY SYSTEMATIC COLD BATHING.

Series No. 5. June 1, 1892, to June 1, 1893.

No.	Admitted.	Sex.	Age.	Day of disease.	Max. temp.	First day normal temp.	Days in house.	No. of baths.

Total number of cases, 74; deaths, 8; mortality, 10.8 per cent. Relapses, 10—13.5 per cent.

The patients were chiefly adolescents and young adults. Children are not received into these wards, as there is in connection with the hospital a children's infirmary; 58 cases (78 per cent.) were under 30 years of age.

Baths: Average number, 44; smallest, 2; largest, 195. Average number of days in the hospital of the non-fatal cases, 33.

Notes on the fatal cases:

No. 7.—G. H., male, thirty-six years of age, was admitted on the tenth day of the disease, having had hemorrhages before admission; he lived sixteen days in the hospital.

No. 32.—M. L., female, nineteen years of age, was admitted on the tenth day of the disease; normal temperature on the sixteenth; relapse on the nineteenth; death on the thirty-third.

No. 46.—A. K., male, twenty-one years of age, admitted in a very weak condition; about the second week of the disease, pulse 172, temperature 106°; improved with the baths, and temperature came down to normal; after a week, relapse began; emaciation extreme; death at the end of the second week of the relapse.

No. 49.—J. K., male, twenty years of age, admitted on the seventh day of the disease; hemorrhages on the ninth day; pneumonia on the fourteenth day; death on the nineteenth day.

No. 53.—G. S., male, fifteen years of age, admitted on the sixth day of the disease; in the morning remissions during the first week the temperature was but twice down to 103.5°; highest temperature 106.2°; developed meningitis and died on the twenty-second day.

No. 58.—B. S., male, twenty-six years of age, admitted on the seventh day of the disease and had great mental depression from the outset; died on the twenty seventh day.

No. 62.—J. C., male, twenty-four years of age, a "walking case," admitted on the eleventh day of the disease, with spots; hemorrhages on the fourteenth and fifteenth days; passing by the bowel one hundred and seven ounces of material consisting largely of blood; death on the fifteenth day.

No 69.—W. C., male, colored, eighteen years of age, admitted on the twelfth day of the disease; hemorrhages on the twenty-fifth and twenty-sixth days of the disease; death on the thirty-first.

The total number of cases treated by this method to June 1, 1893, is 300; total deaths, 20—giving a death-rate of 6.6 per cent. In the entire series of 300 cases relapses occurred in 29 instances; more than one relapse in two cases.

The following statistics, though based on a relatively small number of cases, support the generally accepted statement of Brand that the influence of the treatment upon the mortality is proportionately favorable as it is instituted early in the course of the attack.

In Series No. 5, 20 cases were admitted on or before the fifth day of the disease; of these, none died. Forty-two cases were admitted prior to the tenth day; of these, 4 died, giving a mortality of 9.5 per cent. Twelve cases were admitted after the tenth day; of these, 3 died, giving a mortality of 25 per cent. The day of the disease upon which the patient was admitted to the hospital was not noted in 20 cases.

In Series No. 4,[1] 12 cases were admitted on or before the fifth day; of these, 1 died fifteen days later of a complicating meningitis. Thirty-six cases were admitted before the tenth day; of these, 2 died, giving a mortality of 5.5 per cent. Six were admitted after the tenth day, with 1 death, giving a mortality of 16 per cent. The day of admission was not noted in 24 cases.

Taking Series 4 and 5 together, we note that of 32 cases admitted not later than the fifth day 1, or about 3 per cent., terminated fatally. In 78 cases admitted prior to the tenth day, the death-rate was 7.7 per cent., and in 18 cases admitted after the tenth day the death-rate was 22 per cent.

The dictum of Brand, that none of the cases in which the treatment is instituted prior to the fifth day are likely to terminate fatally, is well known. The fatal case in the fourth series, a boy aged thirteen, was admitted on the third day. The cause of death in this case, however, was meningitis occurring as an early complication.

In civil practice, except in local epidemics, the positive diagnosis of enteric fever can rarely be made as early as the fifth day. In hospital practice only a small portion of the enteric fever cases are received before the fifth day. In the service of the German Hospital patients are subjected to the bath-treatment if, upon admission, the diagnosis of enteric fever is probable or becomes so by exclusion. This practice has led to very few errors in diagnosis.

It is understood that in by far the greatest number of instances the date of the beginning of the fever can only be approximately determined; only exceptionally does the disease begin with an abruptness that fixes definitely the day or hour of its onset. The general rule in taking the cases has been to date the beginning of the attack from the day on which the patient regarded himself as having fever or on which he was obliged to give up his occupation. The appearance of the eruption and enlargement of the spleen, which usually may be noted on the seventh or eighth day, rarely as early as the sixth and seldom so late as the tenth, are clinical events which aid in fixing the date of onset.

Ephraim, of Breslau, in a recent communication

[1] THE MEDICAL NEWS, November 26, 1892.

on "The Significance of the Statistical Method in Medicine,"[1] says: "The statistics of the cold-water treatment of enteric fever are untrustworthy because this disease shows the widest variations in its prognosis, and because for this reason an enormous number of observations are necessary to establish the value of a method of treatment."

The treatment of enteric fever by systematic cold bathing according to the method of Brand now rests upon statistics that fulfil the second requirement of this criticism. The number of reported cases is enormous. They are the results of work done by different observers in all parts of the world, and many of the collections of cases, as those of Brand himself, those of the military physicians at Lyons, those of Hare of Australia, are sufficiently large in themselves to establish the value of this method of treatment.

To these we may now add the statistics of the German Hospital in Philadelphia, which are based upon the observation of a sufficient number of cases and extend over a period of time sufficiently extended to eliminate in part at least the errors arising from the variations in the prognosis of individual cases and in the intensity of epidemics in different years.

Certainly the literature of internal medicine shows no aggregate of statistics in regard to the treatment of any other disease that has reached such proportions and in which the treatment has been carried out with the same rigid adherence to rule.

A remarkable and instructive fact is this, that the statistics from various quarters and from relatively large and small collections of cases show a mortality percentage that is as a rule nearly constant, so that we may now regard it as demonstrated that the death-rate of enteric fever under the treatment of Brand, instituted early in the attack and rigorously carried out, does not range beyond 6 or 7 per cent., while the general statistics show a mortality under various other forms of treatment, most of which are essentially expectant-symptomatic, ranging from 15 to 25 per cent., and exceptionally, far higher.

It seems hardly necessary to dwell upon the importance of this difference in death-rate. What argument in favor of the treatment by systematic cold bathing can be more urgent or more conclusive? From eight to fifteen or more lives saved in every hundred cases, and this in the endemic fever of our historic period—an infection from the effects of which no large community is ever free—which is kept alive and fostered by the methods of living in civilized countries in this age! The from eight to fifteen lives lost in every hundred by adherence to obsolete and traditional methods are, as a rule, picked lives. They are taken from the best—adolescents, young adults, the very flower and hope in every community. This is not the place to speak of the emotional effects of this sacrifice of life to routine. It is, however, proper to suggest the economic aspect of the matter, the appalling waste of young life that could so easily be saved.

We in the Western world are in the habit of speaking somewhat scornfully of Oriental apathy. Enteric fever and tuberculosis, the endemic scourges of our civilization, are in theory at least preventable diseases. Enteric fever is a disease in which, as has been demonstrated, the death-rate can be lowered from between 15 and 25 per cent., to 6 or 7 per cent., by the abandonment of traditional methods of treatment and the adoption of a different plan. Yet the older methods prevail.

Redmond, in a paper read before the British Medical Association in August, 1893,[1] makes the following remarkable statement:

"With the exception, however, of a paper by Dr. Sidney Coupland, in the *Lancet* for 1884, so far as I am aware, no attempt has been made through the medium of the medical journals to popularize the principle and remove that prejudice the undoubted existence of which, both in the professional as well as the public mind, constitutes the chief obstacle to the more general adoption of a line of treatment the practical evidence in favor of which can no longer be doubted by, I venture to affirm, any rational man."

The writer of the foregoing paragraph has overlooked much that would interest him in the medical journals of the last five years. Not to speak of the German and French reports upon the subject, he will find that many attempts have been made in the United States to break down the barriers that are in the way of the general use of the Brand treatment. Are the writings of Baruch, Sihler, Peabody, Thompson, Wilkins, and others on this side of the Atlantic, who have reported cases and detailed the method, wholly unknown to him? Is our work in the German Hospital in Philadelphia since the beginning of 1890, the subject of repeated articles in the journals, no effort to "popularize the principle" and remove prejudice? We have now reported 300 cases; Redmond's paper is based upon four observations.

Guaiacol Topically for Erysipelas.—Bard (*Le Mercredi Médical*, 1893, No. 42, p. 510) reports successful results from the topical application of guaiacol by means of a brush in the treatment of five cases of erysipelas. From fifteen to thirty minims of guaiacol were employed at each application, which extended for a short distance beyond the inflamed area, and was, as a rule, followed by a reduction of the temperature, continuing for several hours.

TWO PROSTATECTOMIES—CELIOTOMY FOR TUBERCULOUS SALPINGITIS.

BY WELLER VAN HOOK, A.B., M.D.,
OF CHICAGO, ILL.;
PROFESSOR OF SURGICAL PATHOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; PROFESSOR OF SURGERY IN THE POST-GRADUATE MEDICAL SCHOOL.

IN two recent cases of prostatectomy I have had occasion, for the control of hemorrhage, to use the tampon recommended by Dr. E. L. Keyes.[1] It has been so satisfactory that I desire to indorse it in a brief report.

CASE I.—Oliver K. H., a Norwegian, aged sixty-four years, referred by Dr. N. E. Remmen, of Chicago, had suffered from the mechanical consequences of enlarged prostate for ten years, and during the last eight years of this period had used a catheter with a moderate degree of comfort. Four months before the patient consulted me he broke off five inches of an old No. 12 soft-rubber catheter in the bladder and prostatic urethra. He had retained the catheter after it had become old and brittle, because its stiffness, increasing with age, had facilitated its introduction. For two days the fragment of catheter remained in this position, allowing the urine to flow continuously. It then slipped back into the bladder, where, strange to say, it caused but little trouble. This was probably due to the fact that the patient had become accustomed to the unpleasant symptoms caused by vesical irritation. At the time the man consulted me the urine was being drawn about every three hours. There was a fair amount of vesical contractility. The urine contained a slight amount of pus, but no casts. Rectal examination revealed a moderate enlargement of the prostate gland. The patient's general condition was good. There was but a small amount of atheroma, and symptoms of toxemia were absent.

Supra-pubic cystotomy readily enabled me to remove the foreign body, which is represented in Fig. 1, and to palpate the enlarged prostate. The obstruction was found to depend upon the presence of a projecting mass the size of a hen's egg, acting as a ball-valve at the entrance of the urethra. This was removed by the scissors and forceps, and a channel, giving free communication between the retro-prostatic vesical pouch and the entrance of the urethra, was dug out in the same way. This part of the operation was performed as quickly as possible; still the hemorrhage from the scissor-cuts, rendered necessary by the toughness of the gland-tissue, was considerable. While hemostatic irrigation of the bladder with hot water was being performed, a tampon was made by tying a strong suture of silk to the middle of a pad of layers of iodoformized gauze four inches square. A steel sound was then passed by the urethra, and the free end of the suture fastened to its beak as it presented in the wound. Upon withdrawing the sound, traction upon the suture caused the tampon to descend, middle first, into the wound, and the finger quickly guided it to the vesical neck. The free end of the thread was fastened to a small roll of iodoform gauze at the meatus. The hemorrhage, after having almost entirely ceased during irrigation, had begun again. Traction upon the tampon now controlled it completely. Upon recovering consciousness the patient complained of no pain, the urine drained freely through the incision, and after thirty-six hours the tampon was withdrawn with forceps, with but little discomfort. The patient's recovery was uneventful.

FIG. 1.

CASE II.—Mr. W., aged sixty-seven years, began in April, 1893, to use the catheter on account of a prostatic enlargement, which had begun to produce obstruction two years before. In spite of daily irrigation of the bladder, catheterism soon failed to relieve the vesical irritability, although the instrument was passed every hour and a half. The patient, exhausted from worry and loss of sleep, begged for operative relief, and was referred to me by Dr.

[1] N. Y. Medical Record, September, 1892.

Reuben Peterson, of Grand Rapids, Mich. Examination revealed a rather large prostate; the residual urine was six ounces; the expulsive force was small; there were no renal casts; the general condition was good. Upon operating, the supra-pubic opening into the bladder revealed a napkin-ring-like mass of prostatic tissue projecting well into the bladder, with the urethral opening in its center. It was evident that the urine could only be passed through such an opening by the exercise of great force. In order to expose the prostatic tissue more freely to palpation, and to facilitate hemostasis and subsequent drainage, a perineal incision was made. The ring of prostatic tissue was incised with scissors in front of the urethra, and the finger was then introduced into this opening through the ventral wound. The new tissue in this case was deposited in nodules varying in size from that of a pea to that of a pigeon's egg. They were enucleated with the finger-tip after some difficulty, three hundred and ten grains of tissue being removed. A "low-level" channel was thus produced. Hemorrhage was not so severe in this as in the preceding case, because it was not necessary to use the scissors so freely. The Keyes tampon was applied, however, in the same manner, except that the suture was brought out through the perineum instead of through the penis. The suture was held in place by wrapping it around a roll of iodoform-gauze, to which it was clamped by a small hemostatic forceps. The tampon was removed after thirty-six hours. The patient made a satisfactory recovery.

The precision and rapidity with which hemorrhage is controlled after prostatectomy by this simple measure encourages the hope that we shall now be able to reduce our death-rate by this and other means to a point so low that we shall be justified in materially extending the indications of the procedure.

Case III. *Tuberculosis of the Fallopian tubes and retro-peritoneal lymph-glands; partial obstruction of the rectum; celiotomy; definitive recovery.*—Mrs. S., twenty-six years of age, a German, has had three children; since the birth of the last, in November, 1892, she has lost her health. For several months her weight has been decreasing; her color is tawny and her appetite poor. Menstruation has been irregular and painful, and she has had leukorrhea. Obstinate constipation was not overcome by the stronger cathartics and the bowels only moved at intervals of about a week, the patient meanwhile suffering intensely from tormina, the vermicular intestinal movements being visible through the abdominal walls.

Examination by the vagina disclosed slight lacerations of the perineum and cervix, as well as tubal distention, upon the right side the size of a hen's egg; upon the left side, that of a walnut.

In preparation for celiotomy one-eighth-minim doses of croton oil were given three times before satisfactory evacuations were effected.

Abdominal section enabled me to remove the tubes in the usual way, although they were matted down tightly to the surrounding pelvic viscera, producing in that way the constriction of the lower bowel that caused the obstipation. Behind the peritoneum, however, the lymphatic glands were enlarged to the size of walnuts in a chain extending from the small pelvis to the first lumbar vertebra. During the first few days there was much gaseous distention of the bowels, and laxatives gave the most meager results. On the twelfth day, however, several passages occurred spontaneously, one of which was enormous and contained fecal masses that were evidently very old. Small doses of cascara sagrada were afterward given, with perfect success, to move the bowels.

The temperature, which was elevated before the operation, fluctuated afterward in the irregular manner common in tuberculosis, between 98.8° and

Fig. 2.

Tuberculosis of Fallopian tube. Transverse section. ×24. Walls of tube much thickened.

a. Infiltrated peritoneum.
b. Defect of peritoneum.
c. Bloodvessels containing blood.
d. Small tubercles with giant-cells.
e. Areas of caseation.
f. Mucous membrane.
g. Defect of mucous membrane.
h. Large tubercle with giant-cells—beginning caseation.

101.8°. After the fourteenth day the temperature remained normal and all the symptoms improved. The patient has recovered her health in every way, and I believe the tuberculosis of the retro-peritoneal lymphatic glands is now in a stationary condition equivalent to recovery. A section of one of the tubes (which, of course, contained tuberculous detritus) is pictured in Fig. 2.

This case is worthy of note, because of (1) the

pathologic nature of the tubal inflammation; (2) the obstipation due to pressure, with recovery after removal of the diseased uterine appendages; (3) the apparently permanent recovery of the very extensive tuberculous lymphadenitis after extirpation of the primary focus.

THE GENERAL PRINCIPLES UNDERLYING ALL GOOD METHODS OF INFANT-FEEDING.[1]

BY T. M. ROTCH, M.D.,
OF BOSTON, MASS.;
PROFESSOR OF DISEASES OF CHILDREN, HARVARD UNIVERSITY.

JUST as the highest aim of medical art should be directed to the province of preventive medicine, so the highest and most noble branch of preventive medicine should consist in the study of the best means and the most practical methods for starting young human beings on their life-race; for preserving them from the perils that surround the early hours of existence; for giving them strength and vigor to resist the attacks that, greater and more dangerous in inverse proportion to their age, must inevitably be made on their vitality. The preventive medicine of early life is preëminently the intelligent management of the nutriment that enables young human beings to breathe and grow and live. In fact, it is proper or improper nutriment that makes or mars the perfection of the coming race.

Infant-feeding, then, is the subject of all others that should interest and incite to research all who are working in the preventive medicine of early life. The subject is a great one, and is worthy of the attention of the greatest minds of the age; worthy of the discussion of the leaders in medical thought of our Western Continent.

The responsibility of introducing such a serious question before such an assemblage of advanced medical thought is a grave one. It should be taken up carefully, and it must be dealt with broadly. For the present we must acknowledge, and in fact it is true, that in the status of infant-feeding, as it has existed until within the last few years the average human breast-fed infant is more likely to live, the other factors of the life-problem being equal, than the infant fed by any other method. But we must remember that the latest scientific work on this subject shows very clearly that it is not breast-milk as a whole that is preëminently good, but that there are definite, known qualities inherent in the different elements of the breast-milk that make it the best known food. It is our province as scientific workers in this most important branch of practical medicine year by year to elucidate and make use of these elements, once covered by a somewhat mysterious veil, but now rapidly becoming laid bare by the searchlight of patient and laborious investigation.

A great advance has been made in our knowledge as to what we are to copy from human breast-milk and what we must achieve in preparing a substitute. The very essence of this practical information that we have gradually acquired lies in the discovery that there is no one perfect nutriment for young human beings as a whole, but that it is the changes in the various elements of the breast-milk that satisfy the demands of the individual, and thus in time suit the many to such a degree that this protean food has erroneously come to be looked upon as one especial unchanging nutriment.

To thoroughly understand and successfully solve the feeding-problem of the early months of life a knowledge of the changes that from many causes take place in the mammary gland must be clearly kept in view. Again, the methods of modifying the milk in the human mammary gland, however limited in scope they may be, should be practically investigated and carefully adapted to the individual, according to its age and size and general physical condition. The mammary gland in its perfected state, uninfluenced by disease or nervous disturbance or by the improper living of its owner, is a beautifully adapted piece of mechanism constructed for the elaboration and secretion of an animal food. When in equilibrium it represents the highest type of a living machine adapted for a special purpose, both mechanically, chemically, physiologically, and economically. When from any cause this sensitive machinery is thrown out of equilibrium its product is at once changed, sometimes but slightly, but at other times to such an extent that the most disastrous consequences may follow when it is imbibed.

To state, then, concisely what I have already referred to in studying the form of nutriment suitable for the early months of life, we should manifestly be guided by what Nature has taught us throughout many ages.

The researches of science, especially in the subject of infant-feeding, are indeed wisely directed to learning to read the truths that Nature presents to us. Great progress has been made in reading these truths; what we are at present endeavoring to do is to copy them.

The constituents of the nutriment that Nature has provided for the offspring of all mammals is essentially animal and never vegetable. Human beings, therefore, in the first twelve months of life are carnivora. It is, therefore, evident that an animal food entirely and always free from any vegetable constituents has been proved to be the nutriment on which the greatest number of human beings live and the least number die.

When good breast-milk, or rather one that is

[1] Address at the opening of the third session of the Section for Diseases of Children of the Pan-American Medical Congress at Washington, D. C., September, 1893.

fairly adapted to the individual infant, cannot be obtained, or, if obtained, cannot be regulated by modification, it is desirable to combine the elements that good breast-milk represents. For perfecting this, which may best be called substitute feeding, we must have a material that, while as closely as possible approaching the analyses of good breast-milk, is also easily accessible.

There is no mammal whose milk-production corresponds sufficiently to human milk to render a direct substitution safe or wise. If, therefore, milk is used, the problem demands for its solution a modified milk. The mammal whose product representing a carnivorous food has been proved from the earliest ages to best satisfy this demand is the cow. Certain breeds of cows are better adapted than others to produce milk that may be used for imitating human milk. For the use of this continent these breeds are the Durham, Ayrshire, Holstein-Friesian, American grades, and common natives.

The infant at the breast receives for its nutriment a fluid that is fresh, sterile, neutral, or faintly alkaline, has a temperature of from 98° to 100° F., and is furnished in an amount proportionate to its age and size. It is this fluid that we should copy in every possible detail when we undertake to prepare a substitute food. We should also consider as foreign matter, to be rigidly avoided, any element that we know is not to be found in the fluid that we are copying. Thus and thus only can we finally arrive at the proper solution of this intricate feeding-problem.

It would seem hardly necessary to suggest that the proper authority for establishing rules for substitute-feeding should emanate from the medical profession and not from non-medical capitalists. Yet, when we study the history of substitute feeding as it is presented all over the world, the part that the family physician plays, in comparison with the numberless patent and proprietary foods administered by the nurses, is a humiliating one, and one that should no longer be tolerated.

I would plead in the name of common humanity, as well as in the name of the intelligence and scientific reputation of our profession, that this representative body of American physicians should, in its endeavor to advance the general subject of infant-feeding, record itself as opposed to the use of patent or proprietary foods of every description. If we are abreast of the times, if we will but recognize and do justice to the work that has lately emanated from our own profession, we surely will not hesitate to boldly relegate to oblivion the statements of the food-proprietors, which on box and can, on bottle and on printed circular, attempt to stem the slow but inevitably progressing wave of scientific investigation.

It may be well to bear in mind that the attempts which in the past have been made to manufacture cheap foods have been markedly failures. We must first, regardless of expense, learn by modification to produce a perfected substitute food before we should endanger the success of our undertaking by allowing the mercantile side of the question to cripple us in the use of costly methods that we know to be the best. We should, in fact, remember that the nutriment which we are endeavoring to copy, far from being a cheap product, is on the contrary a very expensive one.

It is the knowledge of how to determine the best combinations of certain elements, and the best methods of accomplishing these combinations, that in the last year or two has especially claimed our attention and in which we have met with signal success.

There is no doubt but that one of the most important questions connected with the preparation of a substitute food is the proper control of the primal milk-supply. What that control shall be and how it shall absolutely be kept in the hands of those who by education and unselfish interest are most fitted to use their power wisely, is a matter worthy of your deepest thought.

The State control, as represented in Denmark, is indeed a brilliant example of what can be accomplished in this direction. Whether a similar method would prove to be the best for us to adopt has not as yet by any means been proved. The political clouds that continually obscure the highest scientific aspirations on this continent make it probable that, for the present at least, the primal milk-supply can best be perfected by individual enterprise and enthusiasm.

Finally, I would call your attention and consideration to the great capacity of different infantile digestions for assimilating a variety of proportions of the same nutritive elements; and hence, when introducing new methods for preparing a substitute food, the necessity for providing for many prescription-possibilities.

The latest researches on human breast-milk show that the albumin of the milk is not merely an exudation from the lymph-vessels supplying the mammary gland, but that it is actually modified in the breast.

We thus see that the mammary gland, besides being an elaborator and a store-house for infant nutriment, is also a modifier.

Following, therefore, Nature again closely, we learn that the precise modification of an absolutely pure and fresh primal milk-supply is the vital principle that at present should underlie our efforts to perfect substitute feeding, and I trust that those who will to-day take part in the discussion of this very

important subject will especially enlighten us on two matters of extreme interest:

First, what is the best method of obtaining a stable and perfect primal milk-supply?

Second, when this supply is obtained, how shall it best be modified?

A COMMON ETIOLOGY IN THE INFLAMMATROY DISEASES OF THE RESPIRATORY TRACT.

BY EDWIN J. KUH, M.D.,
OF CHICAGO, ILL.

WHILE the literature of recent years shows sporadic instances in which writers emphasize the infectious nature of those inflammatory troubles of the nose, throat, and chest commonly ascribed to "taking cold," I am aware that it has not become part and parcel of the medical consciousness that these diseases are "caught" in a different manner than tradition and our grandmothers would have us believe. Self-observation (see "Etiology and Cure of Asthma" in the *Journal of the American Medical Association*, January 29, 1887) and observation of others have taught me that all the muffling and clothing in the world would not prevent those susceptible to "colds" from "catching" them, if a protection of the body-surface were considered a sufficient prophylaxis against these affections. It cannot of course be doubted that when chronic affections of the respiratory tract *preëxist*, exposure to rapid changes in temperature *per se* can aggravate existing conditions. But the primary affection, it seems, is always inhaled. Such circulatory changes as must occur in the respiratory tract when the vessels of the skin contract through "taking cold" are evidently a predisposing factor to infection; but that is probably all.

We all know how immune we become against "colds" in the severest climates and in spite of most careless exposure, where the air is pure; and we also recognize how susceptible we again become when we return to our city home.

With that cerebral squint, which O. W. Holmes has been pleased to dwell upon, we attempt to explain affections without exposure, with the words, "I must have taken cold."

The surgeon knows that pus implies infection, but the throat-specialist and the family doctor have not yet yielded to the inevitable and logical analogy in their fields of work. Wherever there is pus there has likely been infection; there is no reason why this proposition should not hold good for the mucous membranes as well as in other tissues. A typical acute coryza will, as a rule, run its course as unalterably as a typhoid fever. The same, generally speaking, may be claimed for the acute pharyngeal, laryngeal, and bronchial affections.

In private conversation it has been frequently retorted: "The cold is primary, the infection may follow as a complication." This would be an argument, if the infection did not constantly occur without exposure to cold. The history of the development of our knowledge in regard to pneumonia should silence that objection.

Although this article is not bolstered with bacteriologic tests, it seems a safe and necessery conclusion from the point of analogy and observation to assume that the inflammatory causes of coryza, amygdalitis, laryngitis, tracheitis, and bronchitis are inhaled. The omnipresence of organic dust, laden with bacteria, is the simplest, most constant and most forceful agent in the causation of those inflammations. No explanation for the appalling mortality from pneumonia in our large cities, frequently competing in numbers with that from tuberculosis, offers so perfect a solution as the theory of the dust-origin of that disease. The refuse from those same streets and alleys from which we turn in disgust is blown into our fashionable thoroughfares and inhaled. The utter disregard of these conditions makes our public buildings (court-houses, schools, theaters, railway stations, office-buildings, large retail stores, etc.) foci of infection. It is fairly gambling with a child's health and life to send it to school where provisions for pure air (in the sense of asepticity) are an unheard-of and at present unrealizable postulate.

The publication of the discovery of the tubercle-bacillus is entering upon its twelfth anniversary; and yet how slowly has this most positive knowledge in medicine stimulated us as a body of professional men to common and legislative prophylaxis. We are, it seems, too much interested in individuals and not enough in communities.

The remedy against dust-borne diseases of the respiratory organs would consist in pavements that do not easily pulverize, in honest street-cleaning, and in sufficient sprinkling, in rich and poor quarters, to prevent the raising of dust.

CLINICAL LECTURE.

INGROWING TOE-NAIL AND OTHER DISEASES OF THE NAILS.

Clinical Lecture delivered at Buffalo General Hospital.

BY ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

THIS patient, a young woman, suffers from well-marked ingrowing toe-nail in the great toe of each foot. The condition is almost always the result of bad habits, either past or present, in footwear. I have never seen a case in a person who has habitually gone barefoot, and the condition is practically unknown in those races that do not wear tight-fitting shoes. Moreover, ingrow-

ing nails are not found on the fingers. The ingrowing nail, therefore, is an indication that the feet have been abused and tortured. The majority of women's shoes, whether cheap or expensive, are too tight across the phalanges and exert too much pressure over the metatarso-phalangeal joints. Women's shoes especially are tight at the toes and high-heeled, so that the weight of the body drives the feet forward at each step and the toes are crowded into the shape of a wedge. The soft parts are thus pressed against the edges of the nails; they become tender from the irritation, and, after a time, ulceration may result. The nail, as sharp as many a pocket-knife blade, presses constantly into the granulations of the irritable ulcer and causes exquisite pain, which may even make walking impossible. A workingman or woman cannot afford the time to pet the feet and give up to such an incapacity, and so this girl has entered the hospital for radical relief from this lesion, which is trivial in size but severe in its consequences.

In some cases all that is necessary is to correct the footwear. It has been suggested to pack underneath the edge of the nail a little cotton with a small spatula—ladies use that universal instrument, a hairpin, for this maneuver. The cotton protects the granulations from the edge of the nail, but it has to be changed twice a day, and in cases of any severity it seldom affords permanent relief. Another method is to burn down the granulations with caustics. This mitigates the irritability of the ulcer but requires repetition every few days, and it is possible that the continued stimulation of the ulcer with caustics might bring about a malignant degeneration. Again, it has been advised to scrape the nail very thin with a piece of glass, so that it may yield in the middle and not exert so much pressure on the side where the pain is produced. Of course, the use of local anesthetics, or even of hot water, will afford some relief; but after a person has wasted scores of hours in palliative measures and found that the result is only temporary, she becomes desperate and is willing to undergo almost anything for the sake of obtaining radical relief.

One of the radical operations was suggested by a charlatan, a corn-doctor, and it has proved efficacious in a great many instances. It consists in slicing off the affected side of the toe, passing a sharp bistoury alongside the bone, and removing considerable healthy tissue along with the ulcer. For the time being a larger ulcer results, but, as it heals, the cicatricial contraction draws the soft parts away from the nail. This method has much to recommend it, and, if one does not want to lose the toe-nail, it is the only one that is effective. But it is not so radical as the removal of the offending substance, the nail itself, and the second radical operation consists, first, in a longitudinal division of the nail, and, secondly, in the avulsion of the two halves with a suitable pair of forceps. It is this latter operation that will be followed in the present case. This patient illustrates a rarity in connection with ingrowing nail, for she has one on the third toe of the left foot as well as on both great toes. Usually, ingrowing nail is confined to the great toes.

Even so simple an operation must be performed properly, or it will not be successful. The nail grows from the epiblastic layer of the developing embryo, and is simply epithelium that has become cornified, like the horns and hoofs of animals. We must remove the cells from which it is regenerated or it will be, in some measure, reproduced. It is not, therefore, sufficient to pull the nail out; we must go down to the matrix and clean it out.

The nail is split by passing a knife-blade or one blade of a pair of scissors under it and splitting it down the middle. It is separated from the matrix a little way on each side of the split, each half seized with a strong pair of forceps and torn out by a rolling motion of the forceps. In the present instance, there being three nails to remove, the patient has been anesthetized with ether, but the operation, being so short, although painful, does not usually require a general anesthetic and can be done under cocain; or, if a dentist's office is near by, you can take the patient there and give nitrous oxid. After the avulsion of the nail, the granulating surface of the ulcer is cauterized and the matrix is scraped with a sharp spoon, or touched with nitric acid, to remove all imperceptible epithelial elements from which the nail might grow. The wounds are dressed antiseptically in the usual manner.

There are other diseases of the nails which may involve any phalanges of either hand or foot. There is a condition of unusual growth, which may be called hypertrophy of the nail. This does not apply to a nail that has merely grown to an unusual length, for that is due to its normal growth and would occur in every case if it were not cut off or worn off. The hypertrophied nail is thick and flares out in various irregular shapes. This you will see more frequently in elderly people than in young persons. Sometimes the nail bunches upward into a pyramid a centimeter thick in the middle. Ordinarily, hypertrophy of the nails occurs to moderate extent in old people, and is not serious. When, however, the nail is covered by a shoe, it may catch in the lining and be so constantly disturbed in its matrix as to produce an irritable ulcer beneath. It is then necessary to remove it in order to effect a cure. Sometimes the nail is so loose as to require only to be picked off.

In certain nervous diseases, irregular growth of the nails is common. You may remember the so-called ossified man who was on exhibition in this city and elsewhere. His nails were long and had grown in loose spirals, but they were also irregular in thickness and presented numerous ridges.

There are also inflammatory changes about the nails known collectively as onychia. This condition is due to irritation from chemicals, to the specific poison of syphilis or tuberculosis, or to the habit of biting and tearing the nails. Children are especially prone to this habit and may keep up chronic ulcers about the matrices. It is not strange that such an ulcer may by infection secondarily become tuberculous or syphilitic. Tuberculous children, by auto-inoculation, develop what has been called "scrofulous" onychia. Syphilitic onychia occurs either in the tertiary stage of the acquired disease or in hereditary syphilis. In children, onychia is usually attended with more or less clubbing and enlargement of the fingers on account of hyperplasia of the fibrous tissues. We find a mild form of onychia in many people whose fingers are constantly in dye-stuffs, brine or similar irritating chemic solutions.

Paronychia is mentioned in text-books under the same caption as onychia. It consists in a cellulitis of the

fingers and usually of the terminal phalanges. Inflammation of the cellular tissue about the tendon sheaths is part of the same process; it may spread to the periosteum, and then it amounts practically to a felon.

The specific forms of these lesions call for specific treatment, both local and constitutional. The other forms require, first, removal of the cause, then antiseptic and palliative applications; or, at times, free incision down to the bone and perhaps the employment of a small curet or strong caustics, after which the treatment becomes very simple.

CLINICAL MEMORANDA.

THREE CASES OF LEFT-SIDED APPENDICITIS.

BY GEORGE RYERSON FOWLER, M.D.,
SURGEON TO ST. MARY'S HOSPITAL, AND TO THE METHODIST EPISCOPAL HOSPITAL, BROOKLYN, N. Y.

THE usual location of the caput cecum coli is in the right iliac region, lying upon the psoas magnus muscle, its most dependent point or apex projecting just beyond the inner edge of that muscle. This corresponds, externally, to a point slightly to the inner side of the middle of Poupart's ligament.

Occasionally the cecum will be found external to the psoas, and lying upon the iliacus muscle in the right iliac fossa; or the bulk of the caput may lie upon the latter muscle, while the apex rests upon the psoas. Again, the cecum may hang over the pelvic brim, entirely clear of these structures, or be lodged within the cavity of the true pelvis. After the second month of intra-uterine life the cecum gradually recedes from the neighborhood of the umbilicus, which is its original position, and finally becomes fixed in the right iliac region. To speak of the cecum as occupying the right iliac fossa is scarcely correct in the majority of instances.

Should the fetal type persist, there will be non-descent of the cecum. This will result in a corresponding abnormal situation of the appendix vermiformis ceci, the latter even lying to the left of the median line. In a dissection of a sixteen-year-old boy, Lenander observed the cecum, together with an appendix fifteen cm. long, lying against the spleen in the left hypochondriac region.[1]

The following three cases of abnormally placed, or non-descent of the cecum, with corresponding mal-position of the appendix, have come under my observation. In all three appendicitis occurred, and was not recognized, because of the presence of the abnormality. They are among one hundred and forty cases of appendicitis upon which I have operated during the time covered by these observations.

CASE I.—M. F. N., thirty-five years of age, was suddenly attacked, on the night of December 12, 1890, with colicky pains, which had subsided upon the administration of some domestic remedy that contained opium. The pains were generally distributed over the abdominal region, and were finally referred particularly to the epigastrium. Nausea and vomiting had followed the onset of the pain. The woman had recently lost a friend with appendicitis, and had been informed that if a surgeon had been summoned and an operation performed, her life might have been saved.

The patient's pulse was 80, and the temperature 100° F. She expressed herself as feeling much better than before the administration of the opiate. There was a somewhat diffused and not very acute tenderness at the outer border of the *left* rectus muscle, on a line with the umbilicus. The case was regarded as one of intestinal colic, and treated with a small dose of morphin hypodermatically. I left her with instructions to summon a physician in case of a recurrence of the pain.

Forty-eight hours subsequently I was summoned in great haste, and found the patient in profound collapse. With the exception of pain in the *left* hypochondrium, she had remained quite comfortable until a few hours before, when, in rising to urinate, a sudden accession of pain to the *left* of the umbilicus had occurred, followed very shortly afterward by intense pains, which had rapidly become general. Her pulse became very rapid and weak, and she died, without rallying, seven hours after the relapse of the symptoms.

The autopsy, conducted by Prof. Van Cott, revealed a perforated left-sided appendix. The caput coli was found, attached by a very short meso-colon lying almost directly upon the promontory of the sacrum, with the appendix curled upward and outward beneath the left rectus muscle. The perforation occupied a space one inch long, about midway between its tip and its base of attachment to the cecum. The appendix was three inches in length. Only slight adhesions were present at the site of the rupture, the edges of the latter presenting a ragged appearance. The remainder of the appendix was swollen, infiltrated, and enlarged. No foreign body was present.

Considerable sero-purulent fluid, and some fecal matter, occupied the peritoneal cavity. Septic peritonitis was present.

CASE II.—A. M. M., nineteen years of age, was admitted to St. Mary's Hospital on June 29, 1891, with the following history: Seven days before admission he suddenly developed severe abdominal pain, followed by vomiting. The pain was at no time localized. A tumor had been made out by the family physician, beneath the *left* rectus muscle, two days prior to admission. This was thought to be due to fecal impaction, and cathartics were administered. The tumor disappeared, although the bowels refused to respond to the cathartic medicine which had been administered. The pain, however became much more violent, and the patient became greatly prostrated.

He was prepared for operation immediately upon his admission to the hospital. The median abdominal incision was made. Upon reaching the peritoneal cavity a large amount of sero-purulent fluid was found free in the peritoneal cavity, besides three separate collections of the same sero-purulent matter, partly walled off by adhesions. A violent septic peritonitis was under way. The caput coli lay immediately behind the umbilicus, and the cecum was turned to the left, the appendix lying behind the left rectus muscle, just below the level of the umbilicus. The patient's condition did not admit of an attempt to remove the appendix.

Death took place shortly following the operation, from shock and the preëxisting septic peritonitis. The autopsy showed a gangrenous appendix, which had perforated, in addition to the conditions already described. No foreign body was found.

[1] Sammlung klinischer Vorträge, August, 1893, No. 75.

CASE III.—On September 12, 1892, I was requested by Dr. J. H. Burge to see J. B., a male, sixteen years old. He had been absent from home, without his parents' consent, for more than a week, and had been sleeping in a milkman's stable. Upon the day preceding my visit he had come home, suffering from severe abdominal pain, which had suddenly set in upon the previous day. Nausea and vomiting had followed the pain. The following condition was noted upon the occasion of my visit: The abdomen was considerably distended, with fulness rather more marked upon the *left* side. There was tenderness within an area of about three and a half inches in diameter, beneath the left rectus muscle, commencing at the umbilicus and extending directly downward. Marked dulness on percussion was present in the left iliac region and flank. Sensibility was particularly acute in the left lumbar region, and extending to the lower border of the ribs posteriorly. The temperature was 104° F., pulse 124.

A diagnosis of left-sided appendicitis was made, and the patient was removed to the Methodist Episcopal Hospital for operation. On the afternoon of the same day a median celiotomy was performed. Upon opening the abdominal cavity I encountered a large amount of seropurulent fluid free in the peritoneum. A large abscess-cavity was found to the left of the median line, occupying the locality of the dulness referred to. After thoroughly packing the surroundings with sterilized gauze, thus isolating the general peritoneal cavity, the pus was evacuated. The finger-tip could be passed through an opening a half-inch in diameter, which led directly to the layer of connective tissue behind the peritoneum. The latter appeared to be dissected up in all directions. About fourteen ounces of pus were obtained from the two cavities. The walls of the abdominal portion of the abscess were made up of masses of adhesions, which were not attached anteriorly. The caput coli and the cecum were displaced from their normal position in the right iliac region, being curved to the left and upward toward the umbilicus, and lost in the mass of adhesions which made up the abscess walls.

As thorough a disinfection of the pus-cavities as possible was made, the communication between the two being enlarged to facilitate irrigation and packing. Both cavities were tamponed loosely with sterilized zinc oxid gauze, the ends of which were led out of the abdominal opening. The abdominal wound was only partially sutured.

The patient rallied from the operation, but sank and died on the third day from a continuance of the septic conditions which existed prior to the operation.

The autopsy revealed a gangrenous and perforated appendix, with its caput coli situated to the left of the median line, and, immediately beneath the mass of adhesions which had also formed, the wall of the large abscess-cavity. This communicated, in its turn, with a cavity in the post-peritoneal connective tissue, extending in an upward direction for about eight inches above the point of communication with the first. The ascending colon and the cecum were situated to the left of the median line, and on a level with the umbilicus.

Dr. Herbert R. Spencer has been elected professor of gynecology and obstetrics in University College Hospital, London.

TWO COMPLICATED LABORS; DELIVERIES BY VERSION AND BY CESAREAN SECTION; RECOVERIES.

BY GUY HINSDALE, M.D.,

PHYSICIAN TO THE OUT-PATIENT DEPARTMENT OF THE PRESBYTERIAN HOSPITAL; ASSISTANT PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

CASE I. *Arm and shoulder presentation; version.*—The patient's fifth pregnancy expired April 20, 1881. The fourth pregnancy had ended in a breech-presentation; the previous labors had been normal. On being called to this patient an examination was made at once and the right arm and funis were found presenting, the waters having previously ruptured. Not succeeding in restoring the arm, I called on Dr. E. H. Bell, who also was unable to restore the arm but succeeded in performing podalic version. At first the right foot was grasped and made fast by a fillet. All endeavors to grasp the left leg were unsuccessful. Traction was made, and with great difficulty the hips and left leg were brought down. After the body had been born, the head still remained transverse, and the arms extended at either side of the head. No efforts on the part of either of us succeeded in moving the child. The arms were finally forcibly brought down, sustaining a fracture on the left side of the acromion, and on the right side of the humerus at the middle. Traction was then made, and the head rotating antero-posteriorly, the child was delivered, but was not living, owing to pressure on the cord. The patient made a good recovery.

CASE II. *Labor obstructed by uterine fibroids; Cesarean section (Porro operation) by Dr. Hirst; recovery.*—The patient was a primipara, aged twenty-six, of spare habit. Three weeks before delivery she apparently fell into labor, but after several hours the pains subsided. On October 24, 1893, I was called and found regular labor-pains present, but the os was high up and pointing far over to the left side. The fetal heart was heard most distinctly on the right side and below the umbilicus. Owing to the irregular shape of the uterus, and the oblique displacement of the os, twin pregnancy was at first suspected, but only one fetal heart-beat could be heard. Ineffectual pains continued for the next thirty-six hours, when I determined to etherize the patient and ascertain the cause of the difficulty. As soon as she was under ether it was evident that a large fibroid attached to the neck of the uterus was interfering with dilatation of the cervix and the descent of the head. On passing the forefinger through the os, a brow-presentation was recognized, the nose, chin, and eyes being distinctly felt. Simpson's forceps and the axis-traction forceps were applied to the head, but delivery was impossible, owing to the head lodging against the symphysis pubis. Efforts were made by Dr. F. S. Pearce and Dr. J. B. H. Gittings, whose assistance I secured, to deliver by version, but they were also unsuccessful. I then decided to call in Prof. Barton C. Hirst to perform Cesarean section. We deemed it best to remove the patient to the Hospital of the University of Pennsylvania, three squares distant. After giving her three hours' rest, Dr. Hirst operated in the presence of the class.

The patient having been prepared in the usual manner, the abdominal cavity was opened with scissors, the uterus lifted up and grasped by an assistant who held it

tightly by the neck. The placenta lying posteriorly, the uterus was opened by scissors in the middle line and the child extracted, the cord severed, and vigorous efforts were made by a third assistant to resuscitate the child. Although fetal heart-sounds were heard a short time before operation, the child did not live.

The neck of the uterus was then transfixed in two directions, and a strong rubber ligature applied. A large pedunculated fibroid was found attached to the uterine neck, lying in the pelvis, and another near the fundus. These were nearly as large as the fetal head. The lower tumor was extricated with considerable difficulty. The uterus and attached fibroids were then severed above the transfixing pins.

The stump was treated by the extra-peritoneal method. The patient did well, the temperature reaching normal in less than one week, and she is now nearly ready to leave the hospital.

UNIQUE CASE OF TRAUMATIC TETANUS, WITH GENERALIZATION AND RECOVERY.[1]

BY J. G. ORTON, M.D.,
OF BINGHAMTON (BROOME COUNTY), NEW YORK.

IN reporting the following case of tetanus, I present it not only as a marked illustration of the pathologic reflex state of the disease, having a peripheral irritation for its immediate point of origin, an exaggerated functional activity of the spinal centers for its condition, and muscular contractions for its effects; but also as a remarkable instance of the power of endurance of the human body under long-continued muscular contortions, accompanied by painful paroxysms of spasm involving such important parts as the diaphragm and the muscles of the larynx, and yet followed by complete recovery.

The patient, I. D., nine years of age, of slight build, light-brown hair, blue eyes, and fair complexion, received a contused wound of the left forefinger, at the distal end, which at the time was not thought of sufficiently serious character to call for surgical care.

On the fifth day after the accident the boy was seized with symptoms of trismus, at which time I was called to attend him. The jaws could only be partially opened. The injured finger presented the usual appearance of a neglected contused wound, unhealthy pus surrounding a denuded and dead portion of bone. I removed the diseased portions, giving the parts suitable antiseptic dressing, and the wound rapidly took on a healthy character and in due time fully healed.

On the second day after seeing the boy the muscles of the face became involved, giving the characteristic expression of the *risus sardonicus*. On the third day an invasion of the muscles of the pharynx took place, exhibiting the dysphagic form of tetanus. On the fourth day the extensors of the neck contracted, the lower limbs became stiff, adducted, and extended. On the fifth day, unyielding contractions of the muscles of both arms and fingers had supervened, and on the sixth day generalization was fully established. During a painful paroxysmal spasm involving the whole body, opisthotonos was produced to a remarkable degree, and remained for hours before any relaxation occurred. Besides these continued and powerful contractions of the muscles, painful paroxysms frequently supervened under the slightest external excitation, such as a jar of the bed or walking in the room. Complete intermission never occurred. The generalization was so thorough at times as to involve the integrity of the diaphragm and the muscles of the larynx, and the patient apparently ceased to breathe, becoming as one asphyxiated; finally at one time during these paroxysms there was a simulation of the act of dying, the child becoming pulseless, pale, and ghastly in the extreme. Out of this critical condition he would gradually rally, only to suffer repetitions for many days in succession. The spasms of the jaws and pharynx were for a long time so uninterrupted that he was unable to swallow even liquids, and became extremely emaciated.

The deviation of temperature did not assume any definite cycle, but ranged from 101° to 105°, the pulse from 110 to 150. No evening increase was observed, but the pulse kept quite a close parallel to that of the temperature. During the exacerbations of temperature delirium was always present; otherwise intelligence remained perfect. After generalization became fully established on the sixth day after the first symptoms of tetanus appeared, there was not a moment for a period of forty-five days in which complete relaxation of the contracted muscles occurred. When resolution commenced to take place, it was in the order in which the several parts of the body had become involved by the disease, and assured convalescence was established sixty days from the time of the accident to the finger. Complete recovery followed.

As to the line of treatment pursued in this unique case, I shall only briefly allude to it, for I am far from sanguine that the various measures resorted to, save one, had any special controlling influence over the disease. The amputation of the diseased bone and subsequent rapid healing of the parts accomplished all that could be desired in that direction, but failed to abate the course or severity of the contractions. Ergot, chloral, quinin, Indian hemp, etc., were each given a fair trial, with but, only temporary if any, effects. The excessive contortions of the body, opisthotonos, and the powerful contractions of the upper extremities were only mitigated or controlled by the application of the ice-bag along the cervical region of the spine. By this means, and this alone, was I able to allay the severity of the contractions, which many times seemed about to terminate the case in death by asphyxia during an attack of the dysphagic form of the disease. For a period of twenty days this application was frequently resorted to, and always gave quite prompt relief from impending danger to life; in fact, it was the only remedy that afforded any satisfaction in the treatment of this case.

MEDICAL PROGRESS.

A Large Cerebral Tumor.—CONROY (*New York Medical Journal*, 1893, vol. lviii, No. 19, p. 537) reports a remarkable case of cerebral tumor, the neoplasm almost completely displacing the entire left hemisphere and occasioning relatively insignificant symptoms. The case occurred in a boy who, at the age of fourteen years, was knocked down and kicked in the head by a horse. He was rendered unconscious for a short time, but afterward apparently recovered completely. After a little while,

however, it was observed that hearing was becoming impaired, and a year after the accident paralysis of the right arm and leg appeared. Subsequently speech became affected and the eyesight began to fail. The mother thought that for a year the head had been increasing in size. It was for the defect of vision, which had been observed for two years, that the patient, then twenty years old, came under observation. He was well and symmetrically developed and well nourished. The facial expression was rather dull; the tongue was protruded to the left. Sensation was impaired upon the entire right side of the body, in greatest degree in the leg. Motor power was almost completely lost in the right lower extremity, while the upper extremity was much weaker than the left. The left pupil was slightly larger than the right, though neither reacted to light or in accommodation. There was marked neuro-retinitis in both eyes, though in a more advanced stage in the left. Articulation was greatly impaired. In the situation of the left parietal foramen there was a depression in the skull, but no cicatrix. Pressure at this point induced pain. The child ate enormously and slept well. There had been several convulsive seizures, with loss of consciousness, but without frothing at the mouth or biting of the tongue. A diagnosis of cerebral tumor was made, but the patient was lost from observation for a time, when the question of operation was raised. The optic nerves had now become distinctly atrophied and vision was almost entirely lost. An operation was undertaken, an area of about two square inches of bone being removed in the neighborhood of the depression, which proved to be an opening into the bone. On incising the dark, bulging dura, a hard, lobulated mass, looking like brain-tissue, presented. This appeared to be so extensive that its removal was not attempted. A small piece, however, was taken for histologic examination and the wound was closed antiseptically. For twenty-four hours after the operation the patient appeared to be doing well, but on the second day the heart's action began to fail and death ensued painlessly forty-eight hours after the operation. Upon removal of the calvarium the left half of the cavity seemed to be filled with the tumor, the surface of which was lobulated and fissured. It was invested with a closely-adherent, tough, fibrous membrane, which bound it to the falx cerebri. The left hemisphere occupied the base of the skull beneath the tumor, by which it was flattened and compressed to the size and shape of the palm of a man's hand. Two additional smaller tumors were found on either side of the foramen magnum, attached to the dura of the medulla oblongata. The right cerebral hemisphere was somewhat pressed upon, but otherwise appeared normal. The main tumor weighed twenty-seven ounces. Its long diameter was eight inches, its transverse diameter three inches and a half, its vertical diameter four inches. Of the smaller tumors, the one was of the size of a plum; the other was smaller. All three tumors were of firm consistence and seemed homogeneous throughout. Upon section, they appeared to be constituted of pure fibrous tissue, with here and there a small area of fatty degeneration.

The Symptomatology of Exophthalmic Goiter.—At a recent meeting of the Medical Society of London, Maude (*British Medical Journal*, No. 1712, p. 892) called attention to some not generally recognized manifestations of exophthalmic goiter. He insisted on the constancy of some degree of thyroid enlargement, though possibly but slight and transitory. Among fifty-five cases of enlarged thyroid gland observed in a population of 3000, there were twelve more or less well-marked cases of exophthalmic goiter. A case was reported of exophthalmic goiter in the child of a myxedematous mother. Among the psychoses observed in the course of exophthalmic goiter, in addition to the usual irritability of temper, are (1) an over-sensitive notion of duty, only removed in degree from religious melancholia, with delusion of sin; (2) incoherence of idea (Russell Reynolds' "chorea of ideas"), with, in one case, ambulatory epilepsy, vertigo, tinnitus, and throbbing in the head. The tremor present is more marked in the flexors of the arms, the interossei escaping. It is almost universal and resembles the tremor induced in animals by removal of the thyroid gland; it is more uniform than the tremor of hysteria. Eclamptic convulsions may occur, having a direct relation to and being perhaps determined by, the disturbed cardiac action. Clonic spasm of the face and chorea are common concomitants. Among other bulbar symptoms is a difficulty in swallowing, resembling that encountered in myxedema, with interference with speech, like that observed in disseminated sclerosis. Facial paralysis is common and most patients display some feebleness of the seventh nerve. The ocular symptoms are believed to be due to the paresis of the temporal division of the temporo-facial nerve. In addition to general muscular weakness there is often paraplegia of one of two types: (1) One form in which the paraplegia is only an accentuation of the chronic muscular weakness under the stress of diarrhea, cardiac failure, or other causes; (2) the form in which the paraplegia is sudden in onset and akin to the so-called hysteric or functional paralysis. Astasia-abasia is frequently encountered, but possesses no special significance. There are many symptoms that point to the existence of a peripheral neuritis, and the symptoms of exophthalmic goiter are believed to be consistent with the hypothesis of a general nerve-poisoning, falling principally on the medulla. The constant presence of goiter, the connection with myxedema, and the results of operations upon the thyroid gland are thought to justify the suspicion that the thyroid gland is the source of the mischief.

A Sign of Gastric Carcinoma.—Boas (*Münchener med. Wochenschr.*, 1893, No. 43, p. 805) contends that the presence of lactic acid in the gastric contents, particularly in conjunction with a permanent absence of hydrochloric acid, and with stagnation of the gastric contents, without demonstrable dilatation, is conclusive evidence of the existence of gastric carcinoma. If a solution of lactic acid be treated with an oxidizing agent and be gently heated acetaldehyd and formic acid are set free, and the presence of the former may be demonstrated by the production of a reddish-yellow or red color in the presence of a solution of potassium iodid and mercuric chlorid. For both qualitative and quantitative purposes small quantities of concentrated sulfuric acid and manganese are added to the solution to be tested, heat applied,

and the vapor conducted into an alkaline solution of potassium iodid. If lactic acid be present a precipitate of iodoform is thrown down. As it has been found that most bread contains lactic acid, the trial-meal in these tests should consist only of flour soup without the addition of salt.

Osteomalacia in a Male.—At a recent meeting of the Vienna Medical Club, WEISSMAYER (*Internationale klinische Rundschau*, 1893, No. 43, p. 1625) reported the case of a shoemaker, fifty-two years old, previously well, who was seized, three years before coming under observation, with sharp pain in both thighs which would not yield to treatment. The pain progressively ascended to the clavicles and was so distressing as to keep the patient in bed. All of the bones were painful upon manipulation. Carcinoma, lymphadenitis, and myeloma were excluded, and a diagnosis of osteomalacia was made. Accordingly, the administration of phosforus was begun, at first in daily doses of gr. $\frac{1}{60}$; later, in doses of gr. $\frac{1}{30}$ and gr. $\frac{1}{20}$. The pains soon subsided, and in the course of a short time the patient was able to be up and about.

THERAPEUTIC NOTES.

For Ingrowing Nail.—To expedite the process of healing, following the performance of the radical operation for ingrowing toe-nail, HÜBSCHER (*Corr.-bl. f. Schw. Aerzte*, 1893, No. 20, p. 695) recommends the transplantation of healthy skin to the fresh wound. His course of procedure is as follows: Cocain is injected into the toe to be operated on and also upon the antero-external aspect of the corresponding thigh; then a compressing bandage is applied at the base of the toe, the nail divided, its two halves removed, together with the lateral and posterior portions of the ungual fold; the nasal matrix freshened; the bandage removed; hemorrhage controlled, and a layer of skin transplanted from the thigh. Finally, a dressing is applied and permitted to remain for three or four days. The wound practically heals by first intention. As a precaution an iodoform-collodion dressing should be continued for a few days longer.

Poisoning by Cardol.—WHITE (*Boston Medical and Surgical Journal*, vol. cxxix, No. 18, p. 440) has reported the case of a man employed in a vanilla commission establishment, who presented himself with a puffy face and various forms of inflammatory lesions, papules, general redness, and a few vesicles upon one wrist and forearm. It is not believed that the symptoms resulted from intoxication from vanilla, but with an oil obtained from the rind of the cashew nut, called cardol, and employed for the purpose of giving a black color to vanilla beans of inferior quality.

Ipecac for Hematemesis.—BURLAN (*Lancet*, No. 3569, p. 923) has obtained satisfactory results from the administration of large doses of ipecacuanha for the relief of hematemesis, a dram being given in a bolus with glycerin. The utility of the drug is believed to be dependent partly upon its stimulating action upon the mucous membrane of the stomach and intestines, as a result of which an increased secretion of mucus is induced, thus diverting the blood from its dangerous work, and partly upon its sedative action upon the pulse and heart-beat.

For Sciatica.—

℞.—Pulv. opii . . . . . gr. xij.
Pulv. ipecac. ver. . . . gr. xij.
Sodii salicylat. . . . . ʒjss.
Ext. cascaræ liq. . . . q. s.—M.
Ft. pil. no. xij.
S.—One or two from three to five times a day.
The Asclepiad, 2d quarter, 1893.

The Treatment of Hydrocele.—NEUMANN (*Fortschritte der Medicin*, 1893, No. 20, p. 818) has reported the successful treatment of six consecutive cases of hydrocele by the introduction of a trocar, which was fastened and permitted to remain *in situ* for two days. Thereafter local applications of a lotion of lead-water were made. The entire course of treatment covered an average period of from seven to nine days.

For Diphtheria.—

(BIANCHINI.)

℞.—Resorcin. . . . . 2.
Acid. salicylic. . . . . 3.
Glycerin. neutral. . . . . 10.
Alcohol. absolut. . . . . 20.—M.
S.—Apply with a brush or swab to the affected surface.
La Semaine Médicale, No. 60.

For the Treatment of Uterine Myomata, ROBINSON (*New York Medical Journal*, 1893, vol, lviii, No. 19, p. 536) recommends ligating the ovarian artery, with or without tubal and ovarian structure, and ligating the uterine artery, as it courses along the sides of the body of the uterus for a half or two-thirds of its length from the fundus to the cervix.

For Burns.—OSTHOFF (*Deutsche medicin. Wochenschr.*, 1893, No. 38, p. 931) recommends the application of bismuth subnitrate made up with hot water into a mass having the consistency of plaster-of-Paris, and applied to the affected surface by means of a brush. In uncomplicated cases no other dressing will be required.

For the Removal of Warts, SYMPSON (*Quarterly Medical Journal*, vol. ii, part 1, p. 57) warmly recommends the administration of small doses of arsenic. The desired result is still more speedily brought about if, with the administration of arsenic, the topical application of a salicylic colloid is conjoined.

Calcium Chlorid as a Hemostatic.—Upon the basis of personal experience, SAUNDBY (*Birmingham Medical Review*, No. 182, p. 214) recommends the employment of small doses (not exceeding six grains) of calcium chlorid every four hours in the treatment of hemorrhage or of the hemorrhagic diathesis.

As a Genito-urinary Antiseptic, LYDSTON (*Journal of Cutaneous and Genito-urinary Diseases*, No. 134, p. 451) recommends oil of eucalyptus in doses of ten minims three times a day or oftener.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage in North America.

Per Annum, in Advance . . . . . $4.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, NOVEMBER 25, 1893.

FURTHER COMMENTS ON FOOT-BALL.

The Medical News last week gave a few reasons why the game of foot-ball is running to dangerous extremes, and as at present played is of most pernicious influence upon the morals of the players and of the community, subversive of the true interests of education and of genuine athletics. Our article has been reproduced in a number of lay-journals, and has called out comments, congratulations, and criticisms from private correspondents, and from journalists. There is an almost universal agreement as to the diagnosis of the disease, and nearly a universal agreement as to the prognosis and treatment. The journals that habitually compromise between conscience and salability, are, to be sure, hedgers in this matter, as in all other things; those that see clearly and speak bravely in other things see clearly and speak bravely of the foot-ball evil.

So long as the present rules and practices obtain, the first effect of public discussion will be to still further conceal the seamy side of disreputable facts and customs, and to keep the public hoodwinked as to the injuries to players, much as the railroads hide from the public the results and even the existence of "smash-ups." Another result, and a good one, is suggested by the fact that some of the games of the past few days have been more "open" games, with less "bunching" and less manifest brutality, although one college-boy has been killed in a "great battle" at a Michigan college, in which much bad blood was raised and spilled.

The News will gladly work for evolution and emendation rather than revolution and extinction, if it can be shown, as some kind critics aver, that the game may be made useful to the health, mental and physical, of the players and of the community, and serviceable to the cause of education. But of this possibility we have most profound doubts.

If improvement and correction of the present evils of the game are to be hoped for, they can only come from the most resolute agreement and action on the part of college-officers. But college-officers are too often controlled by the same motives that govern rivals in commercial life. There is a danger that they are coming to think too much of attracting new students rather than of raising the standards of education and culture of the students they have. Jealousy of other institutions in the minds of teacher and student is undeniably more active than it should be.

Harper's Weekly—a journal most clear-minded and clean-handed as to social questions—calls college-authorities to a stinging and sharp account for shirking their most manifest duty. It says to the college professors:

> "There loom up, side by side with the growth of the game and the increasing interest, two evils which threaten not simply to dampen the enthusiasm but to entirely put a stop to the sport. These evils are brutal tactics on the part of the players, and drunkenness on the part of their supporters.
>
> "Some day in the near future, when a player falls never to get up again, because his opponent in the heat of the contest has struck a little harder than he intended, you will seize the opportutity to say 'No more foot-ball.' But the responsibility of that man's death will rest upon you."

The *New York Evening Post*, the journal *par excellence* of educated gentlemen, quotes entire and commends warmly the editorial of The News, and says: "College foot-ball is fast becoming a national calamity." It shows that at Harvard, where the game stands highest, at most only 100 out of 3000 students practice the game, and that about 25 "gladiators" monopolize its "beneficent effects." It further points out a manifest truth that the influence of the game is clearly to undo one of the sublimest and hardest-won products of civilization, respect for the human body as such. "As a spectacle, the game is only one degree removed from the prize-fight, and nobody participates in it or

looks on it without finding his dislike of prize-fights diminished and his respect for prize-fighters increased."

The *New York Herald* publishes the detailed accounts of twenty-six deaths occurring so far in England during this season, directly attributable to foot-ball injuries. During the season of 1891–2 the number of deaths was twenty-two, and during 1890–1 there were twenty-three deaths. During the present season in this country there have been four, probably five, deaths. The list of broken bones and other severe injuries would be simply impossible of computation and of appalling length. If this does not settle the question of "brutality," what, then, is further needed? No wonder the accident insurance companies are refusing risks of the players.

The hopelessness of remedying the brutality lies in the universally admitted and deplored fact that no human umpire is physically capable of seeing the "slugging" that may take place in such a terrific jumble, and that it is asking an impossibility of excited and passionate boys to expect them not to "slug" when they will thereby win the game and make themselves heroes.

If reform is possible, it must follow:

1. That personal violence and injury must be stopped.[1]

2. That no public matches must be allowed during term-time.[2]

3. That, the first duty and function of a college being that of mental training, this during no day dare be subordinated to the rage for games or athletics.[3]

4. The physical development of all students is to be encouraged, not the game-winning powers of a few.[1]

5. An end must be made of rowdyism, drunkenness and gambling, in connection with, or as a result of the games.[2]

Can these things be assured? If so we shall refrain from further criticism.

TWO KINDS OF EXPERTS.

THE expert in insanity is a diagnostician—nothing more or less. His function in court, as in hospital, is to make a scientific diagnosis of a case. This function cannot be enlarged without detriment to him, or curtailed without detriment to justice. His claim to respect and credence is in exact proportion to his display of knowledge and honesty. Above all things he is a professional man, with professional traditions to guide and to support him. His science is one of observation and induction—as much so on the witness-stand as in the dead-house. He is supposed to be the associate of scientists, and to display in his own career the mental processes and discipline that are the results only of conscientious application to the attainment of an ideal.

This ideal of the expert is high and difficult for vulgar men to attain. It is above the level of the zeal of the partisan, the rage for publicity, and the greed for lucre. The duty of the expert, when he gives evidence in a trial that may deprive the the prisoner of life or of liberty and reputation, is in the line of the highest public office. The judge upon the bench has not a more trying duty or a more strictly intellectual and conscientious function. RHADAMANTHUS may preside, but the symbols of law are not necessarily the symbols of knowledge.

---

[1] Col. Ernst, Superintendent of the West Point Military Academy, says in his report in reference to the injuries received by cadets in the foot-ball field:

"It is doubtful, in my opinion, if the benefits derived from playing this game, which I am free to acknowledge are very considerable in some directions, are commensurate with the risks it entails to life and limb, which, according to statistics, are much greater than commonly supposed."

[2] The entire month of November is almost entirely lost so far as study is concerned, and other months are encroached upon.

[3] More than two hours every day are now spent in signal practice. In the forenoon, the hour from 10 to 11 is passed on the floor of the big exercising hall of the gymnasium. The doors are locked and the eleven lines up against imaginary opponents. The coaches criticise the way the plays are put into effect, and the whole series of signals is gone through with again and again.

The hard practice game takes from 2 until 4 in the afternoon, and it is 4.30 before the men are all sponged, rubbed down with alcohol by professional rubbers, and dressed. Supper at the training tables comes at 6 o'clock, and from 7 to 8 comes signal practice again behind sealed doors in the gymnasium. This ends the day's work for the weary band. At 10 o'clock the force of rubbers starts out, and every player is visited at his room, where, just before he tumbles into bed he is thoroughly rubbed and liniment applied to bruises and sprains.

This is the daily life of a university foot-ball man through November. He has the rest of the year in which to catch up with his studies. He does not get very deep into learning while his hair is long and the canvas jacket the sign of his calling.—*Ralph D. Paine in the New York World.*

See another account in the *New York Sun*, November 19th.

[1] Remark the monopoly of the gymnasium and of the field by the professional team.

[2] Note the regulations of the New York police and of the Yale College Faculty as regards the conduct and "celebration" of students after the Thanksgiving game.

These are preëminently in the keeping of the scientist.

This ideal of the expert is nourished first and last upon the Baconian philosophy—it is founded upon the conception of pure knowledge, based upon observation and induction. It inspires a man to ignore rumor, to despise gossip, to curse mendacity and ignorance, to rebuke presumption, and it does not permit him to associate with newspaper reporters. Above all it enables him to keep the faith, to recognize no responsibility but to truth, and no bond of fellowship outside of his own profession. Thus he has the methods of science, but he has also the reticence of priests. He does not pause upon the curbstone for whispered confidences with the public, nor does he pronounce opinions upon the cases of men whom he has never seen. This is one kind of expert.

But, unfortunately, there is another kind of expert, and occasionally he is in evidence. He gives long interviews in the newspapers, in which he delivers himself of opinions upon the mental condition of any or every criminal in the land. The cases of Cochran, who robbed the Philadelphia Mint, and of Prendergast, who killed the Mayor of Chicago, have not escaped the eternal vigilance of the newspaper expert. Their cases are diagnosticated at once by men who live hundreds, perhaps thousands, of miles from them, and who have never had the privilege of more exact knowledge of them than is to be obtained from a sensational newspaper report. We have abstained purposely from comment upon Cochran's case before trial, and we do not intend to comment in detail upon it now, although we are credibly informed that the trial will probably be ended before this writing sees print. We shall only state that we shall publish in due time an authentic medico-legal report of the case by one of the experts employed by the Government to determine the prisoner's mental condition.

Undoubtedly the newspaper interviews, in which opinions are ascribed to physicians, are not always authentic, and sometimes they do the alleged author grave injustice. These interviews, in a word, are evidences of the lax morale that pervades the modern guild of news-getters, rather than of the unbridled speech which is put in the mouth of the unfortunate, but not blameless, expert. Such an interview, among several, has recently come to our notice, in which the case of Cochran is discussed with great freedom. If it is the fiction of a reporter, as we sincerely trust it is, it is all the more appropriate for our purposes as a text, as it thus assumes in our comments a strictly impersonal part.

An alienist who had never seen Cochran was made, by an invidious reporter, to dramatize somewhat as follows. He was made to premise by saying that his opinion was founded upon "data furnished by the newspapers." He was then made, without more ado, to pronounce Cochran's condition to be that between paresis and senile dementia. He "hovered between the two diagnoses," which closely resemble each other (*sic*), until he was more amply informed. He then thought it "reasonable to assume" that the man has premature senile dementia. He thought that Cochran's love for gold is like the fascination of the general paretic for bright objects, but he gave not one scientific datum or observation upon which to base this generous assumption, except a rather stale illustration of paretics "picking gold-leaf from their skins," nothing resembling which in the remotest degree had ever been asserted of Cochran, even in the newspapers. He thought that the prisoner showed a "gross defect of judgment" when he visited Washington, in fear and trembling, to avert the opening of the vault and the disclosure of his dishonesty, and again when, being hopelessly cornered, he confessed. This defect of judgment and this confession are therefore pathognomonic of insanity. The expert is further quoted as having said that in senile paresis thefts are likely to occur "merely from forgetfulness," when even the newspapers described the long years of stealing, the crucible and the melter's tools, and the chests and safes of the old bullion-weigher, most cunningly devised and disposed. He is made to say that such a man "loses sight of the proprieties," when in fact Cochran in appearance was a truly good man and a church-member. He is then described as indulging in vaticination and predicting that Cochran would at once have a lucid interval, so that in court he might present the appearance of a "penitent humbug or clumsy swindler," when in fact we know from good evidence that Cochran has appeared in neither of these rôles. Finally, our imaginary alienist was made to say "to the physician, Cochran would exhibit some exact signs, either of the pupils, of the muscular movements, the reflexes, his speech, his expression of face and his memory, which would establish the morbid nature

of his crime beyond peradventure." But we know that COCHRAN has exhibited none of these.

So we have two kinds of experts. The first and greater of these stands for study, for observation, for candor, for science, for justice, and for professional tradition. The second and lesser of these stands for rumor, for guess-work, for sensationalism, for newspaper notoriety, and, above all, for self.

THE PROGNOSIS OF MALIGNANT ENDOCARDITIS.

WE are too prone to consider malignant endocarditis a necessarily fatal disease. At any rate we waver in our diagnosis if recovery ensue in a given case. If, however, we look upon malignant endocarditis simply as one extreme of the varied types that inflammation of the endocardium may assume, the fact will be forced upon us that there must be some cases in which the degree of malignancy is not so great as to irrevocably condemn the patient to death. The point that we would make is that so-called malignant or ulcerative endocarditis represents a condition removed clinically and pathologically only in degree from other varieties of endocarditis. Certainly, the distinction is often difficult to make, both at the bedside and in the dead-house, and, as we have indicated, the criterion is not uncommonly the survival or the death of the patient.

In view of all of the circumstances then, the diagnosis of malignant endocarditis with recovery at the hands of competent observers cannot be rejected. A case in point is recorded by FINLAYSON (*Archives of Pediatrics*, vol. x, No. 11, p. 937). It was that of a boy, ten years old, who came under observation in an attack of rheumatism, and with a history of two previous attacks. The mother was rheumatic and the father had died of some disease of the heart. The child at no time presented signs of valvular disease. While under observation a pericarditis with effusion developed. In the further progress of the case there were frequent paroxysms of pyrexia, attended with nausea and vomiting. The emaciation was pronounced, and several times death seemed imminent. Toward the close of the illness, which lasted for nine months, there were present for many weeks distinct, soft, fluctuating swellings upon the dorsal aspect of the carpus on both sides. Indications of embolism were carefully looked for, but could not be detected. Recovery was ascribed largely to forced nutrition.

The diagnosis in this case may be criticised from the absence of direct signs of endocardial inflammation, such as a murmur, but it is pointed out that ulcerative endocarditis may be unattended with any lesion of the valves recognizable during life. The knowledge that malignant endocarditis is not necessarily fatal must thus act as a stimulus to its energetic treatment.

EDITORIAL COMMENTS.

Inoculatiom-diphtheria in Milch-cows.—The importance of the question as to the transmissibility of diphtheria by means of cow's milk, and particularly through the intermediation of the udders of diseased animals, is entirely too obvious to require discussion. Any light upon such a subject must hence be extremely welcome. A. C. ABBOTT (*The Journal of Pathology and Bacteriology*, vol. ii, No. 1, p. 35) reports the outcome of an investigation as to the results produced in milch-cows by inoculations of the bacillus diphtheriæ, which are somewhat at variance with the conclusions of a previous study of similar kind made by Klein. While the latter reported the occurrence of lesions upon the udders of inoculated animals, in addition to the local lesions at the site of inoculation, all containing virulent diphtheric bacilli, Abbott failed to observe any lesions upon the udders and was able to find the bacilli only on the local lesion. Klein also found bacilli in the milk of the infected animals, while Abbott did not. Other things being equal, the positive observations in a single series of experiments must have greater weight than the negative observations in a corresponding series, so that a decision in the matter must yet be held in reserve. Further studies will be required to determine which of the two opposed conclusions is to be accepted, and as the subject is of such profound importance, it is to be hoped that these studies will not long be wanting. In Abbott's paper attention is called to variations in the morphologic appearances of undoubted diphtheria bacilli dependent upon variations in the culture-medium.

Farming Out the Business of Surgery.—It seems that a company has been formed with headquarters in New York City, with hindquarters in Chicago—and perhaps with other parts scattered over the country—which makes a business of insuring against accidents and casualties. There also appears to be some mysterious business arrangement whereby workmen, willy-nilly, are to be made recipients of the bounty and the tender care of the contract surgeon. Here is a copy of a letter received by a surgeon in Chicago from the "attorney" of the company:

"DEAR SIR: Your name has been furnished me as a surgeon whom Messrs. —— & —— Company would like to have attend employés injured at their plant.

"Messrs. —— & —— Company are insured in the —— —— —— & —— Company, and, by their policy, this Company, which I represent, pays all reasonable doctor's bills for attendance on injured employés.

"I enclose two schedules of medical charges used by the regular surgeons of this Company, and would request that you look the same over, and advise me if you

would care to work pursuant to the rates mentioned therein.

"Upon receipt of a favorable reply from you I will advise Messrs. —— & —— Company that you have accepted our schedule, and request them to call you in all cases of accident to their employés.

"Yours truly, —— ——."

The following is the schedule of charges:

Day visit	$1 00
Night visit (between the hours of 8 P.M. and 6 A.M.)	2 00
Mileage to unusual distances 10 cents per mile additional fee.	
Office consultation (ordinary)	50
Dressing hand or foot, first time, in ordinary coupling accidents—	
Day	2 00
Night	3 00
Subsequent dressings (at home office) when absolutely necessary	1 00
The following charges include after-treatment in *ordinary* cases. They are established with the understanding that extra attendance, if unusual complications arise in the cases specified, may be charged for in addition; but in such cases, as well as in all others not provided for, the extra charges shall not exceed 50 per cent. of the usual fees in like cases.	
Amputation at hip-joint	75 00
" of thigh	50 00
" of leg	25 00
" of arm or forearm	20 00
" of finger or toe	5 00

The Bicycler Should Sit Erect.—We have previously alluded to the danger to health from the common practice of the bicycle-rider doubling himself up like a capital C. We are glad to notice that a most eminent English physician, Sir Benjamin Richardson, himself an enthusiastic rider, has also been warning the public in this matter. Bicycling is such a noble and beautiful form of athletics that we should do all we can to keep it from becoming injurious by evil habits and tendencies. Sir Benjamin says:

"There is no doubt that a great deal of harm is at present being done by injudicious cycling. The attitude that nearly all cyclists adopt, to a greater or less degree—bending themselves forward over the handles of their machines—is undoubtedly most unhealthy. And, though I cannot explain the reason for taking up such an attitude, I know that I have to keep a careful watch over myself to maintain an erect position.

"The doubled-up position does more harm than people imagine. Of course, everybody knows that it is ugly. The spinal curves are the most perfect in nature, both for strength and beauty, and these are destroyed. The top of the anterior curve is brought forward—and I am not sure that the posterior curve as well is not affected—until the spine becomes almost an arc. The chest-bone is then affected by the unnatural pressure placed upon it. The circulation is impaired, and, no doubt, the lungs are interfered with, too. In fact, there is hardly any possible evil effects which it does not produce."

The Fog-horn Nuisance.—Among the grand benefits of civilization none is more praiseworthy than the safeguards thrown about those "who go down to the sea in ships." The life-saving stations, the light-houses, the channel-markings, and the hundred signs of forethought and solicitude for the safety of our sailors and their freights, are striking instances of the true functions of government and of social progress. It becomes at least very questionable, however, if we are not in some ways running into exaggeration—for example, by putting fog-horns so near thickly-populated shores. We read that on foggy nights, when the fog-horns are continually sounded, a large part of the population of Chicago is unable to sleep because of the intolerable ear-tearing blasts of the instruments guarding the harbor of the city. The sick and nervous people have great distress, and those not sick and nervous are being made so. The noise-injury to the modern nervous system is subtle, great, and serious.

The Etiology of Pernicious Anemia.—Our classification of anemia is eminently unsatisfactory, by reason of our lack of knowledge as to the actual processes upon which the several forms depend. Our therapeusis is thus weakened, for it is not always possible in a given case to determine whether the blood-poverty is dependent upon undue hemolysis or defective hemogenesis. Of the etiology of that special form of anemia to which the designation essential or idiopathic or pernicious has been given, our definite knowledge is perhaps least. Many observers have carefully examined the blood in the hope of finding therein the causative agent, but none of the findings hitherto made has withstood the test of time. The latest contribution to this subject is an article by Perles (*Berliner klinische Wochenschrift*, 1893, No. 40, p. 963), who in a preliminary report describes minute bodies that he found in the blood of each of three cases of pernicious anemia, but failed to find in the blood in a large number of cases of secondary anemia. The organisms are believed to be parasitic protozoa and to exert a destructive influence upon the hemoglobin. They are described as being from 3 to 4 μ long, about one-fifth as wide and about one-twentieth as thick. They are highly refracting and possess the power of spontaneous motion. Appendices have been observed upon some of the organisms, but true flagella were not distinguishable. In the cases examined the number of organisms present was in direct proportion to the gravity of the case.

Organic Liquids.—We have been credibly informed that Brown-Séquard is as firm as ever in his belief in the efficacy of organic liquids prepared according to the methods described by him. He has, however, taken up other lines of work, so that this particular method of

treatment has fallen into a secondary place with him. A circular received from the Laboratory of Medicine of the College of France announces that it can no longer supply the demands of the profession for the organic liquids. The method of preparation is, however, said to be so simple as to be possible of execution by any intelligent physician or chemist. A brochure descriptive of the method has been written by D'Arsonval, the collaborator of Brown-Séquard in the preparation of the liquids, and issued by Masson, the well-known Paris publisher. Attention is called to the fact that no reliability can be placed on any of the numerous officinal extracts of organic liquids upon the market.

A Query in Medical Ethics.—A correspondent inquires whether the following advertisement, inserted in newspapers, is in violation of the Code of Ethics of the American Medical Association:

"Dr. John Smith, physician and surgeon, office and residence ————, will answer calls day or night. Specialty, the treatment of drunkards, with success. No humbug! No treatment by correspondence."

It is, of course, against the Code. Generally speaking, it is a bad thing to do; this particular thing is especially bad, and the particular manner of this doing makes it particularly bad.

The Relation between General Paralysis of the Insane and Syphilis.—DEWEY (*Chicago Medical Recorder*, vol. v, No. 4, p. 233) makes an exceedingly interesting and valuable contribution to the etiology of general paralysis of the insane. He reports three series of cases of general paralysis in both husband and wife, in some of which syphilitic infection was admitted or obvious, while in the remainder it was extremely probable. The frequency with which wives are infected with syphilis by their husbands is difficult of determination, but it may reasonably be great.

The Chicago Clinical Review has undertaken a commendable enterprise in its endeaver to record the titles of the most important contributions to medical literature from month to month, together with an alphabetic list of the more valuable clinical articles. The efforts of the *Review* should receive the hearty encouragement of medical writers and medical journals.

SELECTION.

DR. J. S. BILLINGS ON THE EFFECTS OF HIS OCCUPATION UPON THE PHYSICIAN.

THE word "profession," as applied to medicine, refers to the existence of a body of men who profess, or publicly claim, that they have special knowledge, the result of which, in the shape of advice and, in some cases, of manual skill, they offer to the public. It is understood that the relations which a professional man holds to his clients, to his professional brethren, and to the public at large, are somewhat different from those which exist among laborers, mechanics, and tradesmen. Some of the requirements based upon these relations—such as the really having the special knowledge and skill claimed, and the obligation of secrecy as regards the affairs of his clients—are truly ethical; others are merely matters of custom and manners, and pertain to etiquet rather than to ethics.

For example, it is a fundamental principle of professional etiquet that it is improper to ask the public or individuals to give one employment, except in so far as such a request is implied in a simple notice, giving name, profession, and office-hours. As I have said elsewhere—

"The ordinary forms of business competition, by advertising the qualities of one's wares, or cheap prices, or by calling attention to superior results obtained, are not permitted to the professional man, so far as the public is concerned. He not only may, but should, publish accounts of his work when this involves anything new and useful to his profession, because this is for their benefit; but such publication should be made in a professional journal, and not in the daily press, because in the latter it would be practically an advertisement."

There is nothing essentially immoral or unethical in advertising, so long as the truth is adhered to; but when a physician subscibes to, and agrees to abide by, the regulations of a certain code which, among other things, forbids such advertising, it then becomes unethical to break such agreement. This is the reason why codes are framed: in order to exercise a certain amount of compulsion upon those who subscribe to them. Obedience to such a code becomes a habit, and produces a disposition to consider all the prescriptions of the code as being in themselves ethical, or resting on ethical grounds; and that any man who acts otherwise is acting wrongly and unethically, although he has never subscribed to the code and is not bound by it. Many physicians gradually come to consider their code of medical etiquet as a sort of formula of religious faith, and are almost as much shocked at propositions to change or to abandon any part of it as they would be at a suggestion to change the Ten Commandments, and perhaps it is well, upon the whole, that this should be the case.

The occupation of a physician in general practice influences his habits in several ways. I will specify but a few. First, it tends to make him cautious in the use of intoxicating drinks. Not only are the evil effects of excessive use of alcoholic fluids brought to his notice almost daily, but he knows that it is never safe for him to drink enough to cloud his judgment or to affect his speech or gait. He never knows but that he may be called the next moment to see an important case, and he does know that even a suspicion that he is under the influence of alcohol when thus called upon will seriously injure his business. In the second place, his work cultivates the habit of self-sacrifice. However much he may try to adjust his daily round to suit his own convenience, he must continually obey calls which seriously interfere not only with his pleasures and social enjoyments, but with his comfort, and sometimes with his health. He must turn out from his comfortable bed on cold and rainy nights; he must miss his meals; he must give up the little excursion which he had planned; he cannot plead a headache, or a cold, or weariness, as a sufficient excuse for declining to obey a call from one of his patients.

This self-sacrifice becomes habitual; he does not question, and doubt, and hesitate as to whether he might or might not properly refuse, but under ordinary circum-

stances simply obeys—and it does not even occur to him that there is anything specially praiseworthy in his doing so.

It is a common idea that the practice of medicine tends to blunt the feelings—to make one less sympathetic with suffering, and also to induce a comparatively low view of human nature—owing to the many weaknesses, immoralities, and even crimes with which the physician necessarily becomes acquainted. It is true that the physician knows of many private skeletons carefully closeted, the existence of which the world does not suspect, and in this respect he is like a priest; but he also becomes aquainted with much self-sacrifice, devotion to duty, and love which is stronger than death, which are equally unknown to the public, and upon the whole I do not think that his work tends to the atrophy of his emotional faculties, although it may sometimes lead to their exercise in somewhat special directions. He sees many cases in which what most people call vicious and even criminal manifestations appear to him to be largely due to physical abnormity or disease, cases of periodic drunkenness, of reckless licentiousness, of weakness of will-power, of morbid conscientiousness, and the like, for the evil tendencies and results of which he can hardly hold the persons mentally and morally responsible. It becomes natural to him to consider such manifestations with less aversion, and to be less severe in his condemnation of the individuals in whom they appear, than most people are inclined to do; in other words, he becomes more charitable in his interpretation of motives.

The physician is called upon sometimes to decide very difficult problems in the matter of giving truthful answers to the questions which are asked of him. In a certain number of cases the great majority of, if not all, physicians will decide that it is their duty to give a false answer, or at all events to give a false impression—either for the purpose of avoiding the immediate danger to the life of the patient which a true statement to him might produce, or for the purpose of preserving secret certain information of which he has come into possession in the course of his professional work. I do not think that this tends to lower his standard of accuracy and truthfulness in other matters; but it does tend to make him more independent of the literal verbalism of a creed, and more ready to rely on his own judgment in certain ethical matters. On the other hand, much of the work of a physician tends to make him critically accurate in the observing and noting of phenomena, and in the application of remedies. The use of apparatus for counting, weighing, and measuring, which will give results independent of the personal equation of the user, is one of the characteristics of modern medicine. The doctor does not ask whether the patient has fever, but "what is his temperature?"

This habit of precision and accuracy is increased by the necessity for punctuality in the daily work of a busy physician. His appointments with his patients and with the physicians whom he is to meet in consultation must be kept if he is to succeed, and his time must be portioned by minutes.

The fact that physicians serve the poor without pay exercises a very considerable influence upon the development of their moral character. Undoubtedly much of this service in the earlier part of a physician's life is given for the sake of the experience which he thus obtains, but it is also true that the doing of this makes it a habit, and, as Dr. Weir Mitchell says—

"The virtues which grow to be thoughtlessly habitual are none the less virtues. We tell the truth, are honest, are just, or punctual because the qualities in question have grown to be a part of us. At last they exact no effort, involve no indecision, and above all, no self-praise."

The study and practice of medicine do not necessarily make a man virtuous, or honest, or a gentleman; in a few cases, as shown by the records of the courts, the special knowledge and opportunities of the physician may have led men to commit crimes which they would not have attempted if they had not been medical men—but, fortunately, such cases are very rare.

In the great majority of cases the special influence of the medical life of the present day is to broaden the views of the man who lives it, to make him indepedent in judgment; rather skeptical as to the occurrence of the millennium in the near future; quite incredulous as to the truth of the maxim that "all men are born free and equal;" more inclined to consider and perform the immediate evident duty of the day and hour which lies just before him than to reflections upon the errors of other men; free from morbid fear of death, and of that which comes after death; and none the less a believer in the existence of a Supreme Being and in the fundamental principles of religion, although he may not consider them capable of scientific demonstration.—John S. Billings, in the *International Journal of Ethics*.

CORRESPONDENCE.

A BREECH-PRESENTATION, WITH FRACTURE OF THE FEMUR.

To the Editor of The Medical News,

Sir: During thirty-three years of active practice, and with a record of 2719 cases of childbirth, it had been my good fortune not to have had a case of fracture of any of the long bones in delivery until last March.

Summoned about 4 P.M. to attend a primipara, I found the patient to be a very large, fleshy woman, whose limbs were distended to an enormous degree with water, greatly impeding locomotion. Her pains were regular, severe, and close upon each other. Thinking that labor was progressing rapidly, I requested and made an examination, under antiseptic regulations, and found a very hard, rigid os, dilated to about the size of an ordinary five-cent nickel-piece. Ordering a pill containing five grains of quinine sulphate every hour, I left, promising to return in the evening.

Returning at about 8 P.M., I found the pains still regular, strong, and quite close together. An examination revealed a still rigid os, but somewhat more dilated than at the previous visit, though not sufficiently to permit making out the presentation. I administered an emetic of ipecacuanha, which acted promptly.

After waiting half an hour another examination was made, and I found not only a soft, dilating os, but the membranes ruptured, and a breech presenting. Some twenty minutes later the patient was seized with a

violent convulsion. Morphin sulphate, gr. ¼, was given hypodermatically, and a messenger hurriedly despatched to my office for instruments and assistance. A colleague arrived in a short time, and upon examination and consultation we concluded to deliver as quickly as possible by podalic version. The patient was placed in position, chloroform administered, and efforts made to bring down the feet. This was a somewhat difficult procedure, as the limbs were completely flexed upon the abdomen and chest, and a foot could not be reached. A finger was hooked over the left thigh, and in the efforts to bring the leg down a snap was heard, the limb came down, version was effected, and delivery was soon completed.

The babe, a fine twelve-pound boy, was very much asphyxiated, but persistent efforts at resuscitation were finally successful. Upon examination of the child the left thigh was found to be broken at the upper third, just below the great trochanter. A temporary splint was applied. On the next day, upon receiving THE MEDICAL NEWS of March 25th, I saw Dr. Hubbard's illustrated article, and at once had the father, who is a mechanic, make a splint according to the directions, from a half-inch board. After having padded the splint well it was applied, and the little fellow was kept upon it for four weeks. Upon its removal I found a good, straight, and perfect leg. I think the splint a most excellent one for fractures of this kind, and heartily recommend it to those who may happen to meet with these unfortunate accidents.

The mother made a good recovery, without any recurrence of convulsions, and the babe to-day is in perfect health. Truly yours,

J. HOOD OWINGS, M.D.

DEER LODGE, MONTANA.

A LARGE DOSE OF CHLORALAMID.

To the Editor of THE MEDICAL NEWS,

SIR: A Keeley graduate just back from Dwight, complained of insomnia and severe supra-orbital pain. For a fortnight his wife exhausted all her resources to tempt his appetite, but failed to get him to eat a square meal. He gradually grew languid, restless, and obstinately constipated; but his greatest distress was due to insomnia and the pain in his head. He took to his bed on the fifteenth day after his return home, refused all food, and "behaved himself like a maniac." At ten at night his brother came to me for some hypnotic to give the poor fellow a little relief; I prescribed the following:

℞.—Chloralamid	. . . .	gr. cxl.
Spt. vini gallici	. . . .	℥ss.
Potass. bromidi	. . . .	gr. xl.
Syrup. aurantii Aq. dest.	. . . āā	℥iv.—M.

Sig.—Take a tablespoonful every hour until relieved.

The next morning I was informed that the patient had swallowed the whole bottle at a draught, and was having a "delightful pull of sleep." His wife, however, who had tried to wake him up for breakfast, but had not succeeded in getting him even to open his eyes, sent to me to inquire "whether anything should be done, or if he should be let alone and allowed to sleep it off?"

I hurried to his home, and found him in a stupor, from which he could be aroused for a moment and answer questions intelligently. His pulse was weak, and twenty-five beats to the minute, but fairly perceptible and perfectly regular. Respiration was slow but rhythmic. The surface of the body, the head, and the hands were warm and comfortable. He said he was free from pain, and that his headache was gone, but wished to be "let alone, and not disturbed." He had passed his urine involuntarily in bed some time during the night.

A teaspoonful of aromatic spirit of ammonia, properly diluted, and repeated in fifteen minutes, soon brought him to consciousness and raised his pulse to sixty.

After a while he got up, staggered to the table, ate a good breakfast and then "went back to bed." He slept through the whole day undisturbed, and awoke of his own accord, for supper, late in the evening.

He has been in fairly good health ever since and perfectly free from his head-troubles.

I suppose this is the largest dose of chloralamid on record. M. H. LACKERSTEEN, M.D.

5038 WASHINGTON AVENUE, CHICAGO.

NEWS ITEMS.

Dr. Leon Le Fort, a distinguished surgeon and Vice-President of the French Academy of Medicine, died recently, at the age of sixty-one years.

Bechterew has succeeded Mierzejewski in the chair of neurology and psychiatry in the Military Medical Academy of St. Petersburg.

Dr. John M. Keating, of Philadelphia, died of pneumonia, at Colorado Springs, on November 18th, whither he had gone some three years ago on account of failing health. He was the eldest son of Dr. William V. Keating, and was well and favorably known as an obstetrician, gynecologist, and pediatrist. He made a considerable number of valuable contributions to medical literature, and held a number of important positions in Philadelphia, where he was universally respected and esteemed.

ORIGINAL ARTICLES.

NOTES ON SOME CONGENITAL ANOMALIES CONNECTED WITH THE BRANCHIAL APPARATUS.[1]

BY RUDOLPH MATAS, M.D.,

VISITING SURGEON CHARITY HOSPITAL, ETC., NEW ORLEANS, LA.

I. CONGENITAL INCOMPLETE EXTERNAL FISTULA OF THE NECK, IN THE LINE OF THE FOURTH PHARYNGEAL CLEFT.

ON May 31, 1892, a female infant, two weeks old, was brought to my office, upon the recommendation of the midwife who had delivered the mother, for the purpose of explaining the nature of a peculiar mark on the neck that had been noticed immediately after the birth of the infant. This "mark," when first seen, presented the appearance of a little dot, in the center of which could be detected a minute orifice. On the second day after birth the midwife noticed that a little albuminous fluid oozed from the orifice. There was no redness or evidence of inflammation about this little opening. When I examined the child I found a distinct fistulous orifice at a point about one quarter of an inch above the right sterno-clavicular articulation and on a line with the anterior margin of the sterno-mastoid muscle. The neighborhood of the fistula appeared soft, pliable, and free from inflammatory hardness; nevertheless, by pressing and pinching up the skin around the fistula, a considerable amount, about ten or twenty drops, of a thick, ropy puruloid fluid, was made to exude from the opening. By insinuating a slender probe into the orifice, a tract leading to a sinus nearly two inches in depth was readily discovered. The tract was obliquely directed upward and inward, under the sterno-mastoid muscle, and toward the pharynx, when further progress appeared to be arrested by a *cul de sac*. There was some sensitiveness, possibly pain, aroused by the exploration, as the child would cry when the probe was introduced, though no manifestations of great distress or of a reflex character were elicited. The injection of milk with a small syringe was attempted, but this only distended the tract, and was immediately returned after the withdrawal of the syringe. The orifice of the fistula was carefully watched while the child suckled, and as no milk was seen to escape through it, I concluded that it did not communicate with the pharynx.

The fistula was the only visible or recognizable abnormality presented by this infant; in fact, it was an unusually healthy, robust, and well-formed baby. The parents of the child are both Americans, of English-Irish extraction; the father is a mechanic, aged thirty-four years; the mother is thirty years of age. Both are in excellent health, and know nothing of any condition similar to this in their respective families. The mother has given birth to other healthy children, and cannot account for her baby's condition by any hereditary influence.

From the congenital existence of the fistula, its situation just above the right sterno-clavicular articulation, and along the line of the sterno-mastoid muscle, it was plain that this fistula was a relic of embryonal life, and, to be more specific, a teratoid evidence of imperfect closure of the fourth branchial cleft, or, probably, better, of the *precervical sinus*. (His.)

While congenital fistulæ in this situation are not altogether rare, they nevertheless possess a peculiar attraction to the thoughtful physician because their pathogeny is so intimately connected with the earliest developmental facts of embryonal existence, and their presence recalls a period in human ontogeny which is of critical importance, and when any disturbance or accidental interference with the normal evolution of the embryo is likely to be followed by the most disastrous consequences. This consideration alone encourages me to believe that a few remarks on this and other illustrations of teratoid anomaly will be of sufficient interest to justify their presentation.

Though we are told by G. Fisher[1] that as early as 1789 Hunkowski published two observations on congenital fistula of the neck, it is nevertheless true that a knowledge of the true nature of the condition has not been vulgarized in the profession until the last fifteen years. And yet the correct interpretation of some of the types of this condition is still a matter of discussion among the ablest teratologists. It is admitted by all writers that Dzondi,[2] in 1829, first seriously attracted the attention of the profession to the subject, describing it as "congenital tracheal fistulæ." This designation proves clearly that Dzondi had fallen into a serious error in regard to the true nature of these congenital tracts, but Ascherson[3] (1832) soon demonstrated that they had nothing to do with the larynx, but rather, when the fistulæ were complete, that they implicated the pharynx. The latter author attempted to explain their mode of formation by the embryologic data furnished by the investigations of Rathke, Husche, Von Baer, and Burdach, on the branchial arches.

Following closely upon Ascherson's original paper other observations and contributions appeared in Germany, from Luschka, Roser and Heusinger,

[1] Communicated, with presentation of patients and specimens, to the Orleans Parish Medical Society.

[1] "Historische Notiz zur Angeborenen Halsfistel, Deutsche Zeitschrift für Chirurgie, 1873, Bd. ii, p. 150; also in "Die Krankheiten des Halses," Deutsche Chirurgie von Billroth und Lücke, Stuttgart, 1880, B. xxxiv.

[2] Dzondi: "De Fistulis Tracheæ Congenitis" (Halæ, 1829), quoted by Fisher, loc. cit.

[3] Ascherson: "De Fistulis Colli Congenitis," Berlin, 1832.

and in France, from P. Broca, Faucon, S. Duplay, Sarrazin and Cusset. So much work had been done in this direction that Heusinger, in 1864, had collected 46 cases; Cusset, in 1877, over 70; Fisher, in 1880, had gathered 100; and finally, in 1890, Konstanecki and Mielecki were able to base their most recent and complete study upon a total of 125 observations.[1] This last memoir is based upon the most recent embryologic researches of His, Kölliker, Fol, Rabl, etc., on the normal development of the neck. Though still more recent, and equally important from the critical standpoint, are the chapters in the unfinished *Traité des Affections Congenitales*, by Professor Lannelongue, vol. i, 1891, and the erudite article by A. Broca, in the *Traité de Chirurgie* (Duplay-Reclus), vol. v, 1891, to both of which I am greatly indebted for my references.

We know but very little of the causes that lead to congenital fistulæ of the neck. The most salient point in the etiology thus far obtained lies in the frequency of heredity as an etiologic factor. Fischer was able to associate hereditary influence in 21 cases among 232 observations. Hereditary influence may manifest itself through several generations, as shown in Ascherson's observations, in which eight individuals of the same family were affected with branchial fistulæ in the course of three generations.

Though this condition is the result of a developmental vice of the branchial apparatus or of the precervical sinus (in cases of infra-hyoid fistulæ), it is a notable fact that it is rarely associated with other malformations, though concomitant deformity of the external ear has been noted by Heusinger, and of the middle or internal ear, by Virchow. While sex does not appear to exercise any determining influence, it is nevertheless true that in the latest statistics of Konstanecki and Mielecki, a certain predominance of the male sex is noticeable.

Branchial fistulæ may appear in three different ways. (1) They may be complete, connecting the external integument with the pharyngeal cavity; (2) they may appear as blind external sinuses opening upon the cutaneous surface; and (3) they may be blind internal sinuses, diverticula or *cul de sacs* opening only into the pharynx. This last form, according to Lannelongue, is of doubtful existence. The incomplete external fistula is by far the most frequent. Thus of 75 fistulæ, 52 were of this class, 18 were complete, and 5 were internal. The seat of the external or cutaneous orifice is variable, but it is far more common along the anterior border of the sterno-mastoid and in the infra-hyoid region than elsewhere.

[1] K. Konstanecki und A. Mielecki: "Die Angebornen Kiemen Fisteln des Menschen," Arch. für path. Anat. und Physiologie, 1890, Bd. cxx, p. 385, etc.

Topographically, congenital fistulæ may be classified as follows (Lannelongue):

1. Fistulæ opening into the concha of the ear.
2. Fistulæ opening into the supra-hyoid region, which is common to the four branchial clefts.
3. Fistulæ opening in the infra-hyoid region, *a*, median; *b*, lateral.

The internal opening of the complete fistulæ is almost invariably recognized in the tonsillar region and at the base of the tongue. This internal orifice is usually very small, easily escapes the eye, and can only be demonstrated by injecting the external orifice with milk or some coloring-substance. But Heusinger reports a case in which the orifice was large enough to admit the little finger, and in another instance reported by Mayr it was associated with diverticula or pockets in which food accumulated.

In the case herein reported, exploration has been attempted by the probe, and injection of the external orifice, with the result of demonstrating the incompleteness of the fistula.

In some cases the escape of the ingesta furnishes excellent proof of their completeness. Thus a patient of Heusinger's would frequently notice fragments of bread with water or other fluids escaping through the cutaneous orifice, while at meals; in other cases, such as those related by Santi and Meinet, "a few drops of milk would escape out of the external orifice while the child nursed."

As a rule, the external orifice of the fistula is the seat of a serous or mucoid exudation which resembles saliva (on this account is mistaken sometimes for a salivary fistula), and the resemblance being more pronounced in some cases because this secretion appears to be increased during mastication.

In the majority of cases these fistulæ cause but little inconvenience beyond the discharge of the characteristic secretion. Sometimes the external orifice becomes red, sore, and inflamed, and especially so with some women during the menstrual period. (Maury's case.)

Dysphagia and other disagreeable symptoms have been noticed in many cases but, as a rule, congenital fistula is a very bearable complaint, rarely, if ever, giving rise to dangerous symptoms.

The pathogeny of these fistulæ is probably their most interesting feature. In considering their mode of formation we must revert to the primitive branchial state. We should remember that the first branchial arch originates at the base of the skull in the sphenoidal region and forms the maxillæ. The second branchial arch, known also as the stylo-hyoid arch, serves as the groundwork for the hyoid apparatus, constituted above by the styloid process, which is attached to the temporal, lower down to the stylo-hyoid ligament and terminates

below in the lesser cornua of the hyoid bone. The third branchial arch issues from the temporal region of the skull, and terminates below in the great cornua of the hyoid. Finally, the fourth arch, which is situated behind the preceding, begins above, just behind the third arch, and descends into the neck to form the soft parts of the anterior cervical region, including the larynx and trachea.

"The first branchial cleft,[1] which lies between the first, or maxillary, and the stylo-hyoid arch, does not disappear completely in extra-uterine life. A portion of the auditory canal, formed by the Eustachian tube, the tympanic cavity, and the external auditory canal, remain as permanent vestiges of its existence. The second and third clefts lie very closely together throughout their whole length. For this reason it is difficult to say to which of the first three clefts the fistula belongs. The fourth cleft follows a direction which is clearly indicated by the anterior margin of the sterno-mastoid muscle. The upper half of this furrow lies very near to the third cleft, but its lower half is quite separate and distinct from the upper level of the thyroid cartilage to the manubrium sterni. The fistulæ, therefore, which open along the lower half of the anterior border of the sterno-mastoid are attributable to defective closure of the fourth branchial *cleft*.

This explanation of the origin of these fistulous tracts, especially those of the auricular and lateral supra-hyoid region, has been admitted with practical unanimity as a classical teaching until very recent years; and in fact, an observer so competent and authoritative as Lannelongue (*Maladies Congenitales*, 1891) still regards this theory as the one that best explains their presence, though he admits as plausible the more recent explanation given by His and Rabl. According to these observers and their followers, these embryonal vestiges should be accounted for by an imperfect closure of the *sinus præcervicalis* (His) or the cervical canal of Rabl—a deep anfractuous furrow that is found at the base of the neck, at the end of the branchial period. It is formed by the junction of the ectodermic surface of the branchial arches with the thoracic integuments—the thymus gland appearing at its deep and lower extremity. Any anomaly in the development of this sinus, or even of the thymus itself, would readily explain the persistence of these congenital fistulæ or cysts in this region of the neck. Lannelongue insists, however, that this theory would account for the lower incomplete or blind fistulæ, but that the complete fistula is explicable only by an imperfect closure of a branchial cleft.

There is a great deal to be said in favor and against both the older and the more recent views, especially when we consider the almost constant position of the internal orifice in complete fistulæ, notwithstanding the most variable position of the external opening, but we cannot stop to discuss the embryologic aspect of the question in all its details, and we must proceed with other considerations.

[1] Or, better, pouch, as the later researches of His, Born, Kölliker, Piersol, and others, have demonstrated that no open clefts really exist between the branchial arches.

II. CHONDROMATOUS FORMATION ASSOCIATED WITH INCOMPLETE CONGENITAL CERVICAL FISTULA OF THE THIRD OR FOURTH CLEFT.

One of the most interesting features of these branchial fistulæ is that which refers to the presence of solid cartilaginous or osseous masses that are found attached to the walls of these tracts or along the line of the branchial arches.

In a case reported by Heusinger, he observed a lamella of bone fully three centimeters in breadth at its base, and twenty-eight millimeters in length. Heusinger, Duplay, and Manz have recognized similar osteo-cartilaginous masses in the region of the branchial arches in persons who had no fistulæ.

It was by rare chance that I met with a case that evidently owed its peculiarities to the same pathology.

The patient, a male, laborer, German, aged twenty-four years, was admitted into my service in ward 8, out-clinic, Charity Hospital (in the summer of 1891), for the removal of an inflamed dermoid of the right supra-orbital region. While examining the man I noticed a small chondroid mass situated near the right sterno-mastoid at its anterior margin, about three inches below the mastoid, nearly opposite the thyroid cartilage. The mass had an elongated fusiform shape, and measured about one inch and a half in length. It was very hard and painless; while apparently movable it had ill-defined but deep attachments; it was situated below the deep fascia, and was partially adherent to the sheath of the muscle. About one quarter of an inch below the lower extremity of the mass there was a small depression that contained a very minute opening, so fine that only the bristle of a hypodermatic needle could be insinuated into it for a very short distance. The patient said that he had always had this lump, even from earliest childhood, but as it had never bothered him he had allowed it to remain without disturbance. He also stated that the little opening would occasionally discharge a whitish-looking fluid, but this occurred so rarely that he did not pay any attention to it. He knew but very little of his family history excepting that his parents were healthy and living in Germany. One brother was living, but he was not aware of any abnormality in his case. I suggested the removal of the chondroma and fistula, but he insisted that the removal of the dermoid was enough and that he would come later for the treatment of the cervical growth. But he failed to do so, or at least he did not return again during my term of service.

In this case I believe the diagnosis was congenital chondroma, with associated fistula, of branchial origin, which I would easily have overlooked had it not been that the presence of the dermoid made me think of congenital abnormalities.

Now, what interpretation must be given to these congenital hard growths? Should they be regarded

as rudimentary branchial arches or visceral ribs, following Heusinger's expression, which are developed here in consequence of a defective evolution of the branchial arches?

A rational answer can only be obtained from the data of comparative anatomy and embryology.

Lannelongue, who is deeply learned in these matters, says:

"We know that in the vertebrata that breathe through a permanent branchial system (gills), each permanent branchial arch is provided with a cartilaginous framework which is modeled very much like the ribs of the same vertebrate. Each and all of the vertebræ of fishes, from the caudal extremity to the head, give attachment to ribs. In this class there is no distinct neck. The branchial ribs are continuous above with the cranial ribs and below with the thoracic set. On the other hand, the mammifera are free from cervical ribs, or rather the cervical ribs are reduced to the condition of mere osseous appendages without any definite function, and are united to the bodies of the vertebræ.

"The branchial arches, which are distinct in the embryonal period, become fused later on, and their skeletal frame persists only in a very rudimentary manner. We do not refer to the skeleton of the first branchial arch, which resolves itself into the maxillæ (they are true cranial ribs). But the completely developed branchial ribs, which persist in fishes, are reduced in man, in the case of the second and third arches, to the suspensory apparatus of the stylo-hyoid ligament and os hyoides.

"The fourth branchial arch is entirely deprived of all osseous elements in man, except in the median portion, where the larynx and trachea are formed at its expense. Outside of these respiratory organs, there is no osseous structure to indicate the situation of the fourth branchial pouch in the normal human adult."

Therefore, the skeleton of the branchial arches is very much developed in the facial arch; is rudimentary in the second and third arches, which leave as relics isolated bony and cartilaginous formations, viz., the stylo-hyoid apparatus; and, finally disappear almost *in toto* in the region of the fourth arch. It is true, nevertheless, that the third and fourth branchial arches of the embryo possess rows of cartilages which are analogous to the cartilages of Meckel and Reichert (of the first and second arches). We can readily understand, therefore, that in many instances these primitive cartilaginous formations, instead of becoming atrophied and disappearing, as occurs normally, may, under some disturbing developmental factor remain and develop into the peculiar chondroid and osseous formations that have been herein described.

III. CASES OF CONGENITAL PRE-AURICULAR CHONDRO-FIBROMATA OR AURICULAR APPENDICES.

Apropos of the cartilaginous formations along the lines of the branchial arches and pouches previously described, I have the opportunity of exhibing to the Society a typical specimen of the more common variety of *pre-auricular symmetric* fibro-chondroma, which I removed three weeks ago from the pre-auricular region of a young Jewish gentleman (aged twenty-two years), who thought it a simple "wart," and wanted it removed for purely esthetic reasons. The accompanying photograph gives a pretty clear idea of the appearance of the tumor before its removal. My client had originally two such growths at birth, one in front of each ear (both auricles being perfectly proportioned and well formed), but one was snipped off by a physician some years ago, who also called the growth "a wart," and did not appear to pay much attention to it. These curious growths may be classed with the group of embryonal malformations which are directly traceable to a vicious or teratoid development of the branchial apparatus. The appearance

FIG. 1.

A typical congenital pre-auricular fibro-chondroma, or so-called supernumerary auricle; symmetrical. (Author's case.)

of these little tumors is very characteristic, and when once seen they are not easily forgotten or mistaken for anything like a wart. They appear usually as smooth, slender, elongated, and conoid or club-shaped masses, which usually project rigidly from the skin and measure about three-fourths of an inch in length in adults. They are usually thicker at the free end than at the attached portion, which is narrow and constricted. By palpation a distinct rod of cartilage can be felt imbedded in the mass, and by further exploration it is found connected with the cartilage of the ear. This cartilaginous rod is not always present, especially when the tumor is found in the region of the fronto-nasal plate. These growths are always covered with a skin of perfectly normal appearance.

The congenital appendices here referred to are usually situated, as in the case reported, in the pre-auricular region, near the tragus, with which they are usually connected by a cartilaginous plate; then, much less frequently they are found in the line leading from the tragus to the commissure of the mouth, and more rarely still they are found along

the whole of the median line of the face on the bridge of the nose; again, they have been found springing from the mucous membrane of the lower lip (see Fig. 3) and also in the neck on the anterior sterno-mastoid line along the region of the fourth branchial cleft.

Congenital fibro-chondromata may be single or multiple. There may be one, two or three growths at one of the usual points of election. Generally they are single in the middle external surface of the cheek or on the anterior sterno-mastoid line. They are frequently multiple in the pre-auricular region. In addition they have a tendency to appear symmetrically on the two sides of the face or neck.

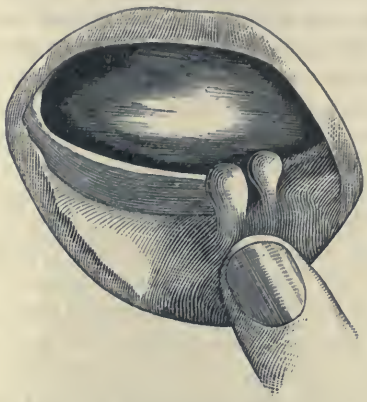
This multiple symmetric tendency was well shown in the case of a little boy, aged two years, whom I chanced

FIG. 2.

Three congenital fibro-chondromatous appendices in the pre-auricular region associated with another pedunculated fibro-chondroma of the cheek, in the line of the intermaxillary clefts. Author's case. Sketch after LANNELONGUE, Obstet., lxxvii; Maladies Congenitales, vol. i, p. 563.)

to see in the streets while paying a visit to a patient in the neighborhood. The child presented an entirely normal appearance, with the exception of the presence of three little tumors on each side of the face in the pre-auricular region; there was also another growth on the cheek which was less rigid and more pedunculated than the others. The parents were very poor, and did not appear to be troubled by the condition of the child in the least. I noticed that the mother had several small fibro-lipomatous masses about the face; two on the bridge of the nose and one on a level with the external canthus of the left eye, all of which were apparently congenital. I made a memorandum of the case, intending to return soon to have photographs of both the mother and the child, but the people had moved out of the neighborhood, and I have never heard from them since. The child's appearance was so strikingly like that represented by Lannelongue on page 563 of his *Maladies Congenitales*, vol. i, that I have reproduced that figure with slight modifications, as it will give an exact idea of the situation of the growths in my case.

FIG. 3.

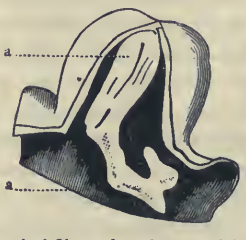


Congenital fibro-chondromata, projecting from lower lip into the mouth. (After LANNELONGUE.)

In my case there was no associated congenital coloboma nor a kerato-conjunctival dermoid, as in Lannelongue's little patient, but the three pre auricular appendices and the growth on the cheek, on a line with the inter-maxillary cleft, were almost identical.

The exact pathogenesis of these growths is still obscure. They have been studied by Sue, Reismann, Rynd, Morgan, Southam, Van Duyse, but particularly by Lannelongue,[1] by Poirier, and Retterer (*Bull. Société Anatomique*, 1880, *Journal de l'Anatomie*, 1890–91; by J. Bland Sutton ("On

FIG. 4.



Section of a congenital fibro-chondroma of the neck. a.a. Cartilaginous, club-shaped rod at center of tumor. Branchial Fistulæ, Cysts, Diverticula, and Supernumerary Auricles," *Journal of Anatomy and Physiology*, 1887, vol. xxi, p. 289); also by A. Broca (*Bull. de la Société Anat.*, 1889, and an article in Duplay et Reclus, *Traité de Chirurgie*, 1891, vol. v.)

In view of the varieties that have been described

[1] Lannelongue et Achard, Traité des Kystes congenitaux, Paris, 1886. Lannelongue et Menard, Maladies congenitales, vol. i, 1891.

it is possible that all are not ascribable to the same pathogeny, though the bulk of evidence is emphatically in favor of their purely branchial origin.

Bland Sutton, for instance, has with characteristic ingenuity and ability availed himself of the researches of His on the development of the pinna to explain the existence of the pre-auricular variety of these "supernumerary auricles" (as he calls them, with other English writers), on the theory of an aberrant or independent development of a primary auricular tubercle, which has been detached from or has failed to fuse with the general mass of the pinna.

"When supernumerary auricles appear in the neck they are to be regarded as outgrowths from the margins of the branchials, repeating the conditions normally existing in the two anterior arches instead of being suppressed." The same author in his delightful lectures on "Evolution in Pathology," (*Lancet*, February 18, 1888) confirms the original observation of Heusinger who had noticed that the pendulous "tags" which are frequently observed in the necks of goats and other animals are analogous to the "supernumerary auricles" found in man, and interestingly shows also that the existence of these appendages had not escaped the attention of the ancient sculptors, who in some of their statues of fawns and satyrs reproduced not only the "tags" of the lower animals, but also the fibro-chondromatous appendices of the neck, as they are seen in man.

Sutton's theory, plausible as it may appear, is not altogether satisfactory, for it does not account for those cases in which these appendices appear in their most typical form in the pre-auricular region of individuals with *perfectly formed ears*. If these were always due to a defective development of the pinna we could understand that the growth has been formed by a detached tubercle, but this not being the case we must seek for another explanation.

At one time Lannelongue, Trelat, and Magitot had thought that the pre-auricular varieties could be accounted for by a vicious budding of Meckel's tubercle, but this opinion has been abandoned by Lannelongue, who, after a careful analysis of all the evidence, now holds "that these congenital fibro-chondromatous appendices of the neck, as well as of the face, originate in an abnormal budding of the branchial arches on a level with the clefts which separate them at a certain period of embryonal life."

The arguments in favor of this view are forcibly presented by this distinguished observer, but I could not appropriately present them here. I will, therefore, forego their discussion. I shall only briefly repeat what has been noted by others, that congenital fibro-chondromata are frequently associated with other teratoid manifestations, viz., macrostoma, auricular malformations, atrophy of the inferior maxillary, which have been observed by Rynd, Morgan, Van Duyse, Trelat, and others. (Broca.) Lannelongue has been particularly struck by the influence of heredity in their production. Van Duyse has insisted upon the importance of amniotic adhesion as a causative factor, but judging from my limited experience and the observations of others it would appear that this association is rather an accidental and exceptional circumstance than a constant factor in the pathogeny.

As to the treatment of these types of congenital abnormalities that are here presented, little need be said except that extirpation is the indication whenever it is practicable. An incomplete fistula may be completely removed by dissection, even in very young children, but the traumatism involved in the extirpation of the more complete variety with a pharyngeal aperture is too great to inflict on infants and even young children. This field of surgery is still comparatively unexplored, and to my knowledge there is but one recorded case of successful extirpation of a *complete* branchial fistula. This is the case of E. Tricomi.[1]

The patient in this case was a woman, aged twenty-four years, who had a complete fistula, the external orifice of which was situated in the right anterior sterno-mastoid line, 2½ centimeters above the right sterno-clavicular articulation, 2 centimeters to the right of the median line, and 8 centimeters below the angle of the lower jaw. The external opening of the fistula measured 2 millimeters in diameter and allowed a probe to penetrate a distance of 10 centimeters in depth. A colored liquid was injected through the lower orifice, and it was discharged into the pharynx, behind the right tonsil, through the internal orifice. Deglutition was effected normally, but the act of swallowing was accompanied by a tugging sensation and severe headache. An incision was made which extended from the external opening to the angle of the jaw on a guide furnished by the probe in the fistulous canal. The whole tract was exposed and readily detached from the neighboring parts to which it was but slightly adherent, and the upper part was dissected out with the help of the finger introduced into the pharynx. The pharyngeal opening was then closed by suture. The result was a complete success.[2]

Irritant injections have been carefully tried. Weinlechner (quoted by E. Albert, Vienna) has thoroughly tested iodin, and has convinced himself of its absolute worthlessness.

It should always be remembered that any procedure that would close only the *external* orifice of a complete fistula would simply create a pharyngeal

[1] E. Tricomi: Un caso di fistola congenita completa dell collo (fistola branchiale), La Riforma Medica, p. 541, August 28, 1891.

[2] Other cases of successful extirpation of congenital fistulæ have been reported; for instance, that of G. Cavazzarri (Riforma Medica, Oct. 7, 1891), and the later cases of Schlange (Verhand. der Deutsche Gessellschaft für Chirurgie, xxii, Kongress, 1893); but I am not certain that they were *complete* fistulæ.

diverticulum wherein food-stuffs and secretions would accumulate with disastrous results, so that the extirpation of a complete fistula should not be undertaken unless it is formally contemplated to remove the whole tract.

While the operative treatment of congenital fistulæ may become a very serious matter, it is otherwise with the treatment of the congenital fibro-chondromata which can be easily, quickly, and painlessly removed under cocain-anesthesia. It is well to remember their deep cartilaginous connections, especially in the pre-auricular variety, in order that a proper cosmetic effect may be obtained.

TYPE OF DISEASE AMONG THE FREED PEOPLE (MIXED NEGRO RACES) OF THE UNITED STATES.

Based upon the Consolidated Reports of over 430,466 Cases of Sick and Wounded Free People (mixed African Races), and 22,053 of White Refugees, under Treatment from 1865 to June 30, 1872, by Medical Officers of the Bureau of Refugees, Freedmen, and Abandoned Lands.

COMPILED BY ROBERT REYBURN, M.D.,
OF WASHINGTON, D. C.;
LATE SURGEON AND BREVET LIEUTENANT-COLONEL U. S. VOLUNTEERS, AND CHIEF MEDICAL OFFICER BUREAU R., F. AND A. L.

INTRODUCTION.

THE organization of the Medical Department of the Bureau of Refugees, Freedmen, and Abandoned Lands, has presented an admirable opportunity to settle definitely some disputed points concerning the type, character, and specific differences, if such exist, between diseases as found in the African and the Caucasian races in this country.

With the view of endeavoring to furnish to the members of the medical profession some information on the points mentioned, the accompanying consolidated reports have been compiled, and I desire, briefly, to call attention to the facts elicited. It may not be amiss, by way of explanation, to state that the operations of the Medical Department of the Bureau of Refugees, Freedmen, and Abandoned Lands were on a much more extended scale than is generally supposed. During the years 1866–68, there were in operation fifty-six bureau hospitals and forty-eight dispensaries. One hundred and thirty-eight physicians were employed, who visited the sick, not only at the hospitals, but at the camps and settlements, where they had been assembled by the results of the war.

The total number of patients (freed people) under treatment from 1865 to June 30, 1872, was a little over four hundred and thirty thousand (430,466). It should be clearly understood that the Consolidated Report (No. 1), showing the cases of disease that occurred among the freed people embraced all the shades of color among them, from the jet-black skins belonging to the pure African race up to the mulatto and quadroon.

This report and Report No. 2, giving the cases of disease treated among the white refugees who fled into our lines for protection during the war, are exact transcripts of the official records now in possession of the War Department. The total number of these cases was twenty-two thousand and fifty-three (22,053).

NUMBER OF CASES OF DISEASE TREATED, AND MORTALITY.

The total number of colored patients under treatment from the organization of the Medical Department of the Bureau, June 16, 1865, to its discontinuance by law, June 30, 1872, was 430,466. This total is somewhat less than that which would be given by adding together the number of patients under treatment, as given in the annual reports of the chief medical officers of the bureau for the years 1865 to 1872, for the reason that to avoid duplication all cases have been dropped from the summary after having been once reported.

The total number of deaths recorded among the freed people was 18,027, or nearly 4.02 per cent. of the number under treatment.

The total number of white refugees under treatment during the period beginning as already mentioned, and ending June 30, 1869, was 22,053, and the number of deaths was 735, or about 3.33 per cent of the number under treatment.

INTERMITTENT AND REMITTENT FEVERS.

On examining the Consolidated Report (No. 1) of diseases prevailing among the freed people, it will be seen that the most prominent on the list, as regards both the number of cases and the number of deaths caused by them, are the so-called miasmatic diseases.

The number of cases of remittent fever, and of quotidian, tertian, quartan, and congestive intermittent fevers combined, reaches the surprising total of 115,855. The number of deaths from these diseases was 1351, showing a mortality of about 1.16 per cent. of the cases treated.

The ratio of the number of cases of remittent and intermittent fevers to the number of cases of all other diseases treated was 26.91 per cent., or nearly 27 per cent.

I have stated that the large number of cases of remittent and intermittent fevers is surprising, and it certainly is so when we consider the statements so frequently made by medical authors that negroes are not subject to miasmatic diseases.

In order to show that the conclusions drawn from the statistics mentioned are correct, I will only refer to the *Medical and Surgical History of the War of the Rebellion*, issued under the direc-

tion of the Surgeon-General, U. S. A., by Assistant Surgeons J. J. Woodward and G. A. Otis, U. S. A., vol. 1, 1873, table No. III, pages 710–712. This table shows that the total number of colored troops of the United States Volunteer Army under treatment from 1864 to 1866 was 629,354. The total number of cases of remittent and intermittent fevers treated among these troops during this period was 152,141, or 24.17 per cent. of the total number of colored soldiers under treatment.

Whatever may be the fact in Africa, it is very certain that the negro of pure or mixed blood, as naturalized in this country, is not exempt from the operations of the causes that induce remittent and intermittent fevers. This large average ratio, however, is surpassed in some localities, for we find in certain places and in certain years that the average ratio is higher than that given; indeed, as it will be seen by the accompanying table, in the year 1868 the ratio of cases of remittent and intermittent fevers to other diseases in Florida was 45.40 per cent., and in the State of Arkansas, in the same year, 54.43—over one-half the entire number of cases of disease under treatment:

TABLE SHOWING NUMBER OF SICK AND WOUNDED FREED PEOPLE UNDER TREATMENT BY MEDICAL OFFICERS IN THE BUREAU OF R., F. AND A. L., IN THE YEAR 1868.

Districts.	Total number of patients treated.	Total number of cases of malarial diseases treated.	Ratio per 1000 of malarial cases.
District of Columbia	4,590	727	15.84
" Virginia	32,770	7,443	22.71
" North Carolina	7,000	1,595	22.78
" South Carolina	39,827	12,084	30.34
" Georgia	14,618	6,310	43.16
" Alabama	1,004	449	44.72
" Florida	1,339	607	45.40
" Louisiana	6,995	2,843	40.64
" Mississippi	5,113	2,000	39.11
" Arkansas	3,972	2,165	54.43

Another point of interest to be noted is the fact that the number of cases of malarial diseases increases in proportion to the number treated, as we proceed south along the States bordering upon the Atlantic seaboard and Gulf of Mexico, just as in pulmonary tuberculosis the proportion of cases to other diseases increase as we pass alosng the Atlantic seaboard in a northeasterly direction.

The number of cases of malarial diseases increases, as stated, till we reach the Gulf States, and finally reaches its maximum in the States bordering upon the lower parts of the great Mississippi Valley. Our hospitals were also, as a rule, necessarily located near the Atlantic seaboard and bordering upon the Mississippi River, these being the most important points of communication, and where were aggregated the largest number of freed people requiring medical assistance.

The total number of cases of remittent and intermittent fevers occurring among the white refugees (see Table No. 2) was 5905, being 26.78 per cent. of the total number under treatment.

The remarkable similarity of the ratio of the white and colored patients under treatment would seem to convey the inevitable conclusion that there is very little difference, if any, between the susceptibility of the colored people and that of the white people of the Southern States to the attacks of remittent and intermittent fevers.

COMPARATIVE FREQUENCY OF VARIOUS FORMS OF MALARIAL FEVERS.

The most frequent form of malarial fevers met with among the freed people of the Southern States is the quotidian, being 41.30 per cent. of the entire number of cases of intermittent fevers under treatment.

It has been a disputed point among authors as to whether the quotidian or tertian is the most frequent form of intermittent fever. Dr. W. C. Maclean (*Reynolds' System of Medicine*, 1870, vol. 1, p. 595) says: "The tertian is said by many authors to be the primary type of fever, and to be the most common of all. This is certainly not the case in India, where, without doubt, the quotidian is the most common and the quartan the rarest of all intermittents." The remarks of Dr. Maclean with reference to the fevers in India are exactly paralleled by the experience of the physicians of the bureau in the treatment of the cases occurring among the colored people of the South. By referring to the *Medical and Surgical History of the Rebellion*, vol. i, page 710, which shows the statistics of sickness and mortality of the colored troops during the war, it will be found that the quotidian form of intermittent fever was also the most common among them, being 42 per cent. of the number of cases of malarial fever under treatment.

It is somewhat interesting to note that when we examine the statistics of cases of intermittent fever occurring among the white refugees, as seen in Report No. 2, and who lived in similar localities, we find a difference in the type of fever, and among them the tertian is found to be the most frequent, being 38.47 per cent. of the cases under treatment. Excluding quotidian and tertian fevers, the form of malarial fever most frequently met with was remittent fever, being found in the proportion of a little over twenty-three (23) per cent. of the total number of cases, and showing an aggregate of 26,793.

SCROFULA AND PULMONARY TUBERCULOSIS.

The total number of cases of scrofula reported was 6613, with 299 deaths. The total number of

cases of pulmonary tuberculosis was 5373, with 1787 deaths. The total number of cases of scrofula and pulmonary tuberculosis together was only 11,986, or a little less than 3 per cent. of the total number of cases under treatment.

The foregoing figures are quite sufficient to disprove the statements so commonly made concerning the extreme liability of the colored race to scrofula and pulmonary tuberculosis. So far from these two diseases being almost universally prevalent among the colored people in the Southern States, these people seem to be no more subject to them than the whites who live under like conditions in our larger cities. Scrofula and pulmonary tuberculosis are, in great part, caused by a neglect of the laws of hygiene and sanitary science. These diseases do not seem to be any more destructive to the colored race than to the white.

TYPHOID FEVER.

Of this disease we have 3820 cases recorded, with 951 deaths; *i. e.*, nearly twenty-five (25) per cent. of the cases treated died. The high rate of mortality found in this disease among the freed people was mainly the result of intestinal lesions, characteristic of typhoid fever, and also of the so-called typhoid pneumonias, which were frequently developed during the course of the disease. The lesions of the intestine were very marked. Indeed, in the majority of the cases during life there were evidences of, and the post-mortem appearances showed, the congestion and ulceration of Peyer's patches, so pathagnomonic of typhoid fever. The symptoms presented were those that generally characterize this malady, and were usually so well-marked as to leave no doubt as to the nature of the disease, with the single exception of the eruption, which was so irregular in its time and mode of appearance as to be of little utility as a means of diagnosis.

The cerebral symptoms developed early, and the delirium was of a low, muttering character, and accompanied by the dry, parched, or brown tongue, the sordes on the teeth, uncontrollable diarrhea, and the other symptoms of the true typhoid condition.

In many of the cases the vitality seemed very feeble, and the progress of the disease was very rapid, frequently terminating fatally by the tenth or fifteenth day after the attack.

The so-called typhoid pneumonia, or, properly speaking, typhoid consolidation of the lung, was a frequent and apparently dangerous complication of many of these cases. It was usually without any evidences of acute inflammation, and presented the characteristics of passive hyperemia of the lung, with a great tendency to effusion into the various serous cavities. The type of the disease seemed to require the energetic administration of stimulants and nourishment. Quinine was given in large doses early in the disease in some cases, but seemed only to abate the violence of the febrile symptoms, and had no other influence upon the course or duration of the fever.

DIARRHEA AND DYSENTERY.

The number of cases of these diseases met with among the freed people was very large, the aggregate of acute and chronic cases being 39,528, with 2346 deaths; of acute diarrhea there were 24,763 cases, with 727 deaths. Of chronic diarrhea there were 4777 cases, with 861 deaths. Of acute dysentery there were 8371 cases, with 432 deaths. The greater portion of the mortality met with (as is always the case) is among children and youths.

The large number of cases of lesions of the various parts of the intestinal tract which existed is susceptible of ready explanation when we consider the entire ignorance of the laws of hygiene that prevailed among these people, and their use of improper articles of food. The staple articles of diet among the freed people were fresh and salt pork and corn-meal, with a very insufficient supply of milk and vegetables. To the continued use of this diet, along with neglect of personal ablutions, and the tendency to crowd together in ill-ventilated huts, may be fairly ascribed the great prevalence of this class of diseases which existed during the first two years of the bureau—1865, 1866. The sanitary condition of the freed people, however, it should be here remarked, improved very greatly during the latter years of the bureau, and has in still greater degree since that time.

It was a common remark among the physicians on duty that the diseases that prevailed among the freed people during the years 1867–1872 were milder in type and less fatal than those during and immediately subsequent to the late Civil War. I have been especially struck with this fact in the case of syphilis and other enthetic diseases. An unquestionable amelioration in the type of syphilis has taken place during the past ten years, and we no longer see those dreadful cases of phagedenic ulceration so frequently met with in the cases of syphilis that occurred among the freed people during the years 1865, 1866, 1867. The same, to a greater or less degree, may be said of all the diseases prevailing among them, and is, of course, due to better food, more comfortable habitations, and increased cleanliness.

EPIDEMIC CHOLERA.

Of this disease there were 1247 cases reported, with 691 deaths—or a little over half the cases died. The cases of this disease met with among the freed people mostly occurred during the epidemic of 1866

and 1867, and the localities chiefly affected were those States bordering upon the southern parts of the Mississippi Valley and the South Atlantic States.

On the news being received in the spring of 1866 that the epidemic was approaching, instructions were transmitted by the Chief Medical Officer of the Bureau to the surgeons-in-chief of each district to cause a thorough cleansing and disinfection of all the hospitals, camps, and quarters occupied by the freed people. My personal experience of this epidemic was very limited, being confined to the few cases (some twenty in number) which occurred in the District of Columbia during the summer months of 1866. In these cases the state of collapse came on very early, and when developed seemed scarcely amenable to treatment. The stringent sanitary measures that were adopted by the local authorities of Washington and the Medical Department of the Bureau no doubt had a considerable influence in arresting the spread of the epidemic. These measures included compulsory cleansing and whitewashing at short intervals of the quarters and localities inhabited by the freed people, together with the prompt removal and disinfection of all refuse and garbage, and, of course, prompt isolation of the patients. The curious and rather discouraging fact was developed by the statistics of this epidemic that, under every variety of treatment, about one-half of the patients attacked died. This was not only true among the freed people, but was also the case among the white, who suffered in a like proportion.

SMALLPOX.

The total number of cases of variola reported was 10,299. The number of deaths reported was 1802, or 17.55 per cent.

The greater number of cases (as will be seen by reference to the consolidated report) occurred during the years 1865 and 1866, and the spread of the disease was greatly facilitated by the condition of affairs then existing in the Southern States. Owing to the disorganization of society and the impossibility of securing remunerative employment on the plantations, vast numbers of the freed people aggregated along the northern frontiers of the border States and in the commercial cities of the Atlantic seaboard and Mississippi Valley. Owing to their destitute condition, the Government was compelled to issue rations, and provide for their temporary support in large camps and settlements, until employment could be found for them.

While I would scarcely like to assert that smallpox ever originated *de novo* by the overcrowding that necessarily resulted, yet some cases of smallpox occurred which were scarcely susceptible of any other explanation.

It need scarcely be said that vaccination and revaccination of all the freed people exposed to infection were strictly enforced, and, as a matter of course, with the same result which has always attended its proper enforcement, namely, the eradication of the disease. A striking exemplification of this was seen in the epidemic of smallpox that occurred in the City of Washington, D. C., during the winters of 1865 and 1866. Instructions were issued to the physicians on duty in the Bureau to vaccinate and revaccinate all the freed people not fully protected. During these two years about 10,000 persons were vaccinated or revaccinated, with the result of causing the disappearance of the disease, which did not reappear in Washington as an epidemic until the winters of 1871 and 1872.

The cases of smallpox were, many of them, confluent in type and presented the usual complications of the disease.

DELIRIUM TREMENS.

The small number of cases of this disease met with among the freed people being only sixty-five, with one death, presents marked contrast in frequency when compared with the large number of cases met with among the white population of our country. This may be partially explained by the fact that chronic alcoholism is not so frequent among the colored people as among their neighbors of the Caucasian race; still, there does seem to be even among those of the freed people who habitually use intoxicating drinks a marked exemption from this disease. In the Freedmen's Hospital, under my charge, at Washington, D. C., which has had under treatment from 1865 to the present time about 5000 patients, I remember seeing only one or two cases, and these were mild in type.

My own belief is that the true explanation of this exemption is to be sought for in the want of development of the cerebral hemispheres, which so often exists among the negroes. Delirium tremens is preëminently a disease causing disorder of intellection, and hence the continued abuse of alcoholic drinks in the negro race is more likely to produce epileptiform convulsions or mania than delirium tremens.

In conclusion, I wish to state that so far as my own experience goes I have found that the negro race does not withstand the attacks of acute inflammation, such as pneumonia, nor do they recover from long-continued illnesses such as typhoid fever, as well as the white race. On the other hand, the power of repair of the negro race, after receiving injuries, and being subject to surgical operations, is excellent.

With the exceptions mentioned in this report, I have never found any specific differences between

diseases as developed in the Caucasian and negro races in this country, the differences met with being in degree, and not in kind.

SYMPHYSIOTOMY.[1]

BY BARTON COOKE HIRST, M.D.,
OF PHILADELPHIA;
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA.

MR. PRESIDENT AND GENTLEMEN: In accepting your flattering invitation to deliver the address on Obstetrics on the occasion of your two hundredth meeting I have chosen for my subject symphysiotomy. The position of this operation in the treatment of labor obstructed by a contracted pelvis is beyond doubt the question of greatest present interest in obstetrics. The glamor of novelty surrounding the successful revival of symphysiotomy may have passed away by this time, but the sober second judgment of the profession is now about to be passed upon it. Thanks to the modern method of collective investigation and observation, a few months have sufficed to show defects and advantages in the operation that it would formerly have taken years to learn, so that we are just now in a position, I think, to assign to symphysiotomy its rightful and lasting place among obstetric operations.

It suits my purpose best to indicate first the weak points of the operation that have been manifested in the two years since it has passed from Italy to many different parts of the world.

Foremost among the objections that could be urged against symphysiotomy stands a mortality much higher than was at first anticipated.

In 212 operations since 1887 there have been 27 maternal deaths, a mortality of 12. 73 per cent., while the deaths of the infants during and shortly after birth brings their mortality to a fraction over 28 per cent. In our own country the figures are 30 operations, 4 maternal and 7 infantile deaths, or a mortality respectively of 13.3 per cent. and 23.3 per cent. It must be admitted that many of the deaths were not due to the mode of delivery, but were caused by prolonged labor, by injuries to and infection of the parturient tract. Still some deaths are recorded as the result of hemorrhage from the incision, and others were due to septic infection of the wound.

Another objection that might be advanced against symphysiotomy is the fact that it must be limited to contracted pelves with a conjugate above 6.75 cm. It will be difficult, therefore, for the general physician and even sometimes for the specialist to decide, on the one hand, whether symphysiotomy in a given case is practicable, or on the other hand, whether forceps or version and extraction will not prove successful.

Other considerations against symphysiotomy are the tediousness of the operation, followed as it must often be by some other obstetric procedure; the need of good assistants; the absolute necessity of as thorough asepsis as is demanded in abdominal surgery; the likelihood of serious tears in the anterior vaginal wall involving, perhaps, the urethra and the bladder; the difficulty of keeping the vulva clean during the puerperium, on account of the close apposition of the thighs; and the still greater difficulty of disinfecting the vagina and uterus when necessary.

In contrast with these disadvantages attaching to symphysiotomy, let us glance at the advantages of the operation with which it comes chiefly in competition—Cesarean section. If I may be permitted to judge from the comparatively limited experience of three symphysiotomies and four Cesarean sections, I should regard the latter as decidedly the easier operation. Moreover, by Cesarean section the child is sure to be delivered easily, no matter what the size and shape of the pelvic canal may be, and there is no necessity for that nice calculation in pelvimetry that is usually demanded before a contemplated symphysiotomy, a calculation in which even the best of us may err. Further, the mortality of the infants is not quite so great in deliveries by Cesarean section. Finally, the after-treatment of Cesarean section in a favorable case is much easier for patient, physician, and nurse. It is obvious, therefore, that symphysiotomy can be preferred to Cesarean section on one ground alone—that it is less dangerous to the mother. If statistics demonstrate this, then it is the duty of every intelligent obstetrician to familiarize himself with the indications for symphysiotomy, and possibly with its technique, for this is not an operation to be lightly undertaken by anyone who does not possess skill both in obstetrics and abdominal surgery.

A careful study of the results of symphysiotomy and of Cesarean section will show that the latter is at the very least twice as dangerous to the mother as the former. In Dresden, Vienna, and Glasgow the maternal mortality of Cesarean section (99 operations) in the hands of the best operators has been about 10 per cent. In this country, Dr. Harris tells me, he has collected the reports of 88 recent Cesarean sections, with a maternal mortality of 39.7 per cent. The table which Dr. Harris kindly gave me in response to my inquiry is so very important and interesting that I add it in full:

Cesarean operations in the United States, commencing with October 6, 1882	88
Deaths (maternal)	35
Operations in New York City	21
Women recovered	12
Children saved	17
Operations in Philadelphia	15
Women recovered	10
Children saved	11

		Women recovered.	Children saved.
Operations of 1887	8	5	8
" " 1888	13	5	13
" " 1889	9	6	8
" " 1890	17	13	16
" " 1891	10	7	6
" " 1892	12	9	12
" " 1893	10	6	6
	78	51	61

It may be seen by the table that the results of Cesarean section in this country are not improving with time. Since 1887 there have been 78 operations, with 27 deaths—a mortality of 34 per cent. In 1893 there were 10 operations, 4 deaths—a mortality of 40 per cent! The

[1] The address on Obstetrics, delivered by invitation, before the Washington Obstetrical and Gynecological Society, Nov. 17, 1893.

same thing is shown by taking the last 10 cases in New York and Philadelphia. In the last 10 of New York City —women died 5, children lost 1; last 10 of Philadelphia— women died 3, children lost 2—a mortality of 50 and 33 per cent. in the two cities where the best surgical work of the country might be expected.

As is well known, the best work in symphysiotomy has been done in Italy. There the mortality is but 4 per cent. in the last 50 cases. It is true that there is one city in the world where the results of Cesarean section approach those of symphysiotomy. In Leipzig there have been 54 Cesarean operations, with 3 deaths—a mortality of 5½ per cent. But there is no other locality with a record so good as this. Further, if the causes of death after symphysiotomy and after Cesarean section be compared, it will be found that the first has very few deaths attributable to the operation itself. Take, for example, the 4 deaths after symphysiotomy in this country. One was the result of double non-septic pneumonia; another was due to the shock and exhaustion of a prolonged labor and many attempts at delivery, the operation being performed upon a dying woman. The third was caused by septic peritonitis from infection of the parturient tract; and only one is attributable to the operation itself, the wound being infected during the operation, an accident easily preventable by sufficient cleanliness and proper technique. This is a mortality of but 3 per cent. On the other hand, almost every death following Cesarean section is due to septic peritonitis or to hemorrhage.

FIG. 1.

Pelvimeter measuring distance between outer surface of symphysis, just below the upper edge, and the promontory of the sacrum.

FIG. 2.

Pelvimeter measuring the thickness of the upper part of symphysis. This measurement is to be subtracted from the other. A curved tip is inserted in the pelvimeter for this purpose.

As long, therefore, as the two operations hold this relation to one another in results, symphysiotomy must be the choice of the conscientious operator whenever it is practicable. It follows, consequently, that every one interested in the practice of obstetrics must to-day be familiar with the indications for and the technique of this operation, and it is to these two phases of the subject that I shall devote the remainder of my paper.

Indications. There are two mistakes to be guarded against in deciding for symphysiotomy in a labor delayed or obstructed by a symmetrically contracted pelvis. One is the resort to this operation when some less radical means would deliver the woman safely of a living child; the other is the attempt to deliver by symphysiotomy through a pelvis too small to permit the passage of a living child, even when the pelvic bones are separated as widely as possible without injury to the sacro-iliac joints. The first mistake has not been uncommon during the excitement attending the revival of the operation. The most notorious example is the delivery by symphysiotomy of a VII-para, who had given birth to her six children spontaneously and had only lost one, which presented by the breech. This mistake is easily guarded against. I have been summoned expressly to perform symphysiotomy more than thrice as often as I have performed the operation. The application of forceps to the head above the brim will, in practised hands, often secure engagement, and if the attempt is carefully made no harm is done, even should it fail. Version and extraction are to be considered, too; but the danger of these procedures to the child is also to be taken into

account. With my own experience of three perfectly uncomplicated recoveries from symphysiotomy, I feel disposed to regard this operation with more favor than version and extraction in a markedly contracted pelvis. The opposite error of opening the symphysis when the pelvis is too small to permit of delivery by this means is more difficult to escape. It will only occur, of course, in a pelvis with a conjugate of 67 mm. or under, a degree of contraction not often seen among us; and, could we always feel sure of the accuracy of our pelvic measurements, the mistake could be pretty surely avoided. But every one knows that, though we report the dimensions of the conjugate diameters of our cases with great precision, we cannot feel absolute confidence that our measurements are always correct. The estimation of the conjugate from the diagonal conjugate is liable to serious error, even though we allow for an increase in the conjugato-symphyseal angle and in the height of the symphysis. For example, I have operated on two rachitic dwarfs, primiparæ, each with a diagonal conjugate of scant 9 cm., say 8¾, and therefore with a true conjugate presumably of not less 67 mm. In one I extracted the child with the greatest ease; in the other I broke the child's clavicles and its neck in my efforts to pull the head, coming last, through the contracted pelvis, though the symphysis gaped widely. In both cases the head measurements were almost identical. To avoid this possibility of false calculation I have had constructed a pelvimeter to measure the conjugate as nearly directly as possible. The idea, you will recognize, is borrowed from Skutsch; but this pelvimeter, I think, is better than his.

I can imagine no more embarrassing predicament in obstetrics than a failure to extract the head after opening the symphysis. I should feel reluctant to operate again at the lowest limit for symphysiotomy unless I had the opportunity first to induce labor and artificially dilate the cervix some two or three weeks before term. In this case I should not hesitate to operate with a conjugate as low as 65 mm., and I believe delivery might be possible with a conjugate of only 6 cm.

Technique.—It is unnecessary to describe in detail all the steps of an operation with which the medical world has of late become so familiar. I shall limit this section of the paper to the discussion of certain moot questions in the technique upon which I entertain strong convictions.

The incision in the lower abdomen, extending to within about three-quarters of an inch of the symphysis, and the severance of the joint from below upward and within outward subcutaneously, are much to be preferred to the incision directly over the symphysis. By the former the wound can easily be kept clean in the lying-in period. Troublesome hemorrhage is not so likely, and the urethra is free from danger. By the latter I do not see how the wound can be kept clean with any degree of certainty. Hemorrhage of an alarming character is to be expected, and the urethra is more likely to be cut. The complaint from some German writers in regard to the fever that follows symphysiotomy is to be explained, I think, by their preference for the direct incision. I have had two entirely afebrile convalescences, and in the third case fever only developed on the twelfth day in consequence of a phlegmasia that had no connection with the operation at all. On the whole, I prefer the old-fashioned model of the Galbiati knife. The long beak enables one to cut almost entirely from below upward, and thus avoid bleeding as far as possible. Dr. Harris's modification of this knife is so closely adjusted to the posterior surface of the symphysis that it cuts as quickly forward as it does upward, and is likely to wound the veins behind the clitoris. I can see no reason for suturing the symphysis. This is troublesome, prolongs the operation, favors inflammation in the joint, and is not necessary. A firm pelvic binder and a close apposition of the thighs, tying the knees together, if necessary, will secure a better approximation of the bones than any stitch could do. It is surprising to read the different methods proposed in recent German articles for suturing the symphysis. I have not yet done this, and, as each one of my cases has had a firmly united pelvis without it, I believe that it is entirely unnecessary.

A very valuable preliminary step in the operation itself is the thorough dilatation of the cervical canal. As the head does not enter the superior strait in the majority of cases in which symphysiotomy is called for, the os will not be well dilated, no matter how long labor may have lasted, so that the cervix will present a serious obstacle to quick delivery after the symphysis is cut, especially in primiparæ. For this purpose I have a Barnes bag twice as large as the largest sold in the shops. After using the three ordinary sizes, allowing each to remain in the cervical canal for some time, I have inserted this largest one, distended it to its full capacity, and allowed it to remain in place for at least an hour. Then, if it is necessary (as it usually is) to apply forceps or to perform version, the child can be extracted as rapidly as the operator desires. In one of my cases, in a primipara, over thirty years of age, the child, now living and well at the age of six months, was delivered in less than five minutes after the pelvic bones were separated. When the artificial dilatation of the cervical canal was begun in this case, it would just admit one finger. Finally, as to the fixation of the pelvis, the cleansing of the vulva, and the care of the abdominal wound. The first is secured by broad rubber adhesive strips and a stout obstetric binder, coming well down over the trochanters. The vulva is protected by a pad of salicylated cotton and carbolized gauze, and is cleansed by a stream of water from a fountain syringe, several times a day, the patient resting upon a bedpan. The wound need not be disturbed for more than a week. When it is desired to expose it, the lower part of the binder is unpinned, a window cut in the adhesive strips, which are reinforced by others over them when the dressing is completed. In this way the pelvis need not be subjected to the least strain.

To prevent stretcthing of the new-formed union in the joint I have kept my patients in bed five weeks.

Novel Prizes are offered by a member of the Anthropological Society, of Washington, D. C., for the best essays (3000 words) on the subject of the elements that go to make up the most useful citizen of the United States, regardless of occupation. The first prize is of $150, the second of $75, and the essays are to be submitted before March 1, 1894. Particulars may be obtained of the Society. Here is a chance for the literary doctor, and we hope he may win!

AN OUTBREAK OF TYPHOID FEVER PRESENTING UNUSUAL FEATURES.[1]

BY WM. C. DABNEY, M.D.,
PROFESSOR OF THE PRACTICE OF MEDICINE IN THE UNIVERSITY OF VIRGINIA.

THE atypical forms of typhoid fever during the past few years have received much attention, and doubt has frequently been expressed whether atypical cases should be considered typhoid at all. A singularly favorable opportunity for studying cases of this character was furnished by an outbreak at the University of Virginia in the winter and spring of the present year (1893), and I propose to give a brief account of the outbreak in this paper.

In order to understand the origin of these cases it will be necessary to state briefly the arrangement of the lodging-rooms and eating-rooms at the institution.

The buildings of the University used as dormitories by the students are scattered over a space of ten or twelve acres, and there are four hotels, or "mess-halls," at which the students get their meals. A student can select his own boarding-house, so that each hotel has "table boarders" from all parts of the University grounds.

At the time of the outbreak—on February 17th—there were about 530 students at the University. Of this number about 350 roomed in the University buildings and took their meals in the University hotels.

There had been no typhoid fever at the institution for many months, nor were there any cases in the vicinity except one, of which I shall speak later.

On the 19th of February I was consulted at my office by Mr. D. D. H., a law student, who complained of loss of appetite, debility, and headache; his temperature was between 101° and 102°. Influenza was prevailing at the time, and I thought it probable that he was suffering with an attack of that disease, but a few days later he sent for me, and I found him with a well-marked attack of typhoid fever, which pursued a mild but typical course and ended in recovery.

A few days later I saw Mr. K., an academic student, who had severe headache, a temperature of 104°, aching in his limbs, and constipation; he had been sick only twenty-four hours; he was given salophen in six-grain doses every four hours, and the next day he went to his home in a neighboring city, where, as I was informed, he had a mild attack of typhoid fever.

These two young men lived in different parts of the University, but took their meals at the same boarding-house and sat at adjacent tables.

Perhaps before going further I should mention that the water-supply of the University is perfect in all respects, and the system of sewerage is excellent.

Just after the occurrence of the second suspicious case I found that there was a negro man—a waiter—ill with typhoid fever in the basement of the hotel where these young men got their meals. On further inquiry I found he had been ill for about four weeks, and that another waiter who lived outside of the University grounds also had the disease. I did not see either of these cases, but was informed by the physician who attended them that they were typical cases of typhoid, one being quite severe in character.

Between this time and the 1st of April there were ten additional cases, making fourteen in all, and these patients lived in different parts of the University grounds, some being a quarter of a mile apart, *but all took their meals at the same hotel.*

Immediately after the occurrence of the second case and the discovery of the ill man in the basement of the boarding-house, the dining-room was closed and a thorough inspection of the building and premises was made by the health committee, consisting of three physicians and two engineers. Nothing was found about the house to account for the sickness, and an examination was then made of the milk-supply. It was found that a part of the milk-supply of this boarding-house came from the dairy of the keeper of the house. An inspection showed that the dairy was situated some distance from the University and on the banks of a creek, into which one of the main University sewers opened and at a point *above* the dairy; it was further found by questioning the milkman that he got water from a point about twenty yards below the opening of the sewer, to wash the cows' udders before milking. Besides this there had been a case of typhoid fever on this creek a mile above the dairy during the previous autumn, and the discharges from this patient—an ignorant negro—were thrown upon the ground without disinfection.

Before proceeding to consider the peculiar features of some of these cases, I wish to emphasize certain points that I have already mentioned:

1. There had been no typhoid fever in or around the University for several months, so far as I could learn, except one case in the vicinity, from which infection was practically impossible.

2. Between the middle of January and the 1st of April there occurred fourteen cases of continued fever among persons living or employed in the University grounds.

3. The persons who had this continued fever had rooms, in many cases, widely separated from each other, but all took their meals at the same hotel.

4. The water-supply of this hotel was the same as that of the other hotels and of the other parts of

[1] Read before the Section on General Medicine of the Pan-American Medical Congress, September 6, 1893.

the University, and the sanitary condition of the building was good.

5. A part of the milk-supply was obtained from cows whose udders had been washed with water contaminated by sewage, and probably infected with typhoid-fever germs. It was in evidence also that at least five of the fourteen persons used milk at every meal. Probably there were others who did so, but I could only get definite information as to five.

Of the fourteen cases of this continued fever, ten were under my professional care and four under the care of other physicians, though I saw one of these four cases at the commencement of the attack, and another near convalescence; several of my cases were seen also by my colleagues, Drs. Towles and Barringer, of the University of Virginia. Of the fourteen cases one was in a child, twelve years old—the daughter of the hotel-keeper; the others were in young men between the ages of 18 and 25 years.

Of the ten cases under my immediate care there were but three that pursued anything like the typical typhoid fever course. The first patient, Mr. D. D. H., was taken sick on February 17th, and his evening temperature was normal for the first time on March 5th; his temperature during this time ranged between 101° and 103°. The eruption in this case was well marked; the bowels usually moved spontaneously, but there was at no time any diarrhea. The only complication was an inability to pass urine, which for a week necessitated the use of the catheter.

Mr. G. was taken sick on March 4th with nausea and vomiting. His temperature ranged from 101° to 105° till March 25th, when he had a profuse hemorrhage from the bowels, with extreme prostration; the hemorrhages recurred at intervals until the 30th; there were no more hemorrhages after that time, but the stools were liquid, very offensive and passed involuntarily. On April 5th, the morning temperature was 101° and the evening temperature 103°, and by the 10th the patient was free from fever, but there was still some delirium. In two or three days, however, this passed away, and he seemed to be progressing very favorably for a week, when he was suddenly taken with violent convulsions, which recurred in rapid succession till his death, twelve hours later. No autopsy could be obtained.

There was but one other fairly well-marked case of typhoid fever among my ten cases. Mr. W. was taken sick on March 14th, but I did not see him till the 19th; his temperature then was 104.5°; his pulse was rapid, and his skin wet with sweat; he had severe headache, but there was no other disturbance of any kind. His evening temperature did not fall to the normal for four weeks, and ranged during the attack between 103° and 99°. A peculiarity about this case was that the temperature was higher during the first week than at any subsequent time. His bowels were constipated throughout and had to be moved by enemata. There was no eruption in this case, nor was there any tympanites, and though I have placed it in the list of well-marked cases, it was far from typical.

The seven remaining cases presented more or less atypical features, and I shall consider the different symptoms in order, to show their atypical course:

1. The ONSET was gradual in six cases, and sudden in one, commencing in this latter with a chill.

2. The DURATION was six days in one case, eleven in another, fifteen days in a third, eighteen days in a fourth, and over four weeks in the remaining cases.

3. The TEMPERATURE in five cases was higher during the first three days than at any subsequent time; the evening temperature on the day that I was called—the first or second day of sickness—being 103.7°, 102.8°, 102°, 101.8°, and 102.6° in the respective cases. One of these cases lasted over four weeks. In the remaining cases the temperature was very variable and the attack in each lasted over four weeks. For example, Mr. A. C. I., a medical student, had a temperature of 102° on the morning of April 1st, 103 4° in the evening; on April 3d, A.M. 100.6°, P.M. 103.4; April 9th, A.M. 99.6°, P.M. 103.5°; these striking variations were entirely irrespective of treatment and were marked throughout the whole attack; this was the only case except the fatal one already mentioned, in which there was diarrhea.

The following case presents somewhat similar variations of temperature: Mr. D. P. was taken sick on

March 26.	Temperature,	A.M. 100.5°,	P.M. 103°
April 1,	"	" 100.6°,	" 103.2°
" 3,	"	" 100.2°,	" 101.6°
" 9,	"	" 100 6°,	" 99.1°
" 11,	"	" 98.2°,	" 99.4°
" 15,	"	" 99°,	" 99 9°
" 17,	"	" 99°,	" 102°

Neither of these patients had ever had malaria in any form, nor did they live in malarial districts, one being from Highland County, Va., the other from Winchester, Kentucky.

4. The PULSE presented no features of especial interest; it was rarely over 100, except in two cases—the one in which there was hemorrhage from the bowels, and in another, that of Mr. D. P., which ran a mild but tedious course.

5. The DIGESTIVE SYMPTOMS. There was loss of appetite in all cases after the first week, but during the first week two of the patients complained of being very hungry. Nausea and vomiting were present for a short time in two or three of the cases, but these symptoms were not marked. Diarrhea occurred in only two cases—that of Mr. G., in which there was hemorrhage from the bowels, and that of

Mr. A. C. I.; in both it was very obstinate and troublesome. In all the other cases constipation was a marked symptom. Iliac tenderness was present in five cases, and tympanites in two.

6. The ERUPTION was present in only two of the ten cases under my care.

7. The URINARY SYMPTOMS were not marked. In one case there was retention of urine, requiring the use of the catheter. Ehrlich's test (for diagnostic purposes) was not employed in any of the cases, as previous experience had satisfied me that it was of little value.

8. WEAKNESS, emaciation, and anemia were marked symptoms in the later stages of all of the cases.

I have thought it well to put the history of this outbreak of fever on record for the following reasons:

1. It furnished a singularly favorable opportunity for studying an unusual source of infection.

2. In an outbreak—of which the cause could be determined with reasonable certainty—occurring at a time when no form of continued fever was prevailing in the community, we find a number of persons infected from the same source, some of whom presented the typical features of typhoid fever, while others had a fever which would never have been classed with typhoid but for the surrounding circumstances.

It is of course conceivable that the cases that seem to me to be atypical typhoid fever were really of a different character, but in view of the facts that all originated from the same source and all grades of severity were observed, such a conclusion seems to me scarcely tenable.

CLINICAL MEMORANDA.

PROFOUND TOXEMIA WITH SLIGHT TUBERCULOUS LESIONS.

BY WILLIAM OSLER, M.D.,
PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

THE symptoms of a profound intoxication in tuberculosis are met with under three conditions: First, in those rare cases, described most commonly in children, in which death may occur with symptoms of a profound toxemia before there are any extensive localized foci of disease. "The children have presented in the course of the disease all the signs of a profound intoxication, and as the tuberculous lesions of the lungs and all other organs are altogether insufficient to produce death, it is quite reasonable to attribute the fatal results to the bacillary intoxication." (Aviragnet.[1]) These are the instances of the *fièvre infectieuse tuberculeuse suraiguë*. Second, acute miliary tuberculosis is often accompained with toxic features, giving to many of the cases clinical pictures of severe typhoid fever. Post-mortem, miliary tubercles are found extensively throughout the viscera and on the serous surfaces. Third, in chronic pulmonary tuberculosis there may develop, with or without fever, a profound toxemia, with dry tongue, delirium, rapid pulse, and signs of intense intoxication. The patient may be admitted to hospital unconscious, with a normal or subnormal temperature, and, as in a case which was under my care at the Philadelphia Hospital, the autopsy alone revealing the true nature of the disease.

The following case may perhaps be regarded as an instance of the *febris tuberculosa peracuta*. The striking features were the existence of a local tuberculous adenitis in the group of left cervical lymph-glands; a miliary tuberculosis of very moderate intensity in the liver and spleen; and a clinical picture of the most profound toxemia.

Joseph S., aged forty-seven, a shoemaker, was admitted to Johns Hopkins Hospital, March 13, 1893, with a swelling in the left side of the neck, cough, loss of appetite, and delirium.

Nothing very definite could be learned about the family history. The patient was married and had six living children. His wife stated that he had had a cough the summer previously for about two weeks, and that he had not been very strong all winter, and had complained at times of pains in the abdomen. He had occasionally had chills and fever and had sweated very much. The existing illness had begun five or six weeks before, with chilly feelings and loss of appetite. About a week later it was noticed that the glands on the left side of the neck were swollen. The man continued at work, however, until three weeks before presenting himself. He had neither nausea nor vomiting, but there was loss of appetite and progressive weakness and fever. For fully two weeks he had been irrational, and at night quite delirious. The chief complaint had been the feeling of profound weakness, and for more than ten days he had been confined to bed, too feeble to walk.

On admission the patient looked very ill; the temperature was 102.7°, and rose by 6 P.M. to 105°. Throughout the day before the temperature had ranged from 103° to 105°, and the man had been delirious. The patient was a fairly well nourished man, and did not look as if he had been ill for any great length of time. The complexion was pale, but the lips and mucous membranes were of fairly good color. The pupils were of medium size, and reacted to light; there was no strabismus. The tongue had a thick, yellow coating. The pulse was rapid, 124, regular, but soft, and the radials compressible. The respirations were a little hurried, 36 to the minute, but the man did not show any marked respiratory distress, and lay comfortably with his head low.

On the left side of the neck behind the angle of the jaw, and in the lower triangle the lymph-glands were moderately enlarged, hard, and not painful. The largest was about the size of a horse-chestnut. There were no other lymphatic enlargements.

The chest was symmetrical, the expansion equal, and there was no change on percussion; the respiration was everywhere clear, with the exception of a few sibilant râles at the bases. The expectoration was muco-purulent, small in amount, slightly blood-stained, and repeated examination failed to discover the presence of

[1] De la Tuberculose chez les Enfants. Paris, 1892.

tubercle-bacilli. The heart-sounds were normal and there was no increase in the cardiac dulness.

The abdomen was symmetrical, full, and generally tympanitic. The patient had five movements of the bowels in the first thirty-six hours after admission. They were soft, but not in any way distinctive. The edge of the spleen could be easily felt and extended three fingers' breadth below the costal margin. The urine was dark reddish-brown in color; 660 c.c. were voided in the twenty-four hours, containing a small quantity of albumin and a few granular and hyaline casts. There was a decided diazo-reaction. The patient was irrational and frequently spoke in an irrelevant manner.

On the 15th, two days after admission, the patient was shown at the clinic, and I extract the following remarks from the report of my stenographer. "As to the nature of this interesting case, from the appearance of the man and the history you would think at once of typhoid fever, though the temperature-chart is unlike this disease in the fourth or fifth week. Still the general features, the enlarged spleen, the diazo-reaction, and the negative condition of the examination render this diagnosis highly suggestive. Against this, however, there are several important objections. The temperature-range, as I mentioned, is more continuous than is usual in typhoid fever at this stage. The abdominal symptoms are slight, and there are no rose-spots, though it is true the spleen shows marked enlargement. Bronchitis is not an infrequent complication of typhoid, and at the bases it is of course common to have diffuse râles. A feature that suggests another diagnosis is the enlargement of the lymph-glands on the left side of the neck, which has increased during the patient's illness. There can be no question that the enlargement here has nothing whatever to do with the ordinary swelling of the salivary glands seen in typhoid fever. Here the affection is evidently in the lympathic glands, and this important fact, with the protracted fever, the delirium, and the enlargement of the spleen, suggests rather that the patient has acute tuberculosis. Two other points of interest may be mentioned. The blood-count shows a marked diminution in the number of leukocytes, only 2000 per c.mm. being present, which is, however, rather against tuberculosis. There is no optic neuritis, and there are no tubercles in the choroid."

The critical condition of this patient continued throughout the 16th and 17th. The temperature ranged from 103° to 105°, rarely falling below 103.5°. The pulse became more rapid, from 140 to 160; the abdomen became distended; the respirations very shallow and rapid; and the patient died early on the morning of the 18th.

REPORT OF THE AUTOPSY (by Dr. Flexner).—Punctiform hemorrhages were found on the skin of the shoulders and neck, and subcutaneous hemorrhage at the back of the neck on the right side, as also hemorrhages in the subcutaneous fat in several situations. The muscles were of a deep-red color. The peritoneum was smooth; the diaphragm on the right side was at the fifth rib, on the left side at the upper margin of the sixth rib.

Both layers of the pleura were united by old adhesions, some of which were pigmented. The lungs themselves were crepitant and deeply pigmented; the lower lobes were congested, and, on section, serum and blood escaped. The bronchi contained frothy mucus. Along the posterior edge of the right lung the pleura was greatly thickened, measuring 3 mm. in thickness. Beneath it the lung was pigmented. The lower lobe of the right lung presented areas of fresh consolidation, and the pleura was covered with fresh, granular fibrin. On section the lung was deep grayish-red in color, and portions excised sank in water. The heart weighed 270 grams. The pericardium was smooth, the valves normal. The heart-muscle was soft and somewhat friable. The liver weighed 2850 grams; the surface was smooth, and there were whitish and whitish-yellow miliary tubercles beneath the capsule, irregularly scattered and not in great numbers. The spleen weighed 500 grams; the section was dark-red in color; the brown pulp was abundant, and there were numerous large tubercles in its substance. The kidneys presented a few atrophic patches in the cortex; the striæ were coarse and pale; the consistence a little firm. There was nothing of special note in the pharynx, stomach, or esophagus. Peyer's patches were a little swollen; the mucous membrane of the intestines was somewhat congested. The appendix vermiformis was obliterated.

On the left side of the neck a mass of tuberculous glands extended from the angle of the jaw to the clavicle. Some of them were closely adherent to the veins in the locality. On section they were yellow and caseous. The group of glands above the clavicle, and the mediastinal glands also, contained caseous tubercles. The bronchial glands were enlarged, deeply pigmented, edematous, but there were no tubercles visible to the naked eye.

On microscopic examination of the solid areas of the lung no tubercles were to be seen. There were numbers of diplococci, with distinct and easily-staining capsules, obtained from the lung on cover-slips. Cultures made from the lung, spleen, and kidneys remained sterile.

The groups of enlarged lymphatic glands in the neck in this case really led to the correct diagnosis. The general condition and appearance of the patient were those of the most severe typhoid fever, though, as I remarked to the class, the fever was rather more persistent and higher than is usual in typhoid fever. The amount of tuberculous infection throughout the body was in reality slight. The tubercles were not numerous in the liver and were only moderately numerous in the spleen. There was no pulmonary tuberculosis and the serous surfaces were not involved. The pneumonia in the lower lobe of the right lung was not extensive, seemed fresh, and evidently had developed within a few days of the patient's death.

A REMARKABLY DISTENDED BLADDER.

BY H. S. COCRAM, M.D.,
OF NEW ORLEANS, LA.;
GYNECOLOGIST TO THE CHARITY HOSPITAL.

SOME months ago an Italian woman, thirty years of age, a multipara, presented herself in the gynecologic clinic of the Charity Hospital, suffering with an abdominal tumor about the size of a nine months' utero-gestation. The swelling was perfectly symmetrical, extending in the median line within an inch of the ensiform

cartilage and touching the ribs on either side for a distance of several inches. She stated that her menses had stopped four months previously, but that the tumor had only commenced to grow six weeks before, and had been in its present condition one month. Her general condition was much below normal; the face wore an expression of great pain and anxiety; respiration was rapid, the pulse quickened and thready, and there was abdominal tenderness, with constant elevation of temperature, especially marked in the evening. She passed a small quantity of urine at irregular intervals, but on the slightest exertion was unable to retain it. Any change of position would cause an unexpected flow of urine mixed with blood and mucus. On examination the mucous membrane of the vaginal canal was found to be so edematous that its folds protruded at least an inch out of the vulva. The cervix was reached with much difficulty and found to be situated in the anterior cul-de-sac, pointing upward and backward. It was soft, much congested, and of a bluish tinge. At the junction of the cervix with the body of the uterus there was a marked retroflexion, the fundus extending downward and backward, reaching within an inch and a half of the anus. Passing one finger in the rectum the other in the vaginal canal, ballottement was well marked. The uterus was of the size of that of a four months' pregnancy. During the examination the patient passed a large quantity of decomposing urine. A catheter was introduced in the bladder, and about one pint of urine withdrawn, when it ceased to flow. The pain was so great that an anesthetic was administered, the legs flexed on the abdomen and the tumor pushed well down. The edema of the vaginal canal was so great that nothing definite could be ascertained by touch through the anterior cul-de-sac, except that the tumor was fluctuating, with apparently thin walls. An exploring needle was introduced just below the umbilicus, and a dark-colored fluid drawn off, with a decided urinous odor.

A large glass catheter was now passed six inches in the bladder. There was a rapid flow of urine, with a synchronous decrease in the size of the tumor that cleared up the diagnosis at once. In one week she was able to pass her urine at will and the uterus had risen to almost a normal position, with every indication of a continuance of pregnancy to full term. Ten days later her temperature suddenly rose to 103°, the abdomen became tense, and vesical tenesmus was so great as to require an anodyne. The small quantity of urine passed at short intervals was mixed with blood and mucus. In attempting to catheterize her it was noticed that the urethral canal was completely occluded. The obstruction was gradually withdrawn, as far as practical, and cut off, the pedicle being pushed back into the bladder. Two days later the remaining portion became detached and was expelled. It proved to be the entire mucous membrane of the bladder which had sloughed off. The openings of the ureters were well-marked.

The distressing symptoms gradually subsided, and in a month after her admission to the hospital she was discharged apparently in perfect health. Several weeks after her departure a miscarriage was produced by an accidental fall from a wagon. The patient was seen at intervals after leaving the hospital, and she suffered no inconvenience whatever from her former bladder-trouble. The two most remarkable features of this case were the great distention of the bladder, without rupture, and the subsequent exfoliation of the entire mucous lining, with absolute recovery, the functions of the organ being completely restored.

17 BARONNE STREET.

MEDICAL PROGRESS.

External Urethrotomy followed by Septic Arthritis.—At a recent meeting of the Orleans Parish Medical Society, FENNER reported the case of a man, twenty-one years old, who came under observation suffering from urethral stricture. He passed his urine with straining and in a very small stream. This condition had been noticed for three months, and had grown progressively worse. A filiform bougie was introduced, with the intention of passing a Gouley sound. The whalebone was old and defective, and, slipping from the grasp of the assistant who held it, was doubled upon itself by the sound and broke off in the urethra. External urethrotomy was now performed, the whalebone extracted, and the whole canal was dilated with steel sounds. Considerable traumatism was inflicted upon the penile portion in this operation. The patient was put to bed, and in the evening his temperature was 101°. For nine days the temperature ranged between 99° and 100°, when it rose to 103°. From this time it remained for eleven days very high, but irregular, owing to the use of antipyretics. On one day the thermometer registered 105.5°, and on another it was again above 105°. On the nineteenth day the man was transferred to a medical ward, on the suspicion of enteric fever. From the day after the operation he complained of pain in the urethra and perineum, but no sign of a phlegmon could be discovered, and the urine was only slightly tinged with mucus. With the advent of the high fever came intense lumbar pain, with some tympanites and tenderness over the abdomen. The man remained in the medical ward for thirteen days, during which there developed an arthritis at the left wrist and at the right knee and elbow. The temperature now ranged between 99° and 102°, generally being about 100°. The condition was one of general sepsis. Abscesses formed and were opened on the shin below the inflamed knee, and in the axillæ. From the right elbow and knee fluid was removed with the aspirator, and in this was found a considerable amount of pus. The joints were immobilized with plaster casts, and in the case of the knee an ice-bag was kept applied for three days before the plaster was applied. In addition to these serious joint-troubles a profuse watery diarrhea for a time complicated the course of the case. Thereafter the man began steadily to improve.

Obstetrics Among the Negroes.—At the recent Pan-American Medical Congress DE SAUSSURE (*American Journal of Obstetrics*, November, 1893, p. 717) read an interesting paper in the Section of Obstetrics upon "Obstetrics among the Negroes of South Carolina." Considerable difficulty was encountered in obtaining exact information, on account of the indifference of the negro as to time and figures. It was found that menstrual life began at the age of 13.1 years. The negro is

not virtuous, and matures early. The average age for the menopause was 48.8 years, though in instances women have been delivered at the age of 53 years. Amenorrhea, dysmenorrhea, and uterine hemorrhage are extremely rare. The negro is more fruitful than the white, the average number of children to the family being 6.8, although for several years past the negro has been shirking his responsibility and taking means to prevent the increase of his family, so that within a few years it is possible that the number of children will be less than 6. With the negro pregnancy is physiologic, not pathologic. Eclampsia is not unusual, and may find its explanation in poverty and anemia or in the imitation of so-called civilized habits of the whites. The induction of abortion before the fifth month is becoming quite common, and is accomplished not by instruments but by drugs. If the abortion occur not later than the fifth month, neither midwife nor physician is called. Notwithstanding the great frequency of abortion, puerperal fever or septicemia is extremely rare. This may be accounted for by the fact that vaginal examinations are seldom made and instruments almost never employed. Syphilis is extremely common among the negroes of the South, at least 70 per cent. having inherited or acquired the disease. The pelvic diameters are larger than in the whites. Labor is a simple act, the physician rarely being called, nine-tenths of the deliveries being accomplished by midwives. Vaginal examinations are not made, and labor almost always terminates without accident, notwithstanding the unfavorable surroundings of the parturient. Among 15,538 deliveries there have been 57 deaths from puerperal infection, including cases of peritonitis, in spite of the fact that the dirt and filth among the negroes is almost inconceivable.

The Relation between Ametropia and Epilepsy.—At a recent meeting of the Ophthalmologic Society of the United Kingdom, DODD (*British Medical Journal*, No. 1713, p. 947) reported the outcome of comparative observations upon the refractive conditions present in 100 epileptics and 50 healthy persons. The observations included examination of the pupils and fundus oculi; the determination of the vision and refraction before and after mydriasis; and the result of treatment by glasses. The comparison showed that of simple hypermetropia there were 28 per cent. less in the epileptic than in the apparently normal class; of astigmatism there were 26 per cent. more in the epileptic division than in the normal one, the amount being made up mainly of compound hypermetropic astigmatism. Of the 100 consecutive cases of epilepsy, 75 were directed to wear glasses. Of this number 23 did not wear them or failed to return. Of the remaining 52, 13 after wearing the glasses for periods varying from one to two months had no attacks; 3 remained in *statu quo;* in 36 the condition had improved after wearing the glasses, the improvement in the majority being marked. In all cases the ordinary treatment had been continued. The inferences drawn are that, given a certain condition of instability of the nervous system, errors of refraction may excite epileptic attacks, and that the correction of errors of refraction, in combination with other treatment, will in many cases cure or relieve the epileptic condition; although in some cases the epilepsy will continue after the refractive error has been corrected, generally in a modified form in consequence of other irritation, even though the refractive error may have been the exciting cause of the epilepsy.

Twenty Cases of Hydatid Disease.—PUKY (*Ungar. Arch. f. Med.*, 1893, i, H. 5, 6; *Centralbl. f. die med. Wissensch.*, 1893, No. 42, p. 695) has reported the results of a study of twenty cases of hydatid disease in which he has operated. These were distributed among eleven males and nine females. Of the former the youngest was eighteen years old, the oldest forty seven; of the latter the youngest was likewise eighteen, the oldest sixty-six. Only four of the whole number terminated fatally. Of these one was a patient in whom the diagnosis was not clear and antisepsis was defective, death resulting from pyemia. In two cases death resulted from pyo-pneumothorax. In the fourth the disease was seated in the liver, in the abdominal cavity, in the kidneys, in the spleen, and in the lungs, and death resulted from repeated hemoptysis. In the remainder recovery ensued without complication. In all of these the possibility was demonstrated of closing the peritoneal cavity so thoroughly (by means of a suture recommended by Max Müller) that not a drop of the cyst-fluid entered. In none of these cases did peritonitis develop, and tenderness was not observed in or adjacent to the wound. The fluid evacuated from the cysts was in some cases perfectly clear, and in some contained a number of larger or smaller vesicles. In other cases the cyst was removed entire. As a rule the patients were able to leave their beds ten or twelve days after operation. At the end of this time the dressing was changed but once a day.

Cyanosis from a Patulous Foramen Ovale in an Adult.—PIC (*Prov. Méd.*, June 17, 1893; *Centralbl. f. klin. Med.*, 1893, No. 43, p. 923) reports the case of a man, forty-two years old, in which, following an attack of pneumonia, intense cyanosis developed, which disappeared in a short time, to reappear at irregular intervals, usually after exposure to cold. The patient came under observation in such an attack of cyanosis. The lower extremities were edematous, and blowing systolic murmurs could be heard over all of the valvular orifices, the point of maximum intensity being at the ensiform cartilage. The patient grew rapidly worse, and succumbed to an intercurrent attack of pneumonia. Upon post-mortem examination, in addition to the pulmonary condition, the left ventricle was found hypertrophied, the right ventricle and the right auricle dilated and hypertrpohied, the tricuspid valve incompetent, and the duct of Botal patulous, readily permitting the passage of the little finger. It is pointed out that perviousness of the foramen ovale may be either absolutely latent or attended with congenital cyanosis, or with cyanosis late in life. Under the conditions last named, it is probable that the duct had not perfectly closed, and that undue pressure within the right auricle has led to the entrance of venous blood into the left auricle.

The Etiology of Scorbutus.—BABES (*Deutsche medicinische Wochenschrift*, 1893, No. 43, p. 1035) has succeeded in isolating from the gums in two patients with

scorbutus, a slightly curved bacillus, 3 μ long, 0.3 μ thick, and pointed at the extremities. In two rabbits inoculated with proper precautions with an emulsion of a bit of the affected tissue, hemorrhagic extravasations took place in various parts of the body. The organisms could not be found in the blood or in the other fluids of the body. They were usually found in association with streptococci, and it was only by first treating the culture-medium with streptococci and then sterilizing it that the bacilli could be isolated. Inoculation of animals with pure cultures of the organisms in large quantities gave rise to abscess-formation and subcutaneous and subserous hemorrhage, and was followed by death, although dissemination of the bacilli could not be demonstrated. The opinion is expressed that the organism found is one of those ordinarily present in the mouth, and that in states of depression and privation it finds the conditions favorable for its vegetation. Its detrimental action is thought to be due to the generation of an agent that exerts a poisonous influence upon the bloodvessels and the blood-corpuscles.

Sudden Death from Pulmonary Hemorrhage in a Young Child.—HOWARD (*Archives of Pediatrics*, vol. x, No. 11, p. 940) has reported the case of a girl, two years and ten months old, with a good family history, who had been "delicate," but had escaped the usual diseases of childhood. Three days before death examination disclosed the existence of condensation over the central portion of the left lung. There was some cough, fever, and dyspnea, but no expectoration, and the child seemed comfortable and continued to play in the open air. Death suddenly took place at night from pulmonary hemorrhage. Post-mortem examination disclosed the existence of primary caseous tuberculosis of the bronchial glands, with calcification, and secondary chronic tuberculous pneumonia in the left lung, with cavity-formation. The hemorrhage had taken place from the rupture of a large vessel in the cavity in the lung. The bronchi and air-vesicles of the right lung were filled with aspirated blood. The mesenteric glands were enlarged, and on section several proved to be the seat of miliary and caseous tuberculosis. The spleen presented a condition of acute miliary tuberculosis.

A Case of Poisoning with Kerosene Oil.—MORTON (*Indian Medical Record*, vol. v, No. 7, p. 222) has reported the case of an old man, under observation for insanity, who in a fit of temporary mania swallowed "half a bottle" of kerosene, and immediately afterward took two ounces of ammonium carbonate. When seen, two hours after the accident, the patient was in collapse. His lips were blue and his face generally cyanosed. The pupils were dilated, and there was complaint of great difficulty in swallowing. A good deal of blood had been vomited and coughed up. Bismuth and soda were administered and warmth was applied to the body. For some days the dysphagia continued, with a sense of rawness of the throat. The food, given in teaspoonful quantities, was occasionally vomited. At no time was there diarrhea. For a week after the accident the urine was passed in small quantities. A month elapsed before recovery was complete. Lozenges of cocain afforded relief from the dysphagia.

THERAPEUTIC NOTES.

A Case of Peritonitis Cured by an Injection of Camphorated Naphthol.—At a recent meeting of the Société Médicale des Hôpitaux, RENDU (*Le Mercredi Médical*, 1893, No. 44, p. 531) presented a woman who was greatly emaciated when she came under observation, with the abdomen greatly distended and accumulations of fluid in both pleural cavities, and the physical signs of pulmonary tuberculosis. The affection had set in with digestive derangement, and was attended with alternate diarrhea and constipation. After eight or ten days of observation some seven quarts of fluid were removed from the peritoneal cavity, and between two drams and two drams and a half of camphorated naphthol were injected and permitted to remain. Slight febrile reaction followed, but this soon subsided. The effusion did not recur, but a hard mass formed which gradually disappeared. The pleural effusions also disappeared, the patient increased in weight, and perfect recovery ultimately ensued.

Caffein Sodio-Sulfate.—With a view of neutralizing the contraction of the bloodvessels that follows the administration of caffein, and thus to augment the diuretic action, HEINZ and LIEBRECHT (*Berliner klinische Wochenschrift*, No. 43, p. 1059) have succeeded in preparing a double salt, the sodio-sulfate, which, in doses of fifteen grains four times a day, they have found to induce diuresis without any ulterior influence upon the circulation, appetite, or digestion. The drug has rather a bitter taste, and is best given in capsules. Lithium and strontium salts have been prepared, in addition to the sodium combination.

For the Relief of Sterility.—BUMM (*Deutsche medicin. Wochenschrift*, 1893, No. 41, p. 1003) has reported a case of sterility in which he afforded relief by massage of the entire uterus, particularly of the cornua, and of the mucous membrane of the cervix, by means of the sound. He recommends the method in cases in which no profound pathologic change exists.

For Whooping-cough BERGEON recommends rectal injections of carbon dioxid, in volumes of a quart or two quarts, given not earlier than three hours after the taking of food, and repeated at intervals of not less than four hours, in accordance with the intensity of the paroxysms. —*Münch. med. Wochenschr.*, No. 44.

WHAT IS LIFE?

FOR a long time the materialists have been having matters much their own way. With fine impertinence they have affected to consider "science" as pertaining only to things physical, and all the phenomena of living things as readily explained by purely physical forces. There have been such flooding breakers of new knowledge pertaining to the material world that the noses and mouths of all but the best swimmers have been filled with over-much undrinkable sea-water. Now, however, we are beginning to wade on the solid earth of systematized knowledge, and are coughing out the bitterness of our emphatic protest.

It has been the fashion of physiologists—they who deal especially with life—to deny its existence! to jeer at the idea that the heart is anything more than a pump, that all secretion and excretion are osmosis (and osmosis is nothing but the action of capillary and physical forces), that all living functions are purely chemic, and that life itself is explainable in terms of mechanics. Nothing was so vehemently laughed at and even spit upon as the atrocious idea of a vital force.

Back of this dramatic contempt lay the logical creed of atheism and bald materialism. In popular "scientific" writings and periodicals and in the multitudinous plebifications of science—with a capital S—it became common to hear much of the "reign of adamantine and unalterable law," deftly varied with sneers at the mistakes of "Nature," the number of atrophied or useless organs of the body, the stupidity of the God of the special creationists and of the believers who could outfit upright-standing man with such a ridiculous mechanism or lack of mechanism as that of the venous valves—*et cetera, ad nauseam et ad infinitum!* The denial of the metaphysical had to be supplemented by the proof of dunderheadedness on the part of the supposititious metaphysical. The inference was clear that no intelligence whatever is far better than the stupid one that could leave "as many as six useless tubes in the abdominal cavity."

In a late number of the *Fortnightly Review* we find an article by an English professor of chemistry that has been extensively copied, and that well illustrates the same noteworthy puerility of logic and prejudice. The article is a good *résumé* of the progress made by chemists in reproducing synthetically quite a large number of "organic" compounds. In order to illustrate the gloating pleasure with which a few simple and insignificant facts are illogically wrenched and forced into the service and rôle of materialism, we quote a characteristic passage from Professor THORPE's article:

> "That particular day in 1828, when Wöhler first observed the transformation of ammonium cyanate into urea should be accounted a red-letter day in the history of science. This discovery virtually gave the death-blow to the notion that the operations which are concerned in the formation of the chemical products of the organic world are fundamentally different from those which take place in the inorganic world. Urea, as a final product of a series of tissue-changes, is preëminently a typical product of animal life: no more characteristic example of a substance formed by the action of the so-called *vital force* could possibly be adduced. By demonstrating that urea can be made synthetically by ordinary laboratory processes and from substances inorganic in their origin, Wöhler proved that vital force is only another name for chemical action; and that an animal is nothing but a laboratory in which a multitude of chemical changes, similar to those which occur in our test-tubes and controlled by essentially the same conditions, is continually taking place."

This remarkable "scientist" and more remarkable "logician" seems not to suspect that his facts knock his theory into infinite and utter smithereens. He would hardly deny that the glorious synthetic chemist, in making these few poor end-products of vital katabolism, was possessed of and did verily exercise marvellous intelligence in his work. The

article, indeed, sings the praises of the almost divine ingenuity required to make, *e. g.*—urea! To "chemical action" alone is ascribed the synthetic product, and the chemist's action is left out of the count. But it would seem that the chemist's intelligence had something to do with the affair! Well, then! Is not the logical conclusion from this more plain than the biggest nose on the smallest face that to make the amazingly complex anabolic products of living tissues requires a wee bit of intelligence also? The argument is designed to degrade all vital processes to the level of mechanic forces, but to an ordinary unscientific observer it seems to demand of the creator of living tissues of astounding and unimagined complexity a proportioned intelligence of awful and unfathomable degree. If some one of Professor THORPE's brother-chemists should succeed in making protoplasm synthetically, how justly profound would be Professor THORPE's admiration of him! If he should succeed in making artificially a ganglionic center, or a whole nervous system, or a self-motile, living organism even of a low order, how limitless would be the veneration of all of us! But, if we remember rightly, there is a chemist who makes protoplasm easily, and who fills the earth with a million varieties of palpitant beautiful organisms. The old name for this wonderful chemist was GOD; the name given Him by the scientists is Nature—sometimes with a capital N, sometimes without. Caught in the crux of the illogical absurdity we have suggested, the scientist has found himself in an unenviable predicament. If, according to Huxleian logic, thought and consciousness are the products solely of molecular changes in the brain, then right and wrong and freedom and religion disappear in the exceptionless laws of the conservation of energy and of rigid necessity.

It is gratifying to note that medical science is quite the first to break through this truly unscientific dogmatism, and to recognize that science pertains to psychologic and metaphysic facts, as well as to material facts, and moreover to acknowledge the logical inductions from physiologic facts, even though they are wholly intolerable and unexplainable. Thus, in EWALD'S *Diseases of the Stomach*, the learned author says:

"Unfortunately we are now nearly everywhere compelled to assume a specific yet absolutely unknown activity of the living cell.

"It is positively demonstrated that the mechanical processes of filtration and diffusion do not suffice to explain secretion, and we must accept the existence of a peculiar activity of the cells.

"Sections of the heart [after all its nerves have been divided] that contain no ganglion-cells continue to beat rhythmically.

"Muscles may both make spontaneous movements, and may also lengthen upon 'stimulation.'

. . . "the unpleasant fact that we know very little about the secretion, absorption, and motility of the stomach. The study of the organ has been undertaken with too many physical propositions, whereas here, as in the digestive tract, biological laws are more important."

In HALLIBURTON'S *Handbook of Chemical Physiology and Pathology* we read:

"The chemical operations performed by the living cell cannot be imitated in the laboratory or explained by any known chemical laws."

At the recent largely attended meeting of the Section on Biology of the British Medical Association Dr. J. S. HALDANE reviewed the progress of physiology during the last fifty years, and showed that the physical and chemic theories as to the nature of life had utterly failed as working hypotheses, and that the vitalistic theory must henceforth be made the scientific working hypothesis.

The same admission is, very grudgingly indeed, but still completely, made by Prof. BURDON SANDERSON in his address before the British Medical Association:

"Mind must be regarded as one of the 'specific energies' of the organism, and should on that ground be included in the subject-matter of physiology.

"If on the one hand protoplasm is the basis of life, on the other, life is the basis of protoplasm."

Then comes the splendid summary of the whole matter by that consummate investigator and master, LIONEL BEALE, Professor of the Principles and Practice of Medicine at King's College, London. We would like to quote the entire address recently delivered at the opening of the course on medicine, but are compelled to restrict ourselves to only a few paragraphs:

"More careful study of the chemical and physical molecular changes and of the circumstances under which they occur will, I think, convince the mind that something far transcending any physical changes and of a different order or nature is requisite before any adequate explanation concerning the simplest life phenomena will be afforded. The more we know about the non-living, the wider and deeper becomes the gulf by which it is and has been separated from the living. In all these physical and chemical hypotheses of life, where is the evidence of progress?

"It seems to me that the evidence in favor of the absolute separation between the living and the non-living

state is conclusive beyond question, whilst every attempt to prove the contrary—that the living and non-living are one, or that the non-living gradually passes into the living state—has signally failed. The nature of life has not been and cannot be demonstrated, but that life-power belongs to a category far removed from that in which every form of energy, of chemical action and of atomic machinery would be placed seems to me to be abundantly proved by scientific observation and experiment.

"The hiatus has not been bridged and cannot be bridged even in thought at this time. The difference remains absolute, not gradational. Most of the arguments of the scientific kind against belief in God may be traced to the primary belief in the assumption that the living and non-living are one, backed by ingenious speculations invented for the purpose of convincing people that the facts of life, as well as those of nature, living and non-living, have been explained by physics and chemistry. It has been argued that, since in matter there are inherent forces and powers adequate to account for all forms of life, the idea of a superintending, governing power is no longer needed to explain the facts familiar to us in living nature. But, so far from any such life-properties or powers having been proved to exist in any non-living matter whatever, the direct contrary remains true, at least up to this very day, and the advocates of the unity of life and non-life have been driven to take refuge in the further assertion that the tendency of thought of the time is in the direction they indicate. But tendencies are not scientific.

"Tendencies of thought, scientific prophecies, and the charming fairy tales of scientific story-tellers are for the delight of scientific childhood and may still be harmlessly enjoyed during the evolutionary period of machine development; but if we allow ourselves to be influenced by facts and reasons we must conclude that life is not a property of matter, that the living world and the non-living world are distinct, and that the former was not a natural outcome of the latter; that if all living things were destroyed the matter of their bodies and the matter of the non-living world would remain indestructible, but would also remain incapable of giving rise to new life; and that up to this day it has not been shown that fundamental religious beliefs have been shaken, destroyed or rendered untenable by the wonderful truths which have been established by the unprecedented progress of scientific discovery in every department of natural knowledge during our time."

PROFESSIONAL ATHLETICS AND EDUCATION.

SINCE our last issue another death from foot-ball has occurred, the young man having been injured October 11th. This makes five deaths in this country this season, still another being probable, the patient lying paralyzed, "with a chance of recovery." At the last Yale-Harvard "battle," "Big ACTON, of Harvard, to settle a dispute on the ground, caught BEARD on the jaw with a right-hander and brought him to earth beautifully." There was a storm of hisses, "but the occurrence was forgotten. Captain HINKEY, instead of thinking of fisticuffs, spent his time wrangling with the referee. His face was adorned with a few souvenirs of the Yale-U. P. game, when OSGOOD probably gave him enough fighting to last him for the balance of his foot-ball career." "THORNE'S nose was broken, and blood gushed from his nose and mouth, dyeing the front of his jacket a bright crimson." These selections are made from the report of the game as published by one of the best and most accurate New York newspapers.

During the past two weeks a wave of indignation and disgust has swept over the country at the travesty of athleticism and mockery of education revealed by the foot-ball disgrace. Almost all the great journals, lay and medical, have pronounced against it in the most unequivocal manner. From one point of view it is a disheartening fact that the reform of this abuse has sprung or is to spring from the healthy and sane good sense of physicians and of the people rather than from those whose duty it is to obviate and whose pride it should have been to control in advance such an abuse. From another standpoint it is gratifying to know that the people are better guides than their *ex officio* leaders. The pride of the country in its educational institutions, in their professors and governing boards has suffered at least a very severe strain, a positive loss of respect that only the most prompt, determined, and energetic action on their part can bring back again. *Puck* teaching educators their duty to education is a significant fact, and one not soon to be forgotten. It was a question, and a difficult one of solution, that of securing a block pavement about St. Paul's Cathedral. "You have only to put your heads together," said the witty Dean, "and the thing is done."

Nor can these gentlemen plead thoughtlessness. We could fill a whole issue of THE NEWS with accounts of the attempts that have been made to reform and the warnings that have been given, many of them by physicians and medical journals. We have received a large number of private letters from physicians bearing evidence of this. Among them we note one from DR. ROCHESTER, of Buffalo, who writes that it was the saying of Professor CHARLES ELIOT NORTON, of Harvard College, that base-ball is a game that would have delighted the Greeks, but that foot-ball is only fit for barbarians. Three years ago, also, DR. BURT G. WILDER gathered enough testimony to convince any cautious man of the baleful tendency. He attempted to get

subscriptions to pay off the debt of the Cornell Athletic Association on condition that what even then he termed "semi-professional college athletics" should be forbidden by the university.

Among the more recent and convincing warnings to which we would call attention is the result of the inquiry made by MR. WILLIAM ODELL, of Torquay, England, who recently addressed the question to the headquarters of some of the large public schools as to whether the boys who excel in athletics are as a rule also excellent in school-work, examinations, and the like. A similar inquiry made by a MR. CATHCART ten years ago elicited answers that were full of enthusiasm and unstinted praise of athletics. The replies to MR. ODELL'S questions are more reserved and critical. One correspondent answered that as a general and rarely broken rule, excellence in athletics and in intellectual work are not met with at the same time in the same person; another, that "the spirit of athleticism needs controlling." DR. HORNBY, of Eton, notes that "some years ago it was quite possible for a boy who had an aptitude for cricket or rowing to attain to the highest excellence, according to the standard of that day, in athletics and school-work. I doubt whether it is so now. Athletics of all kinds have become so developed and brought into a system, and, I may almost say, professional, that the time required for a very high excellence in them is, I think, a serious obstacle to a reading man or a studious boy's engaging in them with a view to athletic distinction. This is a serious evil in our day." And DR. PERCIVAL, of Rugby, says that "the great publicity given to athletics tends to give them an undue prominence in the minds of both boys and men."

THE COCHRAN CASE.

WE publish elsewhere the report of the two physicians appointed by the Government to examine into the mental condition of HENRY S. COCHRAN, who robbed the Philadelphia Mint. This report was made to the United States District Attorney, and seems to have been effectual in bringing the trial of the case to a speedy termination. COCHRAN'S lawyer made no defence of insanity, the prisoner's crime was quickly proved, and a verdict of guilty was promptly rendered by the jury, without leaving the box. It is hoped that the report will be equally effectual in silencing the unfounded assertions that have made their way into the medical as well as the lay press, that the criminal is insane. As no medico-legal contest was developed in the trial it is needless to say that we cannot present a medico-legal report, as we stated in our last issue that it was our intention to do. We desire, however, in view of the medico-legal interest excited in the case, to take some notice of its main features.

COCHRAN is sixty-seven years of age and had been an employé in the Mint for forty-three years. His duties during most or all of that time were those of a weigher, a position in which it is absolutely necessary to rely to some extent upon human honesty. He had charge of the vault in which was stored many millions of dollars' worth of gold bullion in bars. This vault, however, was sealed and had been so for some years. The old weigher took his first bar several years ago; he was enabled to secure it without disturbing the seals, because of some defective construction of the vault. There is reason to believe that he was in some financial difficulty at the time and needed money. He was, moreover, dissatisfied with the amount of his salary, which, considering his responsibility, was small. In order to realize on the bars without being detected he melted them down in a crucible in a third-story room of his residence in Darby, and sent the crude metal thus obtained back to the Mint by express, and thus received the profits of its sale. This, in brief, is the story of his systematic and long-continued stealing.

The detection of COCHRAN'S crime followed as a matter of course when the vault was opened for the purpose of coining the gold. It required no feat of expert detective work; neither was it the result of weak-mindedness in the weigher. When orders to open the vault were sent from Washington during the recent financial stringency, COCHRAN immediately began to betray uneasiness. He expostulated, and plead especially that the vault was the best storage place in the Mint, and that it would be a pity to empty it. He even visited Washington and attempted to influence the Director of the Mint, cunningly saying, however, that his visit to the capital was to look after his political safety, which he feared was jeopardized by the change of administrations. There was no evidence of dementia, but merely of a guilty conscience, in this visit. When at last detection appeared certain he secreted a further number of gold bars in a space above the vault. His object in doing this is not clear, but it is supposed that it had reference to some belief or

desperate hope of the criminal that it would divert suspicion from himself, or at least help to implicate others, and thus enable him to make terms.

In his house at Darby COCHRAN had several ingeniously constructed secret drawers and safes. One of these was made many years ago by the village carpenter for the perfectly legitimate use of storing some family silver. Another was a rudely-constructed, but inaccessible, hiding-place for a small iron safe. After his confession he revealed these places, which contained most of what was left of his pelf. A so-called secret passage-way under ground, leading from the house to the street, which was sensationally described by the newspapers, was simply a vaulted drain. It had no significance or criminal use whatever.

COCHRAN'S house, in which he lived alone, was an old-fashioned, rather large dwelling, with nothing remarkable in it but the accumulation of a lot of nearly useless and almost valueless rubbish. The only significant things in the house were a crucible and melter's tools, taken from the Mint, and a stove and some other appurtenances such as counterfeiters use. These were in a third-story room, in which was a carpenter's bench, tools, etc. These accumulations, about which much was said in the newspapers, consisted of old hats, shoes, umbrellas, and neckties in superabundance; a box of razors—one for every day in the month; and a collection of cheap books, such as are written for boys. Conspicuous among the latter were bibles and hymnals. In the work-room was a pile of iron match-safes after a pattern invented by the weigher; also a large pair of discarded scales, which he had purchased from the Mint.

Personally COCHRAN was a man of very regular habits. He never drank alcoholic liquors, used no tobacco, and contrary to what was hinted in the newspapers, lived a perfectly moral life as far as is known. He was a church-member, a generous giver, popular with children, and generally liked by his acquaintances. His health had always been good, and before his crime he had never been suspected of any mental aberration. Physically he is large and healthy, with no more marks of senility than can be found in the majority of men of his age.

As is shown by the official report of the examining physicians, COCHRAN presents none of the mental or physical signs either of paresis or of senile dementia. His memory is good, his mental reflexes active and sure, his thoughts coherent, and he has neither delusion nor hallucination. He is thoroughly aware of the moral quality of the act and of its consequences. He has none of the signs, such as defects of articulation, tremor of the facial muscles, involvement of internal or external ocular muscles, or of the optic nerve, which it was confidently predicted by some that he would be shown to have.

Upon this very plain and simple, but most deplorable, case of temptation, weakness, and crime, a theory of insanity of the most elaborate structure has been built in some quarters, with the aid of newspaper reporters and voluble physicians. We noticed this aspect sufficiently in our last issue, and publish this rather brief summary of the case merely to show that it is one of common stealing, without any medico-legal bearings of interest or importance.

EDITORIAL COMMENTS.

A Remarkable Remedy for Remarkable Diseases.—We cannot forbear allusion in the most lenient and amused spirit to an interesting specimen of *English as she are translated into* that comes to our notice in the shape of a circular descriptive of a French pharmaceutic preparation, "a coal-tar product" of marvellous efficacy for some forms of disease that may be new to our readers. There are four octavo pages of recommendations; we can only cite a few—the syntax and capitalization being those of the circular:

"In the opinion of the Dr. Bouchut, the best topic into the BUFFY ANGINA consists to employ douches into the pharynx. Since ten years I do not use other means at the hospital; the patient child opens his mouth, inclining himself, with a basin under his chin, and the liquid, injected with strength, go out, without never to penetrate by the windpipe." We suppose the "gastric tube" of the French child must be absolutely without twist or turn from beginning to end. Dr. Dupont also recommends the preparation especially "for to be UNDERSKELTER OF THE INFECTION," and Dr. Lorrain is especially pleased with it "for the disinfection of the woman confined in the preventive against the consecutive accidents at the deliveries." Dr. Bazin finds it "an excellent mean of fortifying the scalp." For this purpose he "had prescribed ordinary some lotions with the acid of one little imbibed sponge extended with 3 at 6 parts of tepid water or water at the bran." "Into the ulcerous affections of the gums the emulsion is possessing one special efficacity for CONSOLIDATING THE BARED TEETH, destroying the leavens or animalcula what often unwrap itself in these organs," etc. For "the TOILED OF THE NURSLINGS," for "THE VETERINARY MEDICINE," "INTO THE LEUCORRHEA (wite flowers)," for "CRUSTS AT THE HEAD," etc., the good "Emulsion at the 30th, 40th, and 50th," are alike efficacious, employed "into the eyes, the eyelids, the buccal and vulvary gangrene, the fluent hemorrhoids," etc. This caution is wisely added: "The seat and the nature of the lesions as so as the most or less great captiousness of the organs de-

mand in many circumstances the coaltar be added with unmingled water." "The EMULSION-MÈRE at the 5th shall be the starting post for the attenuation."

This matter of translating from one's native language into another without the faintest knowledge, and solely by the aid of a dictionary, has proved a source of unfailing amusement to many generations. If one knows French well one can trace every twist of the poor translator's mind. For example, one would be puzzled to understand the notices in our circular that "the Principal Stock Fort the Great Britain, is at etc., and Fort the United States," if one didn't remember that the French word *magasin* (warehouse or storage-depot) may have an English synonym in the dictionaries, *Fort* or *Fortress*.

The Treatment of Enteric Fever.—Apropos of the expression of regret, in the review (THE NEWS, November 18th, p. 586) of Dr. Yeo's *Clinical Therapeutics*, that a discussion of the value of cold baths in the treatment of enteric fever was not fully entered into, Dr. J. M. Deam, of New Carlisle, O., calls our attention to a method of treatment employed by him, and described in the September number of the *Columbus Medical Journal*, p. 105. The mode of procedure followed is to give all patients throughout the entire illness podophyllin in doses of quarter of a grain as frequently as may be necessary to change the color of the stools—first to green and afterward to the normal color observed in health. In addition the official solution of potassium arsenite is administered hourly in doses of half a drop. Further, hot alkaline sponge-baths are given twice a day, or oftener, the number being regulated by the effect upon the temperature and the nervous system. If colicky pains be present morphin is administered. "The diet is practically unrestricted, with the exception that milk is absolutely forbidden. The patient is never asked to take nourishment in any form, nor ever refused when he asks for it." About twenty-five cases have been submitted to the treatment outlined. The appetite was found to return in from six to eight days; the fever to be gone in from eight to ten days, and the patient to be up and about in from ten to twelve days. In his letter Dr. Deam expresses a readiness "at any time to demonstrate the truth of" his "theory in any hospital under the supervision of competent diagnosticians, so that no cavil may arise regarding the nature of the disease, as also its course and duration under" his "treatment." However great a degree of skepticism one may feel in a matter of this kind, the privilege is not given to condemn without experience that which another claims to have value.

Coroner Reform.—The propriety, if not the necessity, of the coroner being a man with a medical training, as well as with a judicial mind, received a rather ludicrous demonstration the other day in the city of Philadelphia. In a case in which the cause of death was uncertain, the attending physician had declined to issue a certificate; but the coroner's jury, no doubt upon and with the authority of the learned coroner, brought in a verdict of death from heart-disease complicated with senility, although the attending physician had stated in reply to an inquiry that during life no disease of the heart was recognizable. In the same city and in the office of the same coroner post-mortem examinations have been made, and the reports based upon an inquiry into the history of the case, perhaps also upon the opinion of the attending physician and upon a superficial view of the body, incision and further investigation not being deemed necessary by an official who knows practically little or nothing of anatomy and pathology, but who seems able and capable of assuming arbitrarily a good deal of authority. The remedy for a system so defective lies in making the office of coroner a non-partisan one, and filling it with a medical man.

The Richardson Memorial of the Medical Department of Tulane University, at New Orleans, is a gratifying evidence of medical progress. It was dedicated November 4th with appropriate services. It is a commodious and imposing structure of four stories, containing in all seventy-two rooms, located on Canal Street, between Villere and Robertson Streets. The main lecture hall is fifty-five feet square and twenty-eight feet high, seating four hundred students in opera chairs. The building is the gift of Mrs. Ida A. Slocomb, in memory of her husband, Dr. T. G. Richardson, who devoted thirty-one years of his life as professor in the medical faculty of the school. The planning and erection of the building has been under the supervision of Professor Souchon. Judging from the reports the building is the outcome of the most diligent thought and study as to the construction of medical college buildings. May the school labor to send forth her graduates with an educational outfitting worthy of the unselfishness of the donor and of the excellent mechanism she has provided.

Medical Illustrations and Obscene Literature.—We are not at all certain that there have not been in the past such errors in illustrating medical literature, or in advertising medical appliances and devices, such as posture-tables, that the mistakes have not been far more and worse than mere faults of taste. But, of course, we can have nothing but condemnation for any interpretation of the law, or for any legal proceedings, that would forbid or prevent the free passage through the mails of whatever may be justly called medical literature. We learn that an instance designed as "a test-case" has been submitted to Commissioner Fairchild for his decision. A special example might possibly be forbidden the service of the United States mails, but it is doubtful if any general rule could be made that would not be opposed to medical progress and unjust to the profession.

Vegetarianism and Physical Endurance.—In a recent pedestrian contest between Berlin and Vienna two vegetarians came out far ahead of their carnivorous competitors. This is an old lesson newly taught, but the modern man thinks he must have large quantities of animal flesh three times a day "to sustain his strength." It would seem that in this respect civilization is reverting to the habits and characteristics of the carnivora instead of progressing out of it. We suppose the scientists would say that if it were not for cooking we would have to re-develop our canine teeth, so called, into the olden *de facto* type.

"*The Misuse of Drugs in Modern Practice*" is the title of an instructive paper by Dr. John T. G. Nichols, of Cam-

bridge, Mass. (the annual discourse delivered in Boston before the Massachusetts Medical Society, June 14, 1893), which should be read, pondered over, and inwardly digested by the general physician.

CORRESPONDENCE.

THE TESTIMONY OF PHYSICIANS IN COURTS.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of July 29, 1893, you editorially speak of a new law recently passed in New York, which you regard as remarkably liberal toward that part of the medical profession which reaps benefit by its provisions. Your editorial is headed, "A New Procedure in Medical Testimony," on page 132 of THE NEWS.

I was struck with the evident surprise your language indicated at such unexpected liberality toward physicians by law-makers, even in the great and progressive State of New York.

I wish to say that Tennessee has for years had a statute of similar, but more universally applicable character, which shows to the profession eminent fairness in the matter of medical testimony other than in criminal cases. In this State a physician cannot be *compelled* to attend court *in person* except in criminal cases—though most of the doctors do not know this, and go when summoned. But the *law* permits—and I have taken its privilege for years—that a doctor may indorse upon a subpena that "he is a practising physician, and claims exemption from attendance at court in this case, and that his deposition shall be taken regularly out of court." This exempts his attendance, and puts the *attorneys* to the inconvenience *instead of the physicians*, placing upon plaintiffs the burden of getting up their evidence before the case is called, or hazarding the absence of the medical testimony, and a postponement of the case—as has frequently happened by reason of my own insistence of my rights under the law.

Now the workings of this law favor materially the physician, especially in small country towns where the necessities of general practice exact prompt and proper attendance to their patients by absence of competition, and by exempting them from *court* attendance (with its often exasperating delay and time-consuming by the dragging along of court proceedings) have proved practical and just. Prior to my own locating in this city I was a witness in every court (thrice each year) that convened in my town for a number of years. Many of the cases were frivolous damage-claims, without hope of remuneration for the witnesses whatever. And when, at length, I ascertained my professional exemption, I found solace by fortifying myself behind its provisions against the arbitrary demands of civil suits, which possessed neither interest nor profit for me in any event, but furnished great annoyance and tax upon time, income, and patience.

I find that a few attorneys "raise Cain" because I invariably insist upon my rights under this law, and point me to numerous doctors who attend readily on summons, most of them through ignorance of their exemption, others by reason of choice to air their attainments in public for the indirect advertising thereby secured. And I even find the legal brethren largely unaware themselves that physicians enjoy any exemptions in this State, except from jury duty and road-working, all of which are ours here.

Another comfort we (or at least I) reap from this statute is the opportunity for calm statement of facts in cases within our knowledge, generally at our own offices and convenience, writing the same leisurely ourselves in reply to written interrogatories. I am not, thus, subjected to annoying public cross-examination with a view of entangling me in my evidence through legal cunning, nor is the witness tortured by legal posing "for the galleries," before the jury, at his expense. It renders medical evidence dignified, and secures for it reasonable importance and respect before the court. It likewise relieves the too frequent appearance of a witness "rushing" forward—as grows common of late—to make a strong case for *his own patient* in these fashionable suits for personal damages, thus placing the profession in an attitude of fomenting and favoring the growing litigation along this line. Of course, this naturally breeds a leaning by doctors toward impulsively pressing or defending personal interests of others simply because of their patronage—in my own opinion a pernicious influence, because the doctor should only take interest in these matters through the plain equities of the various cases involved wherein he happens to (professionally) become a casual witness; and often his evidence must, if fair and unbiased, be diametrically antagonistic to the interests of his own patron. Such has at least been my own experience more than once; yet the simple fact that I had attended the plaintiff was taken as undoubted ground that my testimony would strengthen his case, even without so much as interrogating me in advance of filing the suit. Professional antagonisms and animosities spring from a like status.

When the witness calmly insists that he can *only* be used as a witness by deposition out of court, it shows on its face that *he is not inclined* to foment trivial damage-litigation, and whichever way his evidence goes, and when formally taken, it carries greater weight, and bears the appearance of unprejudiced testimony. And I find that the trouble it entails saves me from being utilized at all in trivial cases, or those greater ones in which my evidence is not of essential importance, the attorneys preferring to establish the facts sought by other witnesses, or even to forego such claims as my evidence might otherwise project into the case. Thus I am afforded freedom to a large degree from this tax on my time, and thereby enjoy enlarged opportunities for *personal* affairs as against arbitrary service hitherto at behest of irresponsible litigants often.

Of course, in criminal cases no exemption is allowed, nor ought to be, the doctor then standing to the case as an unprejudiced witness, just as I hold he should do in cases of every character—and largely conduced by our privilege here in civil actions, as already set forth, according to *my* idea of effects.

Very truly yours,

A PHYSICIAN OF TENNESSEE.

Kaposi and Neumann, after twenty-seven and thirty-two years of service respectively in the University of Vienna, have been made ordinary professors of dermatology.

NEWS ITEMS.

Report on the Mental Condition of Henry S. Cochran.—(A copy of the original as sent to the District Attorney.)

To ELLERY P. INGHAM, Esq.,
United States Attorney for Eastern District of Penna.

SIR: Agreeably to your request of September 30th last, the undersigned visited Henry S. Cochran in Moyamensing Prison, October 30th ultimo, and November 8th instant, between the hours of 11 A.M. and 12 M., for the purpose of making an examination into his mental condition, and now submit the following report:

The examination was conducted by propounding questions calculated to draw from the defendant a connected history of his life; of his business relations or occupations; of his domestic and social concerns. From the answers that might be elicited, we expected to form an opinion of the defendant's mental coherence; whether the answers were responsive; whether the memory was good or poor; whether the mental reflexes were active; also, whether he might exhibit any delusions, delusive ideas, or disorders of the senses, such as belong to, or are symptoms of, active insanity; or, that failure of the mental powers which sometimes is an accompaniment of the decay of old age.

On the occasion of both interviews we found the defendant willing to reply to questions freely, and did not hear or observe anything that led us to believe or suspect that he prevaricated or attempted to feign insanity.

We also made such physical examinations as possibly might have a bearing upon the question of insanity.

We found that answers to questions made by the defendant were responsive; without any exhibition of incoherence; his memory of events was reasonably exact and connected; his conversation was rational; and we could not infer from his life-history, as thus furnished, that at any time had there been any such departure from his normal or usual mental state as would lead to an opinion that an attack of insanity had occurred. Neither could we discover from our examination, the manner of the defendant, or his dress, the existence of any delusion, or hallucination of the senses.

The defendant stated he had been properly trained in his youth as to his moral duties and obligations; knew the difference between right and wrong; understood the nature of the charge against him, the reason of his present confinement, and that he was awaiting trial.

An examination of the eyes did not disclose any inequalities of the pupils. The pupils responded equally to the influence of light. The face was somewhat shrunken and the facial lines deep; the face had a pale hue; the tongue was pale and flabby, but both tongue and face were free from tremor. From the defendant's statement, and from the loose appearance of the clothing, assuming that it had at one time fitted him properly, there had been a marked loss of weight, amounting probably to fifty pounds. The pulse was normal in frequency, the artery at the wrist furnishing the sensation that characterizes the degeneration of arterial vessels in advanced life. The action of the heart was below the normal force of strength. No defect of the speech or articulation was observed.

An examination of the urine failed to disclose any marked abnormality; there was no appearance of albumin, sugar, or sediment, and the specific gravity was 1028.

The impression left on our minds, while not discovering evidences of organic disease, was that the general health was below the normal standard such as might appear at the age of the defendant, and might be induced partly by changed circumstances and environments.

As conclusions, we are of the opinion,

1. That the defendant, Henry S. Cochran, is not insane; and,

2. That he has a knowledge of right and wrong, of the nature of the charge against him, and the consequences of his acts.

Signed, JOHN B. CHAPIN, M.D.
JAS. HENDRIE LLOYD, M.D.

DATED PHILADELPHIA, PA., THE 14TH DAY OF NOVEMBER, 1893.

The Samuel D. Gross Prize.—The Quinquennial Prize of One Thousand Dollars under the will of the late Samuel D. Gross, M.D., will be awarded January 1, 1895.

The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the successful competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery.

The essays, which must be written by a single author in the English language, should be sent to Dr. J. Ewing Mears, 1429 Walnut St., Philadelphia, before January 1, 1895.

Each essay must be distinguished by a motto, and accompanied by a sealed envelop bearing the same motto, and containing the name and address of the writer. No envelop will be opened except that which accompanies the successful essay.

The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

To Succeed Charcot.—M. Brissaud has been delegated to take charge of the service of the late Professor Charcot at the Salpêtrière for a year, until a permanent successor has been appointed to the Chair of Diseases of the Nervous System. M. Potain has been appointed to fill the vacancy in the Medical Section of the Academy of Sciences.

A New Physiologic Institute at Moscow was recently opened. The building is said to have cost $60,000, and the furnishing $5000. The institute is said to be the best fitted of its kind in Europe.

The International Medical Congress, which was postponed from September 24th, on account of the prevalence of cholera in Italy, will be held at Rome from March 29 to April 5, 1894.

BLOODLESS AMPUTATION AT THE HIP-JOINT.

A Report of Forty Cases by the Author's Method.[1]

BY JOHN A. WYETH, M.D.,

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; ATTENDING SURGEON TO MT. SINAI HOSPITAL; CONSULTING SURGEON TO ST. ELIZABETH HOSPITAL, ETC.

As recently as 1881 Professor John Ashhurst, Jr., one of the highest authorities in modern surgery, wrote:[2] "The removal of the lower limb at the coxo-femoral articulation may be properly regarded as the gravest operation that the surgeon is ever called upon to perform, and it is only within a comparatively recent period that it has been accepted as a justifiable procedure."

This author further voices the accepted opinion of surgeons when he adds: "The most pressing risk in any operation at the hip-joint is that of hemorrhage."

Beginning with aortic compression by digital or mechanical means, as advised by Pancoast, Lister, Abernethy, and others, and later the intra-rectal lever of Davy for compressing the common iliac artery against the pelvis, the first really practical and valuable suggestion for controlling hemorrhage was the figure-of-eight elastic bandage of Jordan Lloyd,[3] which included the posterior aspect of the thigh in its grasp and then passed over the rim of the pelvis, making compression of the external iliac by means of a roller bandage placed beneath the elastic bandage and over this artery. This was in fact a figure-of-eight bandage around the thigh and abdomen.

So far back as 1865,[4] Dr. A. Hewson, an American surgeon, first employed acupressure in an amputation at the hip-joint. There was much loss of blood before the needles were placed and the patient died without reaction. In 1880 (July 28th) Trendelenburg, at the suggestion of Newman,[5] also employed acupressure as a means of controlling hemorrhage in hip-joint amputation:

"A steel needle 38 cm. long, 6 mm. broad, biconvex on cross section, and in the thickest portion or center 2 mm. thick, was inserted just below the anterior iliac spine and carried in the direction of the perineum, passing between the neck of the femur and the vessels, and emerging on the inner aspect of the thigh, near the perineo-femoral crease. A figure-of-eight ligature was then thrown over the ends of the needle and in front of the thigh, thus constricting the femoral artery and vein. The limb having previously been emptied of blood by the application of Esmarch's bandage as high as the middle of the thigh, a long knife was carried through the front of the thigh 2 cm. beyond the needle and parallel with it (Lisfranc), and a flap formed by cutting by transfixion. The vessels were then tied, the needle and figure-of-eight loop removed, and the head of the femur disarticulated. The needle was again introduced behind the bone, the figure-of-eight carried posteriorly, and the posterior flap then formed."

In 1886 (August 10th) Dr. Muscroft, of Cincinnati, employed a similar method:[1]

"A needle one-eighth of an inch wide, slightly bent at the point, about the thickness of a dime and four inches long, was introduced perpendicularly into the front of the thigh about an inch and a half below Poupart's ligament. The exact point of entrance was one-fourth of an inch internal to the combined sheaths of the vein, artery, and nerve. The point was pushed beyond the vessels, then turned outward until the needle had passed beyond them; the point was then pushed out through the integument. The needle was then behind the vessels and nerve. A piece of cord was passed under the heel and point of the needle, forming a figure-of-eight ligature."

Myles,[2] of England, advised a steel skewer to be passed through the thigh, the point entering an inch below Poupart's ligament, going external to the femoral artery and internal to the neck of the femur, emerging a little above the gluteal fold. An India-rubber cord in figure-of-eight fashion was then to be thrown over the ends of the skewer and the inner aspect of the thigh. The amputation was by lateral flaps.

In theory and practice any method of constriction that only controlled a part of the blood-supply at the hip, when, in the formation of flaps, the other portion was exposed to hemorrhage, must prove less satisfactory than one that permits the operation to be completed with absolute compression of every vessel passing the level of the coxo-femoral joint.

In 1888 I removed the outer half of the clavicle, the glenoid, acromion, and coracoid processes, and part of the body of the scapula, together with the upper extremity, of a patient suffering from a large sarcoma of the upper end of the humerus. Not wishing to perform a preliminary deligation of the

subclavian in its third division, I transfixed with a stout mattress-needle the major pectoral muscle about three inches from the shoulder, and, at about the same distance from the joint on the *dorsum scapulæ*, I introduced a second needle in such a way that when I carried a strong rubber tube several times around the shoulder above these needles with strong traction, the compression was so great that hemorrhage was well-controlled during amputation. It occurred to me at the time that the same plan was equally feasible at the hip.

In 1890 I had the good fortune to apply the method successfully, and as, in the light of subsequent experience, I now believe, to establish an operation in which hemorrhage at the hip-joint is as safely and easily controlled as at the middle of the thigh. In 1890 I demonstrated the method at the meeting of the American Medical Association at Nashville, also at the International Congress at Berlin, and at Louisville before the Mississippi Valley Medical Association.

Under strict antisepsis the operative technique is as follows:

1. With the patient in the usual position for a hip-joint amputation, the limb should be emptied of blood either by elevation of the foot and lowering of the trunk, or by the Esmarch bandage applied from the toes to the trunk. Under certain conditions the bandage can be only partially or may be not at all applied. When a tumor exists or when septic infiltration is present, pressure should only be exercised not quite to the diseased portion for fear of driving septic matter into the vessels. After injuries attended with great destruction, crushing, or pulpification, of course the Esmarch bandage is not applicable, and one must trust to elevation to save as much blood as possible.

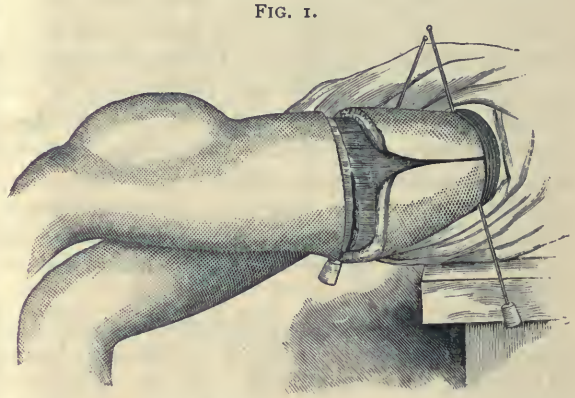
2. While the member is elevated or before the Esmarch bandage is removed, the *rubber-tubing* constriction is applied.

The object of this constriction—and it is the chief point in the method—is *the absolute occlusion of every vessel at the level of the hip-joint safely above the field of operation.*

To prevent any possibility of the tourniquet slipping I employ two large mattress-needles or skewers, about three-sixteenths of an inch in diameter and ten inches long, one of which is introduced one inch below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse superficially the muscles and fascia on the outer side of the hip, emerging on a level with and about three inches from the point of entrance.

The point of the second needle is made to enter one inch below the level of the crotch internally to the saphenous opening, and, passing squarely through the adductors, comes out an inch below the tuber ischii. The points are at once shielded by bits of cork to prevent injury to the hands of the operator. No vessels are endangered by these skewers. A piece of strong, white-rubber tube, half an inch in diameter and long enough when tightened in position to go five or six times around the thigh, is now wound very tightly around and above the fixation-needles and tied. If the Esmarch bandage has been employed, it is now removed. Dr. Lanphear succeeded in holding the constriction in place with only one (the outer) needle. Dr. Deaver was equally successful in holding the tubing well up by two strips of roller bandage, one before and one behind, held by an assistant, and thus dispensing

FIG. 1.



The needles and constrictor applied. Circular and longitudinal incisions for skin-flap.

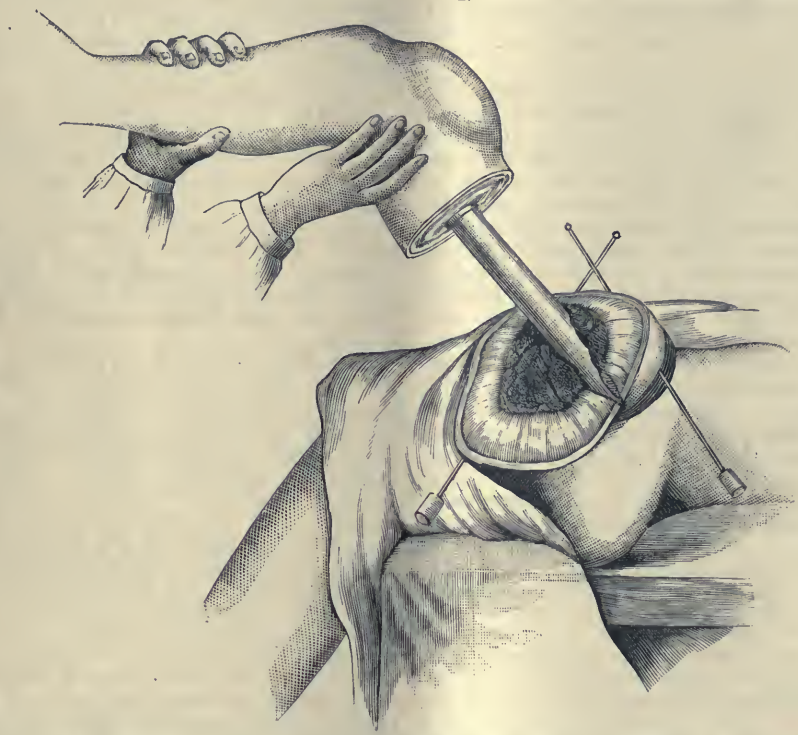
with the needles. Since the needles are, however, absolutely safe, easy to obtain and inexpensive (a piece of telegraph wire, even, will suffice), and entirely out of the way, I do not see any benefit to be derived from their disuse. On the contrary, I should be afraid to operate without them.

3. In the formation of flaps the surgeon must be guided by the condition of the parts within the field of operation. When permissible the following method seems ideal:[1] About six inches below the tourniquet a circular incision is made, and this is joined by a longitudinal incision commencing at the tourniquet and passing over the trochanter major. A cuff that

[1] At Bardstown, Kentucky, in August of 1806, Dr. Walter Brashear amputated at the hip in a negro lad, seventeen years old, on account of a severe fracture of the femur and laceration of the soft parts. A circular incision was made, the muscles divided well below the hip-joint, and the vessels secured as the operation progressed. Then a longitudinal incision along the outer side of the limb exposed the remainder of the bone, which, being freed from its muscular attachments, was disarticulated at the socket. (Prof. D. W. Yandell, in American Practitioner and News, 1890.) Dieffenbach's name has been prominently associated with this operation among surgeons, but Dieffenbach did not take his degree in medicine until 1822, sixteen years after the pioneer Kentuckian had performed his operation, the first hip-joint amputation performed in the United States.

includes the subcutaneous tissues down to the deep fascia is dissected off to near the level of the trochanter minor. At about the level of the trochanter minor the remaining soft parts, together with the vessels, are divided down to the bone by a circular cut, and, in order to facilitate the search for the vessels, the soft parts are rapidly removed from the femur for several inches below the line of the divided muscles. At this stage of the operation the larger vessels, *veins* as well as arteries, should be tied with good-sized catgut.[1] As suggested by Professor Murdoch, of Pittsburg, I now leave the entire extremity intact and use the full length of the limb as a lever in dislodging the head of the bone.

FIG. 2.



Cuff of skin and subcutaneous fat turned back, muscles divided at level of small trochanter, bone partly stripped, and large vessels exposed for deligation.

When the larger and easily-recognized vessels have been secured, the muscular attachments to the upper extremity of the bone are lifted off with scissors or knife, keeping along very close to the bone. Holding the soft parts away with retractors, the capsular ligament is exposed and divided in its circumference. Forcible elevation, abduction and adduction of the thigh permit the entrance of air into the socket, and, at the same time, rupture the ligamentum teres, and the disarticulation is thus easily and rapidly effected.

Properly conducted up to this point, not a drop of blood has escaped, except that which was in the limb below the constrictor when this was applied. If now the tourniquet be carefully and gradually loosened each bleeding-point may be determined and the forceps applied as required, until the tube is entirely removed.

Should any difficulty be encountered in the effort at enucleation (which is scarcely possible), the same precaution in securing all bleeding-points should be exercised in removing the tourniquet, and enucleation completed with the tourniquet out of the way.

4. There remains the closure of the wound, with the usual precaution of drainage. I prefer silkworm-gut for suture-material and one good-sized rubber drain from the acetabulum out at the most dependent part of the wound.

When by reason of the proximity of a neoplasm or the destruction of the parts by accident or disease, this ideal method is not practicable, any modification may be practised, preference being given to the incision that keeps furthest from the tumor or gives the healthiest flaps. When there is not sufficient material for perfect closure it is even safer to err on the side of an unclosed wound and trust to granulations or grafting for ultimate closing of the wound.

Before concluding the consideration of the tech-

[1] I employ catgut in all cases and have never had a secondary hemorrhage.

nique I wish to emphasize a point of great importance. When, by reason of severe hemorrhage before operation, or when from any pathologic anemia or condition of weakness, the operation should be rapidly completed and the small amount of blood that will necessarily be lost from capillary oozing should be saved, suturing of silkworm-gut should be rapidly introduced, the wound packed with hot sterilized plain gauze (not iodoform or bichlorid gauze), and the sutures temporarily tightened for snug compression of the wounded surfaces. This packing at once controls all oozing and can be removed, and in from twenty-four to forty-eight hours after reaction the sutures finally secured.

I have been able to obtain the histories of forty amputations at the hip by the foregoing method, of which the following brief histories are given:

CASE I.—By Dr. John A. Wyeth, of New York City, in 1890. Rev. J. H. S., thirty-nine years old. Twelve years previously he had noticed a small, hard tumor in the popliteal space. This gradually increased until the whole lower half of the femur was involved, forming a large osteo-sarcomatous tumor. On February 4, 1890, the first step was completed by amputation through the femur at the lower trochanter. The second step, February 20th, consisted of enucleation of the neck and head of the bone. Recovery was without interruption. (This is the first case on record.)

CASE II.—By Dr. John A. Wyeth, 1890. From J. G., a male, thirty-four years of age, a neuro-sarcoma of the internal popliteal nerve below the knee was removed by Dr. D. M. Stimson, on October 15, 1888. There was recurrence *in loco*, and amputation followed at the middle and lower third of the thigh by Dr. Wyeth in February, 1889. The growth again recurred in the stump in the winter of 1889–90, and in March, 1890, amputation was performed at the hip. Recovery was without interruption.

CASE III.—By Dr. John A. Wyeth, 1892. Miss J. B., seventeen years of age, had an osteo-sarcoma of the left femur at the knee. It was first noticed October, 1891. Amputation was on February 5, 1892, by Dr. Allen, of Cleveland, Ohio, at about the middle of the femur. The wound never healed, the growth recurring at once. On April 22, 1892, I disarticulated at the hip-joint. Recovery followed.

CASE IV.—By Dr. M. J. Ahearn, of Canada, 1892. The patient was a male, twenty-two years of age, with osteo-sarcoma of the femur. The man had acute nephritis, passing four and a half grams of albumin to every liter of urine. The operation was practically bloodless, and the patient recovered.—*L' Union Méd. de Montreal*, 1892.

CASE V.—By Dr. J. B. Murdoch, of Pittsburg, Pa., 1892. The patient was a male, seventeen years of age, with osteo-sarcoma of the thigh. Death from shock followed twenty-two hours after the operation, which was performed February 20, 1892.

CASE VI.—By Dr. W. W. Keen, of Philadelphia, 1892. The patient was a female, thirty years old, with an enormous osteo-sarcoma of the left femur extending from the knee to within ten inches of the hip. The first symptoms of the trouble dated back seventeen months. Operation was on January, 1892, the patient being five months pregnant. Recovery was uninterrupted.

CASE VII.—By Dr. Frank Hartley, of New York City, 1892. The patient was a female, twenty-six years old. On March 19th a tumor of the tibia, near the ankle-joint, was incised, and proved to be a giant-cell sarcoma. On March 25th amputation at the knee showed the femur to be involved. Amputation at the hip was performed May 14, 1892. There was no hemorrhage and no shock. Primary union followed, and the patient was discharged cured June 22, 1892.

CASE VIII.—By Dr. Charles McBurney, of New York City, 1890. A male, thirty-four years old, had sarcoma of the lower and middle thirds of the right femur, infiltrating the muscles. Amputation at the hip was performed May 3, 1890. The limb was elevated to empty it of blood, and Esmarch's bandage was not employed. "The hemorrhage was extremely light, and estimated as being perhaps an ounce of blood in all, and the operation in consequence was finished with great rapidity." Rapid and uninterrupted recovery followed.

CASE IX.—By Dr. J. McFadden Gaston, of Atlanta, Ga., November, 1890. A man, the age not given, had an enormous osteo-sarcoma of the left femur. The tumor weighed seventy-three pounds. The external iliac artery was also tied. There was profuse diarrhea twenty-four hours after the operation, and this continued for ten days. The man died on the twenty-sixth day after the operation from septicemia.

CASE X.—By Dr. A. J. McCosh, of New York City, 1892. The patient was a male, twenty-seven years of age, with an osteo-sarcoma of the femur involving the head, the neck, and the upper fourth of the shaft.

CASE XI.—By Mr. R. L. Swan, of Dublin, Ireland, 1892. A female, nineteen years of age, had had morbus coxarius from her fifth year. There was pathologic dislocation of the caput femoris. The thigh and leg were extensively infiltrated and burrowed by sinuses. There was extremely little shock, and a good recovery followed.

CASE XII.—By Dr. A. M. Phelps, of New York City, 1891. A male, fifty-five years old, had recurrent sarcoma of the middle third of the thigh, the clavicle having been removed two years previously for sarcoma. The operation was concluded in fourteen minutes. The patient was extremely anemic. Not more than one ounce of blood in all was lost. He recovered uninterruptedly. Operation performed at Charlottesville, Va.

CASE XIII.—By Dr. A. M. Phelps, December, 1891. A male, twenty-four years of age, had hip-joint disease of long standing. The operation was unattended with shock, rise of temperature, or bleeding, and the patient was up on crutches in two weeks.

CASE XIV.—By Dr. A. M. Phelps, 1892. A male, sixteen years old, had extensive osteitis of the whole lower extremity of two years' duration, and was almost moribund from septic absorption. Portions of the pelvic bones, which were involved, were also removed. No blood was lost. The patient died from exhaustion twelve hours after the operation. Dr. Phelps advised against operation in this case, and only did it at the urgent solicitation of the parents.

CASE XV.—By Dr. G. A. Baxter, of Chattanooga, Tenn., 1891. The patient was a negro lad, seventeen years of age, with compound comminuted fracture and pulpification of the right leg and foot, and of the left lower extremity as high as the middle of the thigh. He had been hauled in a wagon over a rough country road for two miles, and was found by Dr. Baxter in profound shock. So soon as reaction had set in, amputation of the right leg at the middle and of the left thigh at the hip-joint was performed. "Wyeth's technique was closely followed." There was no loss of blood, and disarticulation was easily effected. The patient rallied encouragingly, but four hours after the operation, contrary to the directions of the doctor, he raised himself to the sitting posture and instantly expired. Heart-failure was evidently induced by loss of blood prior to the operation, and by profound shock following the injury, to which was added

the shock of operation. "The control of hemorrhage by the method employed was perfect."

CASE XVI.—By Dr. W. B. Johnston, of Ellicottville, N. Y., 1892. The patient was a male, thirty-nine years old, who had sustained a railway injury in which the foot, the leg and thigh, to a point above the middle third, were "pulped," and the femur divided near the trochanter minor. "There was no arterial bleeding whatever, and only slight oozing from the muscles." The man died from shock and exhaustion ninety hours after.

CASE XVII.—By Dr. J. D. Thomas, of Pittsburg, Pa., 1891. The patient was eighteen years of age. On July 31st, while attempting to grasp with tongs a red-hot bar of iron passing through the rollers, he was struck by the rod in the left thigh. The bar penetrated the tissues and seared through the saphenous and femoral veins and the femoral artery. The loss of blood was at once almost fatally profuse. Dr. J. M. Duff, who first saw the man, placed a compress and bandage over the wound. As the patient rallied slightly, bleeding occurred chiefly from the proximal end of the divided femoral vein. The wound was packed by Dr. Thomas with iodoform-gauze, and over all was placed a cotton bandage. Heat was applied locally and stimulants administered hypodermatically. On the third day amputation at the hip was proposed on account of threatened gangrene, but was not permitted. Ligatures were applied to the large vessels. On the seventh day amputation was performed. The man rallied well for thirty-six hours, then failed rapidly, dying eight and one-half days after the injury.

CASE XVIII.—By Dr. W. F. Fluhrer, of New York City, 1890. A female, eighteen years of age, had osteo-sarcoma of the left thigh of six months' history. There had been spontaneous fracture of the thigh at the middle, on April 26, 1890. Amputation at the hip was performed on May 2d, and on July 1st the patient was up and out on crutches.

CASE XIX.—By Dr. Merrill Ricketts, of Cincinnati, O., 1893. A female, twenty-three years of age, had osteo-sarcoma of the right thigh, and was operated upon on February 2, 1893. "Operation bloodless." She recovered promptly.

CASE XX.—By Dr. C. A. White, of Atlanta, Ga., 1891. A male, twenty-three years, had osteo-sarcoma of the left femur, involving the whole length of the shaft. The tumor was four times the size of the thigh. Operation was performed on May 26, 1891. The patient recovered rapidly, gained twenty pounds in weight, and by June 22d was up on crutches. He was seized with acute pneumonia on the 27th day and died five days later. The pneumonia was independent of the operation, as the wound was entirely healed a week before the onset of the malady that carried him off.

CASE XXI.—By Dr. John B. Deaver, of Philadelphia, October, 1890. A female, twenty years of age, had extensive osteo-arthritis of the upper end of the femur and acetabulum. Excision of the head of the femur had been performed in 1889 by Dr. J. Ewing Mears. Numerous sinuses and extensive infiltration of soft parts were found. On November 30th the patient was "entirely well."

CASE XXII.—By Dr. John B. Deaver, 1893. A male had osteo-myelitis of the femur. He was greatly emaciated and depressed from long septic absorption. The amount of blood lost did not exceed two ounces. The fixation-pins were discarded and the circular constriction at the hip was held up by an assistant with strips of bandage. There was a good recovery.

CASE XXIII.—By Dr. J. Ewing Mears, of Philadelphia, 1892. The patient was a boy, ten years of age, with chronic osteo-arthritis of the hip and femur. Recovery.

CASE XXIV.—By Dr. Archibald E. Mallock, of Hamilton, Ontario, Can., 1892. The patient was a man, thirty years of age, with chronic osteo-arthritis of the hip, for which excision of the head of the femur had been performed December 16, 1891. Amputation was performed on March 12, 1892. It lasted thirty-five minutes, and several deep sinuses were exsected. Recovery followed.

CASE XXV.—By Dr. Charles B. Nancrede, of Ann Arbor, Mich., 1893. This was a case of tuberculous osteitis in a man thirty-one years of age. The femur was implicated as high as the trochanter and there was general infiltration of the soft parts. Operation was performed on May 1, 1893, and was followed by an uninterrupted recovery.

CASE XXVI.—By Dr. Charles B. Nancrede, 1892. The patient was a man, thirty-two years of age, with a history of injury to the left thigh several years before the operation. An osteo-sarcoma developed for ten months. The operation was performed in November, 1892. The disease involved the soft structures close to the joint-level. Hemorrhage was quite free after the tube was removed. Recovery followed.

CASE XXVII.—By Dr. Emory Lanphear, of Kansas City, Mo., 1890. The patient was a colored boy, nine years old, with osteo-myelitis of the shaft of the femur. Excision of the knee had been performed October 21, 1890. On October 24th the condition of the patient was so desperate that longer delay meant death, and amputation at the hip was performed. Scarcely an ounce of blood was lost. There was uninterrupted recovery.

CASE XXVIII.—By Dr. Emory Lanphear, 1892. A male, fifteen years old, had "osteo-myelitis of the entire shaft of the femur, with profound septicemia." The operation was completed in twenty-nine minutes. "Not more than two ounces of blood could have been lost, and this was from parenchymatous oozing." The patient died from septicemia.

CASE XXIX.—By Dr. Emory Lanphear, 1892. The patient was a woman, twenty-eight years old, with a history of severe neuralgic pain in the great toe, for which, in 1888, her physician had amputated this member. No relief followed, and Chopart's amputation was performed by another operator. Subsequently amputation was performed just above the ankle; again just below the knee; once more through the condyles of the femur; and still again at the middle of the thigh; finally, on August 28, 1892, Dr. Lanphear amputated at the hip. A sharp process of bone was found developed from the femur near the trochanter. This had penetrated the sciatic nerve and caused the severe pains. The patient recovered and was relieved.

CASE XXX.—By Dr. Emory Lanphear, 1893. A man, twenty-eight years of age, had osteo-myelitis of the shaft of the femur occurring after amputation at the junction of the lower and middle thirds. The operation was performed on February 24, 1893, and was followed by recovery without interruption.

CASE XXXI.—By Dr. Samuel H. Pinkerton, of Salt Lake City, Utah Ty., 1892. A boy, six years old, sustained a compound comminuted gunshot fracture of the femur. He died two hours after operation, from shock.

CASE XXXII.—By Dr. Samuel H. Pinkerton, 1892. A male, seventeen years old, had extensive tuberculous osteitis of the femur. The disease had been in progress many years. Recovery was slow, and was succeeded by subsequent curetting of the acetabulum.

CASE XXXIII.—By Dr. Samuel H. Pinkerton, 1892. A male, seventeen years of age, had tuberculous osteitis of the upper end of the femur, and acetabulum. There was recovery, the wound healing by granulation.

CASE XXXIV.—By Dr. Samuel H. Pinkerton, 1892. A boy, ten years old, had tuberculous osteitis of the femur. The operation was followed by recovery.

CASE XXXV.—By Dr. Samuel H. Pinkerton, 1892. A man, forty-three years old, had necrosis of the femur, and there had been spontaneous fracture. The patient died ten hours after the operation, from shock.

TABLE.

No.	Operator.	Date.	Age.	Sex.	Diagnosis.	Result.	Remarks.
1	John A. Wyeth,	Feb., 1890	39	Male	Osteo-sarcoma.	Recovered	At first operation femur was divided at level of lesser trochanter; sixteen days later head of the bone was enucleated.
2	John A. Wyeth,	Feb., 1890	34	Male	Neuro-sarcoma of internal popliteal nerve.	Recovered	The tumor of the nerve was extirpated Feb., 1888; recurred, and limb was amputated at lower third of thigh Oct. 1888; recurred again, and amputation at hip-joint was performed.
3	John A. Wyeth,	1892	17	Female	Osteo-sarcoma of lower end of femur; amputation and recurrence in stump.	Recovered	Amputation through lower third of femur was performed by Dr. Allen, of Cleveland, Feb. 5, 1892.
4	Wm. F. Fluhrer,	May, 1890	18	Female	Osteo-sarcoma of femur.	Recovered	Spontaneous fracture at middle of thigh April 26, 1890.
5	Charles McBurney,	May, 1890	34	Male	Osteo-sarcoma.	Recovered	
6	Frank Hartley,	March, 1892	26	Female	Osteo-sarcoma.	Recovered	
7	Merrill Ricketts,	Feb. 2, 1893	23	Female	Osteo-sarcoma.	Recovered	
8	C. A. White,	May 26, 1891	23	Male	Osteo-sarcoma.	Recovered	Patient was up and about after operation, but on twenty-seventh day was seized with pneumonia and died five days later.
9	A. M. Phelps,	1891	55	Male	Osteo-sarcoma.	Recovered	
10	W. W. Keen,	Jan., 1892	30	Female	Osteo-sarcoma.	Recovered	Patient was five months pregnant at date of operation.
11	M. J. Ahern,	1892	22	Male	Osteo-sarcoma.	Recovered	
12	J. B. Murdoch,	Feb., 1892	17	Male	Osteo-sarcoma.	Died	Death from shock twenty-two hours after operation.
13	Chas. B. Nancrede,	Nov., 1892	32	Male	Osteo-sarcoma.	Recovered	
14	J. McFadden Gaston,	Nov, 1890	?	Male	Osteo-sarcoma.	Died	Death on twenty-sixth day, from septicemia.

32	G. A. Baxter,	1891	17	Male	Railroad pulpification of right foot, leg, and left lower extremity as high as middle of thigh.	Died	Patient rallied well; four hours later raised himself in bed to reach a glass of water and instantly expired.
33	W. B. Johnston,	1892	39	Male	Railroad pulpification of lower extremity, as high as middle of thigh.	Died	Death ninety hours after operation, from shock and exhaustion.
34	J. D. Thomas,	1891	18	Male	Femoral vessels divided in Scarpa's triangle by red-hot bar of iron; impending gangrene.	Died	Great hemorrhage from the accident. On seventh day after injury, amputation; death thirty-six hours later.
35	Samuel H. Pinkerton,	1892	6	Male	Compound, comminuted gunshot fracture of femur.	Died	Two hours after operation death from shock.
36	Emory Lanphear,	1892	28	Female	Osteoma of femur penetrating sciatic nerve.	Recovered	
37	H. O. Walker,	1892	14	Male	Osteo-sarcoma.	Recovered	
38	H. O. Walker,	1893	21	Male	Chronic hip-joint disease.	Recovered	
39	H. O. Walker,	1893	Young	man	Chronic hip-joint disease.	Died	Exhaustion in four hours.
40	F. W. Parham,	Oct. 5, 1893	3	Male	Osteo-sarcoma.	Recovered	

CASE XXXVI.—By Dr. Samuel H. Pinkerton, 1892. A man, forty-two years of age, had extensive necrosis of the femur. Recovery followed the operation. Healing took place by granulation.

CASE XXXVII.—By Dr. H. O. Walker, of Detroit, Mich., 1892. A boy, fourteen years old, had seven months previously been kicked by a horse. Osteo-sarcoma developed in the middle of the femur. Amputation performed on September 27, 1892, followed by recovery.

CASE XXXVIII.—By Dr. H. O. Walker, 1893. A man, twenty-one years of age, in whom six years previously hip-joint disease had developed. There had been exsection of the head of the femur on August 11, 1891. Amputation was performed in August, 1893. Recovery followed.

CASE XXXIX.—By Dr. H. O. Walker, March, 1893. The patient was a young man with chronic tuberculous osteo-arthritis of the hip. Operation was undertaken with but little hope of success as he was in a very low condition, the temperature ranging from 102° to 105° F. He died four days after operation.

CASE XL.—By Dr. F. W. Parham, of New Orleans. A boy, three years old, with osteo-sarcoma of the femur. The operation was performed on October 5, 1893. Recovery followed. "The method gave thorough satisfaction. Not over two ounces of blood were lost.

This limited number of cases—40 in all—gives a death-rate of 22.5 per cent. (Five were re-amputations.)

	Cases.	Deaths.	Per cent.
Sarcoma	17	2	11.76
Inflammatory bone-disease	18	3	16.6
Violence	4	4	100.0
Nerve-injury	1	0	——
For disease	36	5	13.88
For injury	4	4	100.0

Ashhurst's table of 633 cases gives a total mortality of 64.1 per cent.

	Cases.	Death-rate per cent.
For disease	276	40.2
For injury	309	82.4

Luning gives:

	Cases.	Death-rate per cent.
Gunshot wounds	239	98.0
Disease	153	42.0

Without discussing statistics, I claim it safe to conclude that by the method given bleeding after hip-joint amputation is as safely and as securely controlled as for an amputation of the thigh lower down. In no single case has it failed, and it has been employed now by operators of all grades of experience.

Prof. W. W. Keen, who employed this operation successfully at the Jefferson Hospital, Philadelphia, in January, 1892, for an enormous sarcoma of the thigh (the patient being five months pregnant at the time), in reviewing all the methods of controlling hemorrhage, said:[1] "It was reserved for an American surgeon to devise what is undoubtedly the best method and, in fact, what I think we can call now the only method of hemostasis in amputation at the hip-joint."

[1] THE MEDICAL NEWS, March 26, 1892.

Prof. J. B. Murdoch, of Pittsburg, who has four times performed hip-joint amputation, and once by my method, says:[1] "I believe this method to be the best and the one destined to supersede all other methods for the temporary arrest of hemorrhage."

Prof. W. F. Fluhrer[2] emphasized "that as little blood had been lost as in an ordinary amputation at the middle of the thigh."

Prof. McBurney[3] expressed the opinion that "no other appliance that had been suggested for the purpose could in any way compare in utility with that of Dr. Wyeth."

Prof. Emory Lanphear, of Kansas City, who has four times amputated at the hip by this method, says:[4] "This operation (Senn's)[5] is certainly better than any other yet devised save that which is known as the 'Wyeth bloodless method,' by which method failure to control hemorrhage seems to me to be impossible."

Prof. McFadden Gaston, of Atlanta, says:[6] "There was absolutely no trouble from hemorrhage . . . . and I feel satisfied that with this process all bleeding may be prevented in amputation at the hip-joint."

Dr. B. Merrill Ricketts, of Cincinnati, writes me that "the operation was entirely bloodless."

Dr. W. B. Johnston, of Ellicottville, New York, writes: "There was not one drop of arterial blood and only a slight venous oozing from the muscular tissue."

Prof. H. O. Walker: "We have in this a safe and reliable method for controlling hemorrhage which, in my judgment, is superior to any yet offered."

By personal communication Professors McCosh, Baxter, A. M. Phelps, Hartley, and Parham have expressed themselves that the method met every requirement in the prevention of loss of blood.

The question of *shock* is very important in this major operation. It is strongly brought out by Prof. Murdoch, who insists that "the greatest care must be exercised to maintain the vital forces by the moderate use of stimulants before the operation and the protection of the surface of the body from cold and exposure during its performance." To this

[1] Annals of Surgery, January, 1893.

[2] International Journal of Surgery, 1890.

[3] Ibid. [4] Kansas City Med. Journ., May, 1893.

[5] This method, devised by Prof. N. Senn, requires an incision eight inches in length, commencing three inches above the trochanter: the capsule, trochanter, and upper portion of shaft are exposed, the trochanteric muscular attachments severed, the digital fossa emptied, the capsule divided, and the head of the femur dislocated before any constriction for the control of hemorrhage is attempted. I do not think that this method will be received with favor by surgeons. The only instance in which it has been applied, to my knowledge, was by Dr. W. D. Foster, of Kansas City. "The patient was the subject of chronic coxitis, was much emaciated, and very weak. The operation was tedious, protracted, and bloody, and the patient survived between three and four hours." (Private communication.)

[6] Transactions Alabama State Medical Association, 1892.

should be added the minimum of anesthetic and the maximum of rapidity in technique consistent with thoroughness and the prevention of bleeding.

When ether is employed the Ormsby inhaler secures the safest narcosis with the smallest amount of ether.

NOTE.—Since the paper was read I have done a fourth amputation for tuberculous osteo-arthritis at the hip, without loss of blood and with recovery. The patient was a male, twenty-seven years old, and the disease had existed from childhood.

THE EFFECT OF CASTRATION ON WOMAN, AND OTHER PROBLEMS IN GYNECOLOGY.

BY WILLIAM GOODELL, M.D.,
HONORARY PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

THERE are problems in gynecology not yet fully solved, on which I purpose in this paper to give my own individual opinion—an opinion that I do not claim to be infallible, but which is based upon a large experience.

One question not yet satisfactorily answered is this: What effect upon a woman has the removal of her ovaries? Unquestionably there usually follow the annoyances of the change of life. These, in my experience, are long spun out, because, when menstruation has been abruptly and artificially stopped, the change of life, especially in young women, takes more time to become fully established than when the menopause has been naturally induced. Consequently, years may elapse before the victim of the operation escapes from the perspirations, the flashes of heat, the skin-tinglings, the numbness of the extremities, the nerve-storms, and all other vaso-motor disturbances, the name of which is legion. My experience, therefore, coincides with that of Hegar, who says that "the artificial menopause induced by the operation is often attended with more serious complications than those which are not rarely observed in the natural change of life."[1]

Then again the unwelcome fact cannot be shirked that mental disturbances may be traced directly to the removal of the ovaries as a cause. These are manifested by brooding, by low spirits, by melancholy and even by insanity. Every ovariotomist has met with such painful episodes in his practice. Glavaecke, who has made a study of this subject, goes so far as to declare that "in almost all cases the mind becomes more or less affected, and not infrequently melancholia results."[2] Keith has stated that ten per cent. of his patients who recover from hysterectomy subsequently suffer from melancholia or from other forms of mental disease.[3] Yet this result must come, not so much from the extirpation of the womb, which is merely a muscular bag, as from the associated ablation of the ovaries, of which the womb, physiologically, is only the appendage.

Whether this deplorable event is due directly to the nerve-shock of the operation itself, together with its emotional environment; whether to the abrupt arrest of an habitual flow; or whether to the absolute need of the ovaries for mental equilibration—is yet an open question. We know, however, that sexuality is a potent factor in woman as well as in man, and that even certain sexual functions—such as coition, menstruation, gestation, parturition, and lactation—of themselves tend not infrequently to disturb the mental poise. I am disposed, however, in a measure to attribute the attacks of insanity in those women who have lost their ovaries to their brooding over the thought that they are unsexed; and if brooding may be deemed in itself a mental aberration, Glavaecke's sweeping statement is not an extravagant one.

But, after all, the burning question is: Does the removal of the uterine appendages affect the sexual sense of the woman, or in any way unsex her? Here we have an embarassing diversity of opinion. Some operators contend that in these respects castration does not affect her at all; others that it does so, and often very decidedly. The truth in such cases usually lies in the mean, as I shall try to show.

In my *Lessons in Gynecology* and in my early teachings I maintained that the removal after puberty of the ovaries and the tubes does not unsex the woman—at least not to a greater extent than castration after puberty unsexes the man. In the one the ability to inseminate is lost; in the other the capability of being inseminated; but in both the sexual feelings remain pretty much the same. Males who have lost their testes after the age of puberty are said to retain the power of erection, and even of ejaculation, the fluid being of course merely a lubricating one. The amorous proclivities of the ox or of the steer are the scandal of our highways. Alive to these facts, Oriental jealousy demands in a eunuch the complete ablation of the genital organs. Not only are the testes, therefore, removed, but also the scrotum and the penis flush with the pubes. Hence, to avoid the soiling of his clothes, every eunuch carries in his pocket a short silver tube, which he inserts merely in the pubic meatus whenever he passes his water. I contended, further, that, apart from cessation of menstruation and from inevitable sterility, the woman after castration remains unchanged, having the same natural instincts and affections; that the sexual organs continue excitable, and that she is just as womanly and as womanish as ever. I held that the seat of sexuality in woman had long been sought for, but

[1] British Medical Journal, December, 1886, p. 1280.
[2] N. Y. Medical Journal, July 20, p. 73. [3] Ibid., p. 73.

in vain. The clitoris had been amputated, the nymphæ had been excised, and the ovaries and tubes extirpated; yet the sexual desire had survived these mutilations. The seat had not been found, because sexuality is not a member or an organ, but a sense—a sense dependent on the sexual apparatus, not for its being, but merely for its fruition. My inference was that the physical and psychic influence of the ovaries upon woman had been greatly overrated. In the popular mind a woman without ovaries is not a woman. Even Virchow contends that "on these two organs (the ovaries) depend all the specific properties of her body and her mind, all her nutrition and her nervous sensibility, the delicacy and roundness of her figure, and, in fact, all other womanly characteristics." This statement I held to be true only in so far as the ovaries are needful for the primary or rudimental development of woman, but not true when once she is developed; for then they are not essential to her perpetuation as woman.

In time, however, I slowly found out that the removal of the ovaries does blunt and often does extinguish ultimately the sexual feeling in woman; although the removal of the testes after puberty is said not to impair the virile sense of the male. This random opinion, however, I very much doubt, despite the maudlin sentiment expressed even about eunuchs by De Amicis and by other travellers in the Orient. For the secretion of the seminal fluid is in itself the great aphrodisiac, and how otherwise can we explain the changed behavior of Abelard toward Heloïse after his forcible castration? Giving up this analogy, therefore, in my more recent teachings I adopted that of the menopause as suggested by Kœberlé. I accepted his analogy, although I could not wholly accept his inference that woman is not affected sexually by the natural cessation of her menses. Kœberlé sums up his opinion in the following words: "In my own experience the extirpation of both ovaries causes no marked change in the general condition of those who have been operated on. They are women who may be considered as having abruptly reached the climacteric. Their instincts and affections remain the same, their sexual organs continue excitable, and their breasts do not wither up." [1]

A riper experience, of which time was the main element, has led me still further to modify my views on this subject. Unquestionably the natural change of life when fully established, but not until it is fully established, does very sensibly dull and deaden the sexual sense of woman, which ultimately disappears in her long before virility is effaced in man. Nor is the survival of this sense after the menopause so essential to woman, because after the cessation of menstruation she loses the power of procreation, which is retained to an advanced age by man. This is a wise provision of Nature, for, did the sexual sense of the wife outlast that of the husband it could not be gratified. Sensible of these changes, a gifted French authoress makes one of her heroines say, with italicized emphasis: "*Men* may forget the course of years; they may love and become parents at a more advanced period than we can, for Nature prescribes a term after which there seems to be something monstrous and impious in the idea of (our) seeking to awaken love. . . . . Yes; age closes our mission *as women* and deprives us of our sex." Now what happens in the natural menopause holds good in that artificially and abruptly produced, with this important difference, that in the latter the sexual feeling is sooner lost. I am willing to concede that in some women, by no means in all, whose health had been so crippled by diseased appendages as to extinguish all sexual feelings, there is, after castration, a partial recovery of the lost sense whenever health has been regained. Yet even in these cases, as far as I can ascertain—for women are loath to talk about these matters—the flame merely flares up, flickers, and soon goes out.

My own experience would lead me to the conclusion that in the majority of women who have been castrated the sexual impulse soon abates in intensity, much sooner than after a natural menopause, and that in many cases it wholly disappears. This tallies with Glavaecke's conclusion that "in most of the cases the sexual desire is notably diminished and in many cases is extinguished." In corroboration of this statement let me cite, out of my many cases in point, a few of the more salient ones. The wife, aged thirty-four, of a farmer, so exhausted him by her sexual exactions that his health suffered very seriously. The appendages were diseased and fixed by adhesions. After their removal menstruation and the sexual impulse continued unabated for a little over a year, when the former wholly ceased, and the latter not long after disappeared. Another case was the very ardent wife, aged thirty, of a man who was not so well-mated to her. She was sterile and had excessive menorrhagia from a uterine fibroid, for which her ovaries were removed. Menstruation did not reappear, and in less than two years all sexual feeling was lost. In a third case, a young lady of high intelligence was reduced to a pitiable condition of ill-health by menorrhagia and by frequent acts of self-abuse. She was not insane, yet, incredible as it may seem, she sometimes masturbated no fewer than eight times in the four and twenty hours. For several months after the removal of the ovaries, which were apparently healthy in every respect, she kept up her bad habits, although

[1] Nouveau Dictionnaire de Médecine et de Chirurgie, tome xxv, p. 487.

the monthly flow never returned. Then the sexual feeling gradually vanished, and she gave up her solitary vice. In a fourth case I removed the healthy ovaries of an unmarried lady of middle age who was queer, but not insane enough to be confined. Toward her monthly periods she was goaded by so irresistible a desire for sexual intercourse that she herself feared her going astray. Not long after her castration, which was done more to save her from reproach than to cure her insanity, she lost the desire wholly and absolutely. She did not, however, regain her reason, and ultimately had to be placed in an insane asylum.

Imlach's case is a celebrated one in medico-legal jurisprudence. This skilful surgeon, after removing the appendages of a woman, was prosecuted by her for unsexing her, and by her husband for spoiling thereby his marital pleasures. The special committee appointed to investigate Imlach's numerous cases of castration at the Woman's Hospital, in Liverpool, reported that they found "a distinct loss of sexual feeling to such an extent as to cause serious domestic unhappiness in not a few instances." The correctness of this report is corroborated from cases in my own practice, of engagements broken off, of conjugal estrangements, and of marital infidelity.

Let me here remark that I was once consulted by the late Dr. Kerlin about the propriety of removing the ovaries from a feeble-minded inmate of his institution, whose shameless intercourse with the other sex was the only bar to her being at large. Being very sanguine that the operation would succeed in its object I urged its performance. He, however, could not get the official sanction which we both wished for our own legal protection, and nothing further was done than to keep the girl under lock and key.

In other sexual characteristics I have not found in these women any marked changes, either physical or psychic. Their affections seem to remain the same; their breasts do not flatten or wither up; they do not become obese; abnormal growths of hair do not appear on the face or on the body, and the tone of their voice and its quality are not changed. In one word, there has not been in a single one of my cases a tendency toward any characteristic of the male type. If any change has taken place, it has been in the direction of old-maidhood.

In close relation with this subject four questions come to the fore, and grave ones they are:

a. Do chronic diseases of the appendages often lead to a fatal issue?

b. To restore health to the woman suffering from such diseases of the appendages, is it needful invariably to invoke the aid of surgery?

c. After an abdominal section has been made, and after adhesions have been broken, must the now free appendages always be removed?

d. Is castration of the female a warrantable operation for the cure of insanity or of epilepsy?

To the first question I answer that the death-rate from chronic diseases of the appendages is greatly overrated, so much so that, in my opinion, more deaths result from the operation of removing the tubes and ovaries, in the hands of even the most successful gynecologist, than from the disease itself. Knowsley Thornton states that "in his own experience pyosalpinx is not necessarily a fatal disease." In my experience, after the patient has safely passed through the acute stage of the inflammatory attack, her life is in very little danger. Chronic diseases of the appendages usually affect the well-being of the woman, but they ordinarily do not threaten her life in any other way than by the wear and tear of prolonged discomfort. This may shorten her days, but fatal attacks of peritonitis, even in so-called leaky pus tubes—if such ever exist—are the exception. Paradoxic as it may seem, the life of a woman with but one ailing appendage is in greater danger than the life of a woman with both of her appendages diseased. The explanation is a simple one: Parturition very generally relights a chronic inflammation of the pelvic organs, but when both appendages are diseased pregnancy rarely takes place.

To cure the ill-health of a woman whose appendages are diseased, or to relieve her from her sufferings, a surgical operation is by no means always necessary. Many women with adherent tubes and ovaries, and, for the matter of that, some even with pus in these organs, suffer either no inconvenience whatever, or very little indeed from that condition *per se*. There are, again, others who have pains or aches only at their monthly periods. But let their health break down, say from influenza, from malaria, from overwork, or from nerve-strain, then symptoms may arise from hitherto latent pelvic lesions. Yet, in most of these cases, if the woman can be restored to her former condition of health—that is to say, to that which she enjoyed just before the final breakdown—she will lose her local symptoms and become symptomatically well. On this matter I can speak positively, for many a patient has been sent to my private hospital in order to have her distinctly diseased tubes and ovaries removed, who has been restored to health without the use of the knife. Now, by the term "*restored to health*," I do not mean that the treatment has released the adherent appendages, but that it has freed the woman from every pain and restored her fully to all her social and domestic duties and pleasures. She has been cured so well as to be able to row, to swim, to dance, to take long walks, to ride on horseback

and to exercise in the gymnasium—and what better vouchers of good health than these can be given?

I will go yet further and assert that even cases with all the subjective and all the objective symptoms of ovarian or of tubal abscess have been cured by me without any operation whatever—the pus having disappeared either through absorption or through inspissation. What is still more strange, in a few cases of abscess of each uterine appendage—very few, I will acknowledge—the treatment by massage, electricity, local applications, and by a general building up of the system was followed by conception, pregnancy, and parturition. These were cases in which I did not advocate castration until other means had been tried first, but all had been sent to me by their physicians for the purpose of having their ovaries removed.

I come now to two cases on which I urged castration. Perhaps I have had more, but I cannot recall them. Each one had the fixed, sausage-like, tubal tumor on either side. Yet each patient, to my very great surprise, conceived and bore children. The one, a patient of my friend Dr. D. Murray Cheston, first consulted me and afterward a gynecologist of world-wide renown, who corroborated my diagnosis of double pus-tubes, and doomed her, as I had, to hopeless sterility. The puerperal convalescence was stormy and at one time threatening; but she ultimately got well. The other case is a standing joke of my friend Professor Parvin, who knew the circumstances. The woman presented similar characteristics to those of the preceding case, and I urged an operation. This she luckily refused to undergo, and a year or more afterward gave birth to twins. Of course, the rejoinder will be made, that my diagnosis, although shared by other specialists besides myself, was a faulty one. But I can as unhesitatingly reply that had the objector made the examination he inevitably would have followed it by an abdominal section, and as inevitably would have removed both appendages, as I certainly should have done had I opened the abdomen.

Now, in these cases, the pus was either confined to the ovaries, or, as I supposed from the sausage-like form of the tumors, it lay sealed up in the tubes, and the closed-up lumen of one of them was, by returning health, restored to full patency. The possibility of a closed-up tube regaining its bore is I know strongly disputed, even ridiculed, and *a priori* reasoning would certainly justify the doubt. If, however, solid uterine fibroids of stony hardness and of several pounds weight will through absorption wholly disappear, as every gynecologist has seen them disappear, why may not the tubal barriers and septa also break down and become absorbed. I have read somewhere, but the reference I cannot now find, that, in order to prevent conception in a case of narrow pelvis, both tubes were ligated, without establishing sterility. On the other hand, great disorganization of the ovaries is not incompatible with pregnancy, for it appears that a very small amount of ovarian stroma goes a great way. Menstruation often continues, however diseased the ovaries may be, and Atlee reports two cases in which one ovary having been removed, the other became so cystic as to need *repeated tappings*. Yet each woman not only menstruated, but conceived and gave birth to a child.[1] In one of these cases, a cyst of the sole ovary, the other having been removed many years previously, was tapped twice before conception, twice before delivery, seven times afterwards and then was extirpated. Robertson[2] mentions a remarkable case in point, which occurred in his practice. He removed both the ovaries, which were diseased, of one of his patients, yet she afterward conceived and gave birth to a child. His explanation is that he must have left, unwittingly, a scrap of healthy ovarian tissue in one of the stumps. But on the other hand, the ovum could not have descended into the womb, unless the lumen of one tube had reopened at the point where it had been sealed up by the adhesive inflammation set up by the ligature.

With regard to the third problem: Supposing simply therapeutic measures fail, and the physician is driven to surgical interference, must he, after breaking up the adhesions, always extirpate the now free uterine appendages? Most surgeons contend not only that the diseased appendage should be removed, but also that both appendages should be extirpated, even if one alone is diseased. This advice is given on the ground that the healthy one is liable in its turn to become affected. My own course, under such circumstances, would be never to remove the healthy appendage unless the menopause had been established already, or unless there obtained a good reason for hastening it on. On the other hand, should both ovaries be intrinsically diseased and their tubes contain pus, I would always remove both uterine appendages in their totality, no matter what the age of the patient might be. Generally, however, the pus is limited to the tubes, and in that case sometimes one ovary, barring its adhesions, which, of course, must be broken, is healthy enough to be left behind. In such a case the tube alone, if possible, should be removed, and not the healthy ovary or the healthy ovaries—if both happen to be sound. Further, rather than wholly remove all ovarian stroma, I should try in such cases to leave behind even a small fragment; for, in several of my cases in which a piece of an ovary, not larger than a bean, was left behind, not

[1] Atlee: Ovarian Tumors, pp. 38 and 39.

[2] British Medical Journal, September 27, 1890, p. 722.

any menstrual or sexual changes whatever took place in the woman. Should the uterine appendages be merely adherent, and not intrinsically diseased to any extent, I would as a rule, during active menstrual life, release them, and perhaps extirpate the worse of the two, but not both of them.

My reasons for this conservative treatment are, that the complete extirpation of these organs, as I have shown before, tends to destroy the sexual feeling, to disturb the mental equilibrium, and to produce prolonged nervous perturbations, all of which come from the abrupt and untimely suspension of menstruation. There is yet another very excellent reason for this advice: The majority of physicians, and all laymen, look upon women deprived of their ovaries as unsexed: Just as castration is in the male, so the analogous operation is in the female deemed a sexual mutilation to which common consent attaches a stigma. No woman would marry a eunuch, and few men would wed a woman deprived of her ovaries. In my own practice I have known of several very sad cases of marriage engagements broken off, of marital infidelities, and of bitter estrangement between husband and wife, all of which would have been avoided had one ovary been spared, or, indeed, had a mere fragment of one been left behind.

Upon the question of the removal of the uterine appendages for the cure of insanity and of epilepsy, I have very few words to say, but they are all based upon cases occurring in my own practice. If the insanity is limited to periodic outbreaks, strictly ovarian in their character and with the menstrual flux as a storm-center; if the epileptic fits are preceded by an ovarian aura—that is to say, if they pivot around the monthly period and appear at no other time—the removal of the appendages, by suppressing a pernicious menstruation, usually will bring about a cure in either disease. But when these organs are extirpated merely as a panacea *per se* for these mental and neural disorders, irrespective of an ovarian origin, the operation affords no relief. At the same time I am free to confess that, in order to stamp out insanity, I am strongly inclined to advocate the legal castration of every man and of every woman who is the unfortunate victim of this hereditary curse.

CLINICAL LESSONS.

Three Cases of Remarkable Spinal Anterior Curvature with Mental Aberration.

BY S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND DISPENSARY FOR NERVOUS DISEASES, PHILADELPHIA.

I SHOW you to-day two out of three cases of somewhat unusual character. The third member of the group I have not here. You cannot fail to observe at once the attitude of this girl. Let me ask your attention to this singular case. The curvature came and grew complete within a few months. It is still remarkable, and was far more so. The whole spine was bent, the belly protruded, and the head carried back, to enable her to see objects on a line with the eyes. There was no possibility of straightening her either by passive efforts or through volition, but these attempts gave rise to no pain. The spine seemed to be rigid, and she could neither make it erect nor fully bend to one side; the head also possessed small power of rotation or flexion, while the neck muscles were not rigid. With gain in her mental state, these peculiar symptoms have become notably less.

This description applies nearly throughout to the man, except that his spinal difficulty was altogether above the lumbar region. The girl's case is, no doubt, largely hysterical, and so also is that of the boy who had in an extreme degree the spinal peculiarity.

The man's condition hardly justifies the label hysteria; nor did that of two others alluded to later.

Here, then, are three people, a boy, a girl, and a man, all more or less insane, and all showing a disorder of the vertebral column, which comes with the mental state, and lessens as this gets better, and is not due to appreciable organic disease.

How very strange are the postures is shown in Dr. Taylor's clever sketches. In a large experience of all forms of mental disorder I have never seen elsewhere anything just like these in the pronounced character of the curves and in the immobility which they manifested.

The boy's case is less distinct, but the resemblance to the others suffices to justify the grouping. Perhaps this collection of symptoms may be accidental. The chance grouping together of symptoms in a trio of cases may readily deceive one into the belief that we have before us an undescribed clinical type. I have been patiently reticent, and have long withheld these three cases from publication, in the hope of seeing others like them, which might permit of a larger numerical comparison. My patience has not been rewarded with success, and I am now tempted to call attention to a peculiar set of symptoms, with the hope that others may contribute like cases to my meager list, so that a larger experience may become possible. I incline to the belief that the cases I here exhibit illustrate a novel clinical group, which may be non-hysterical or may assume the hysterical type.

I ought to say, also, that in the past I have met with at least three patients who had this collection of symptoms, but of these I have no notes, as they were seen long years ago, and only in consultation.

The question is now in this form: Is there a clinical type, hysterical or not, characterized by

mental failure, physical weakness, retinal changes (?), and rapidly evolved spinal curvature, extreme in degree and otherwise unusual in type, not due to organic vertebral disease?

CASE I.—F. B., female, thirteen years of age, was brought to Dr. Mitchell's clinic, April 4, 1890.

FIG. 1.

The family history is negative. The child was born at term. The labor was easy, and instruments were not used. She was breast-fed. She began to walk at thirteen months, and to talk at about the same time. She has never had any serious illness, except pneumonia, seven years ago. She developed well, mentally and physically, until about eleven months ago, when her mother noticed that she would have fits of causeless crying and great depression. At times she would convulsively break out in attacks of violent anger. While previously she had always been number one in her school, she soon lost all interest in study, fell to the foot of the class, and finally refused to go to school at all. She sits all day, careless and unconcerned as to what is going on around her. She will have nothing to do with her old school-friends, shows no affection for her parents or brothers and sisters, and never speaks except in answer to a question, save that sometimes she talks to herself, and, as if under the influence of an hallucination, will cry out, "What do you want?" "Get out of here," etc. She has largely lost the sense of personal cleanliness, and is dirty in her habits.

Her general bearing is striking. The abdomen is thrown forward, the shoulders back, the right one being much higher than the left, while the head is thrown forward, the chin at times resting upon the chest. The left thumb is strongly flexed, the forearm pronated, and the arm rotated inwardly. The entire spine bends stiffly, and it appears impossible for her to stand erect. There is no evidence of spinal bone-disease, no angular curvature, no pain on pressure, no sensitiveness to heat or to cold. While there is quite a little general muscular weakness, there is no true palsy, and except for slight pallor, she is well nourished. There are occasional slow lateral movements of the head, and the hands are slowly passed over each other. Whether these movements are purposive or automatic cannot be determined. The fingers of both hands can be passively hyperextended.

Her expression is fatuous and idiotic. She seems to take no notice of her surroundings, and is absolutely without interest in anything. Her replies to questions are silly, her speech slow and somewhat thick.

She sleeps well now, but formerly badly, and seemed to fear the dark. Menstruation has never appeared, though she is quite well developed. Her appetite is fair. The urine is normal. The knee-jerk is slightly large, but not spastic. Sensation is normal.

Dr. de Schweinitz examined her eyes, and reports: "Concomitant convergent squint. No swelling of disc, but there is a diffuse retinal haze, especially marked above and below the discs. Both eyes are hypermetropic."

The patient was seen again in February, 1893. Her mental condition was even worse than before. She never spoke except in a silly fashion, and had to be attended to like an infant. She still has outbursts of anger. Physically she was in about the same condition as already described, except that the protrusion of the abdomen and the large anterior curvature of the lumbar and lower dorsal spine were less marked.

FIG. 2.

September, 1893. She has steadily but slowly improved since the last date, with lessening curvature, but the gain in the physical aspects of the case far outstrip the gain in the mental condition. The eye-grounds are better.

CASE II.—L. W., male, twenty-five years old, married, a mill-hand, came to the clinic November 22, 1889.

The family history is negative. The patient denies venereal disease, and no evidence of it is discoverable. He has never used liquor at all and tobacco only moderately. He has always been well until June, 1888, when his employer discharged him on the ground of mental unfitness for work. He himself complained and complains of backache and headache. He says that he often hears voices of invisible people talking to him, but he cannot remember what they say. He denies that he ever gets despondent, and is totally unconscious of any mental trouble.

His general bearing is similar to that of the first case described, but not so marked. The eyes are held half closed. The gait is shuffling and slow, and the right foot is much everted. Station is good. The knee-jerk is large, but not spastic. Sensation is normal. There is no paralysis.

His expression is dull and sleepy. Mentally he is stupid. He understands what is said to him, and replies intelligently, but often his statements cannot be relied on. He will unwittingly falsify. He has lost all interest. His inability to work is evidently due to mental insufficiency and not to the pain of which he complains. He is harmless and never subject to fits of anger, and on the other hand he is without affection. In other words, he is in a condition of dementia.

The abdominal and thoracic organs are normal. The eyes were examined by Dr. de Schweinitz, who reports that there is a slight retinitis.

He was seen again some months later, in the spring of 1890, and had improved sufficiently to do odd jobs, but still was unfit for continued work. The spinal curve was far less and the mobility nearly normal. The eyes were reported to be materially better. He was far more cheerful, and observed with interest that he was more erect and did not have to tilt his head back to get a view of the faces of people. At this time there was a complete reexamination, which added nothing to the simple statements already made.

CASE III.—L. R., male, sixteen years of age, was sent by Dr. Pearce, of Steubenville, Ohio, in March, 1890. The family history is negative. The patient suffered no injury at or near birth. He has never had convulsions or any other serious acute illness. He has always been very retiring, seldom speaking unless spoken to, never mirthful, averse to society, and not fond of amusement. He attended the public schools for six or seven years, but was always careless and indifferent about his studies, and as time passed grew duller and duller. About two years ago his comrades annoyed him so much that he was taken from school, and for a while he was taught at home. Finally, however, all efforts at education had to be abandoned. He still possesses intelligence enough to read, but rarely does so. He understands perfectly all that is said to him, but is morose and irritable. He cries a great deal and is without affection. He is extremely disobedient and without fear of punishment. He protests that there is nothing the matter with him, says dramatically that he will live a thousand years, and that he wants to be left alone. He often gets upon his hands and knees on the floor, and turning his head in an objectless manner toward the ceiling remains so for a considerable time. His usual position is sitting with the thighs strongly flexed on the abdomen, the legs flexed on the thighs, the arms clasped around the legs, and the head down, with the chin resting upon the knees. This knotted position he maintains for hours. At times he suddenly rises, hops, or runs around the room, whining the while, always going to the left if he meets a table or chair or other obstruction. He will stop suddenly, jump up and down many times, frowning and looking horror-stricken, and then walk away

FIG. 3.

and sit down in his accustomed attitude. He objects much to being touched, saying that it hurts him, but deep pressure does not give as severe pain as a light touch. His hyperesthesia is mental, not peripheral. He is reluctant to talk to anyone or even to answer a question, and when he does so he repeats words, a clause, or even a sentence several times, so that frequently it is difficult to comprehend what he says. He is, however, sometimes boisterous, and will swear roundly and scold everyone around him, and squirm and jump and throw himself about, and finally fall to the ground exhausted, panting for breath, grasping at his chest as if in deadly fear of suffocation. He complains bitterly of new clothing, saying that it is too tight and binds him. He has great trouble in dressing and undressing, but objects strongly to being assisted. He will apparently forget what he is doing; will put on a shirt and not remember that a coat should follow. The same peculiarity is shown in eating. It is no unusual thing for him to sit at table for hours muttering to himself, and only now and then taking a mouthful of food. So bad is this at times that he sometimes suffers from want of

nourishment. He goes to stool of his own accord, but may be found there hours afterward. The character of his sleep varies much; sometimes it is quiet and restful, at others much broken.

The illustration shows well the peculiarities of his usual position when standing. The legs are slightly flexed at the knees, the abdomen thrown forward, and the shoulders rounded. There is an increase in the normal antero-posterior spinal curvatures and slight left lateral curvature. There is no evidence of bone-disease. There are also apparent slight curvatures of the legs at the knees. They can be overcome by passive, but not by active motion, and the spine can by no means be straightened. The skin is yellowish and harsh. The knee-jerk is lessened, but distinctly reinforcible. The thoracic and abdominal organs are normal. Careful watching has failed to detect evidence of masturbation. The eyes appear to be normal.

When last heard from, three years later, he had improved considerably, the change coming on rather suddenly in March of this year. He said one day that he had been out of school so long that he would be behind the boys, and asked for his books. A teacher was obtained for him, and he became obedient and cheerful and desirous to study. The gain has been happily continuous, and, as in the other cases, the change in carriage and the lessening of spinal immobility has gone on as the mental state has become clearer.

ORIGINAL LECTURE.

CYSTITIS.[1]

By CHARLES G STOCKTON, M.D.,
of Buffalo, N. Y.;
Professor of the Practice of Medicine, Buffalo University.

The urine of this woman is characteristic of a mild cystitis. She entered the hospital about a month ago suffering with facial erysipelas, for which she received the ordinary treatment, making a good recovery. Directly after the passage of a catheter, however, she began to suffer from irritability of the bladder. She had a frequent, almost continuous desire to urinate, with a sense of burning and vesical tenesmus. The examination of the urine at that time verified the diagnosis of cystitis, which the symptoms suggested. The patient left the hospital, but has been compelled to return. She has been about the house, not confined to bed, passing urine every fifteen minutes or half-hour. The urine contained epithelium from the bladder, pus-corpuscles, some free red blood-corpuscles, and mucus. In a well-marked case of cystitis the urine contains such a large amount of mucus that it will cling to the bottom of the vessel when the urine is decanted. The color depends largely on the degree and nature of the inflammation. If it is a mild catarrh, the mucus is whitish. If there is extensive and severe catarrh, it is grayish or perhaps tinged with red. If the urine decomposes in the bladder, there is the well-known ammoniacal odor. It is often the case that the irritation that gives rise indirectly to ammoniacal decomposition of the urine is a highly acid state of the urine, which contains crystals of oxalate of lime and of uric acid, until the cystitis assumes the septic form.

The question naturally arises: What is the cause of the cystitis in this girl? Was it the passage of the catheter? Experiments on animals seem to show that the introduction of microörganisms into the bladder is not sufficient in itself to set up cystitis. If, however, the bladder has been over-distended so as to produce a certain degree of paralysis of the muscular wall and an injury of the mucous membrane, then the microörganisms will find a proper seat for development, and cystitis will result. When cystitis follows the passage of the catheter, you may accuse yourself of carelessness in having introduced septic germs with the catheter, but you must also look for the predisposing cause that rendered the bladder susceptible. One of the most common predisposing causes of cystitis is the distention of the bladder from urine too long retained. If a person has not passed water for six or eight hours or longer, the ultimate cause of the retention should be inquired into. Palpation and percussion should be practised, to determine the size of the bladder, and the patient's sensations should be taken into consideration. In this patient's case there was undoubtedly a retention of urine that called for the use of the catheter and that rendered the bladder liable to cystitis; but the question arises: Was the catheter septic, or did the bacteria enter the bladder at a later time, and after the cystitis was well established? Probably the catheter was not septic—at any rate it was undoubtedly fairly clean. Even an aseptic catheter may set up cystitis in a bladder that has previously been over-distended, though manifestly a dirty instrument is much more likely to cause trouble.

The urine, you notice, is smoky, an appearance characteristic of cystitis, with the presence of blood. There is also a cloudiness of the urine, which would undoubtedly precipitate if the urine were allowed to stand for some hours, and under the microscope would be shown to consist of pus, epithelium, and mucus. I have alluded to the ammoniacal reaction of the urine in cystitis. The urine is not ammoniacal when secreted, but, on account of the presence of bacteria in the bladder, a decomposition of urea occurs, forming ammonium carbonate. I have already said that one of the commonest predisposing causes of cystitis is a highly acid and irritating urine. After ammoniacal decomposition has taken place the reaction is changed, but the urine is equally irritating, and the indication is to keep it at the neutral point. This cannot be determined by examining the urine at a daily visit; the urine must be tested with litmus paper every time it is voided, and the medication should be governed accordingly.

We must remember a sign that is especially liable to be seen in old people. This is the gradual trickling away of urine; this indicates not that the urine is passed as it is secreted, but that the bladder is over-distended, the enlarged prostate acting as a dam over which the urine runs slowly.

In the treatment of cystitis not only must the urine be kept neutral, but it must also be kept diluted, and hence bland. Large amounts of absolutely pure water, distilled, or rain-water, must be used. Mucilaginous drinks

[1] A clinical lecture delivered at the Buffalo General Hospital.

also have some curious influence to make the urine bland. The mucilage itself, of course, does not pass out with the urine, but probably some constituent of the mucilage does. Balsamic preparations also render the urine bland. The oil of sandalwood is perhaps as useful as any. It may be given in capsule, gtt. v–x, every four hours, until the urine is moderately impregnated. Improvement likewise follows the use of less balsamic diuretics, such as buchu and uva ursi. Fluid extract of buchu, fifteen minims (one cubic centimeter), every two or three hours during the day and perhaps once during the night, acts as well as any of this class.

The remaining treatment of cystitis is local; this means washing out the bladder. A clean catheter is used; the urine is first drawn off, then the bladder is washed with distilled water so as to remove shreds of epithelium and mucus. Following this, astringents, stimulants, or sedatives may be used according to the indications of the case. I was an interne in this hospital when the local treatment of cystitis was first talked about in this country. I well remember seeing patients lie here month after month without any attempt at local treatment, and I remember one boy whose bladder I had to wash out every day, and I looked upon this treatment as a hardship and as quite heroic. This patient had a gonorrheal cystitis, and he became worse under treatment as the bladder was washed out with a strong astringent solution. At the time I condemned the method of treatment, but now I have no doubt that, if milder solutions or even distilled water had been used, the patient would have recovered under this treatment. He improved somewhat after the washing out of the bladder was discontinued, but he did not entirely recover.

One of the best preparations to use in washing out the bladder is boric acid, making a saturated solution in cold water, then heating the water to about the temperature of the blood and introducing it gradually. If the solution is allowed to run in quickly, it will induce a spasm of the bladder. The next day after this treatment a solution of hydrogen dioxid (25 per cent. of the fifteen-volume solution) may be used. The balsams may be suspended in water by the aid of magnesia and introduced after filtration. I do not know exactly how to state the strength of the solution. I usually prepare it by rubbing up a dram of oil of sandalwood with magnesia, putting this on a filter-paper, and passing through it a pint of distilled water. Just how much of the sandalwood remains in solution I do not know.

There is one other important point in the treatment of cystitis—rest in bed. This girl was walking about the ward when I took charge of her, and passing water every half-hour. She now rests in bed and passes water every two or three hours. The diet should be perfectly bland. Milk is often the best food, but it sometimes causes fermentation in the stomach and upsets the system. Vegetable and starchy foods are usually admissible, but little or no meat should be given. Coffee and tea, as well as all condiments, spices, and salt, should be excluded. One often goes astray in thinking that milk-diet should always be used in such cases.

The Northwestern Ohio Medical Association will hold its forty-seventh semi-annual meeting at Toledo, Ohio, December 14 and 15, 1893.

CLINICAL MEMORANDA.

A CASE OF HYPEREMESIS GRAVIDARUM TERMINATING IN RECOVERY AFTER AN INDUCED ABORTION OF TWINS.[1]

BY CLARA T. DERCUM, M.D.,
OF PHILADELPHIA.

VARIOUS and many are the theories that have been proposed in regard to the etiology of hyperemesis gravidarum, but as a matter of convenience they may be divided into two classes. The first is that in which there are local lesions present, such as displacements and flexions of the uterus, erosions, lacerations, and various structural degenerations of the cervix uteri. Among this class the various lesions of the gastro-intestinal tract must also be included. The other class comprises those cases in which no visible or symptomatic local lesions exist. The simple uncomplicated cases that occur in women of a neurotic type are considered as neuroses. In the first class of cases treatment should be directed to the local lesions present, and their cure generally results in an amelioration, if not an entire cessation of this affection. In the second class, however, treatment, to be of any avail, must be of the most diverse kind, and must be chiefly directed to the hyperesthetic nervous system, with a view of sustaining, strengthening, and increasing its resistance to the added strain. Under the burden of our modern civilization the sensitive nervous system is generally the first to suffer, and consequently we have developed a state of lessened resistance, which perhaps may be better expressed in the more familiar term of neurasthenia. Under ordinary conditions the individual may not be conscious of this state of lowered vitality, but when pregnancy occurs in such a one the delicate nervous apparatus shows an abnormal sensibility to the physiologic change that manifests itself in various reflex phenomena. When in connection with this lessened resistance there exists a local lesion either of the organs of generation or of the gastro-intestinal tract, the effect will be all the more marked.

In the ordinary vomiting of pregnancy the food that has just been taken is vomited without much effort, and there is an absence of nausea and ptyalism, thus showing that the higher nervous centers are not involved in the action; it is merely a reflex act, peripheral in origin, the afferent impulses proceeding from the stomach; it does not extend beyond the vomiting and respiratory centers in the medulla. On the contrary, however, when nausea and ptyalism coëxist with this act the afferent impulses proceed from the higher nervous centers, and the act of vomiting occurs independently of impulses received from the stomach. Therefore, as nausea and ptyalism are always present in any case of severe vomiting of pregnancy, it shows that the nervous system is mostly at fault, and that there is a lack of coördination between the higher nervous centers that manifests itself by this abnormal action of the alimentary canal.

I shall not attempt to enumerate the drugs that have been used in this affection; their name is legion; it is enough to say that those remedies that act as sedatives

---

[1] Read before the Alumnæ of the Woman's Medical College May 5, 1893.

to the nervous system, such as bromids, chloral, and opium, have yielded the best results.

It is understood that if there be a local lesion present treatment must, if possible, be directed toward its removal. Varied, strange, and amusing, indeed, are some of the accounts of the treatment of this disease. A Frenchman reports a desperate case successfully cured by hypnotism; a Russian, the cure of an equally serious case by injections of morphin into the fetal sac.

I shall now report a case that came under my own observation. The patient, M. T., is an American, of pronounced. neurotic type; her family record is not good, as shown by the following history. The father died of pulmonary tuberculosis shortly before the daughter's birth; one brother has since died of the same disease, and another one is at present suffering with it. A sister died of convulsions (cause unknown) during a pregnancy; the mother is still living, and has always been an inveterate alcoholic. The personal history of this woman is as follows:

She had always been healthy until puberty, which occurred at sixteen years of age; she then had a violent attack of chorea, for which she remained at the Orthopedic Hospital three months under the care of Dr. Wharton Sinkler; she was married at eighteen, and shortly became pregnant. Up to the eighth month of pregnancy vomiting and ptyalism existed to a profound degree. About one year after the birth of her child she had an attack of typhoid fever. One month after recovery from this disease she again became pregnant, and vomiting and ptyalism again made their appearance, but in a more aggravated form, so that at one time her attending physician, the late Dr. Elijah B. Shapleigh, considered the advisability of an abortion, but as her condition gradually improved the idea was abandoned. I saw her on the 18th of March, 1892. She stated that she was pregnant for the third time, and that she thought she had been so for about six weeks, as she had seen nothing of her menses since the 10th of February. Vomiting, nausea, and ptyalism had been present for about four weeks, and these derangements had so steadily increased in severity that not even water could be retained on the stomach. The mere sight of water was sufficient to cause a flow of saliva, and then the effort made to swallow it would bring on an attack of vomiting. This flow of saliva was so profuse that, without exaggeration, in a few hours a quart could be collected by allowing it to dribble into a basin. Calomel, cerium oxalate, bismuth subnitrate, wine of ipecacuanha, cocain hydrochlorate, soda-water, champagne, blisters and sinapisms to the epigastrium; morphin and atropin, hypodermatically; bromids and chloral by the rectum, were successively tried, without producing any effect whatever; the vomiting and ptyalism continued incessantly, both by night and by day, and independently of either food or drink. On the morning of the 22d rectal feeding was begun, peptonized milk being used for the purpose; the woman's pulse now rose to 120, and the prostration was extreme. Her physical appearance was most abject; she lay in a profound stupor, only arousing to perform the almost incessant act of vomiting, and during the intervals of the vomiting the saliva dribbling from her mouth over everything. She had marked Cheyne-Stokes respiration, and it was impossible to rouse her.

Dr. Eleanor C. Jones and Dr. F. X. Dercum saw the woman with me on the morning of the 23d. The advisability of performing an abortion was discussed, but we decided to wait a little while before resorting to such an extreme measure. The following plan of treatment was instituted: Opium, bromids, and chloral by the bowel were ordered, to act as sedatives to the nervous system; rectal feeding with peptonized milk, liquid peptones, and whiskey; hypodermatic medication of atropin, strychnin, and digitalis to support her strength. Two days in succession the cervix was dilated with rapid dilators, and iodin was applied to the canal and to the vault of the vagina. High rectal injections were also given, in order to move the bowels thoroughly, so as to be sure that the vomiting (as the matter ejected sometimes had a characteristic fecal odor) was not due to obstruction of the bowel. The food and medicines given by the rectum were retained and the patient soon began to show some signs of improvement, as she vomited only from about fifteen to twenty times in the twenty-four hours. Dr. Joseph Price saw the patient with me on the 26th; he approved of the treatment pursued, and as her condition was slightly better advised that an abortion be deferred. On the 28th she refused further medication by the hypodermatic method, and the medicines that had been so administered were continued by the bowel, the dosage being doubled. The patient ceased vomiting suddenly on April 1st, after partaking of a lamb chop; she was, however, still partially nourished, as well as medicated, by the bowel. She gradually improved, and by April 6th all medicine and food were taken by the mouth and were retained.

I was again summoned to see her on April 25th, vomiting, ptyalism, and nausea having recommenced on the 23d. The same treatment was again resorted to, but this time without any result. She rapidly grew worse, and her condition again became alarming; then the same stuporous state as formerly developed, with occasional intervals of violent delirium; at times her suffering seemed unbearable, and as she threatened to commit suicide she was closely watched. Active interference was postponed from day to day with the hope that this condition would cease as suddenly as before.

On May 8th, after a consultation with Dr. Joseph Price, an abortion was performed. For this purpose two rubber catheters were introduced to the fundus and allowed to remain, the vagina being packed with wool to keep them in place. On the 10th, twins —a boy and a girl—in separate sacs, and from ten to twelve weeks old, were delivered; the placental tissue was adherent; and on the 11th, without etherizing her (for she was in a very precarious state), it was detached with the aid of a curet. The uterus was thoroughly washed out with a solution of mercuric chlorid 1:4000. Although the vomiting, nausea, and ptyalism ceased immediately after the expulsion of the contents of the uterus, there was now such extreme prostration and emaciation as to make recovery exceedingly doubtful. Respiration was 50, the pulse 180, the temperature 102°. The treatment was now chiefly directed toward improving the strength, stimulants being freely ordered for the purpose. The woman continued in this

condition, with but slight variation in respiration, pulse, and temperature until May 16th, when she had a severe chill, her temperature rising to 104°. She complained of intense pain during urination and defecation, and a physical examination revealed a mass about the size of a hen's egg in the right broad ligament. Large doses of quinin were given her, and cantharidal blisters were applied to the iliac regions, with large douches of hot water for the vagina. An ice-bag was placed over the precordial region, as the heart's action was violent and rapid; this soon made an impression upon this complication. For several weeks following the abortion the patient had various delusions, and at times was so violent that it was difficult to restrain her and impossible to keep her in bed; but as time passed and she regained strength these gradually disappeared. She made a complete recovery in almost two months.

It seems remarkable in this case that after vomiting had once ceased and apparent recovery had taken place vomiting should have again recurred. I know that it is a physiologic law that the child goes on developing at the expense of the mother, no matter what her physical condition may be; but nevertheless I would offer this explanation, that in the absence of all nourishment for several weeks the fetuses developed very slowly, and therefore for a little while the cause of these nervous manifestations remained in abeyance, but as the nutrition of the mother improved and their development went on in a more vigorous manner the same conditions presented themselves. I am also of the opinion that if there had been but a single pregnancy it would have gone to full term as previously, but the reflex irritation, produced by the more rapidly developing uterus under the conditions mentioned, being so much greater, the nervous system could not resist it. At the seventh week of pregnancy the uterus was so much larger than one would expect at that period that she was told that she must be mistaken in regard to the time, *i. e.*, was further advanced than she thought, but she assured us positively that she was right, and of course the possibility of a twin pregnancy never occurred to us.

A CASE OF ANKYLOSTOMIASIS.

BY W. L. BLICKHAHN, M.D.,
OF ST. LOUIS.

CASES of ankylostomiasis (*Egyptian Chlorosis, St. Gothard Tunnel Disease*) are certainly rare, if not unknown, in the United States. I have been unable to find a record of a previous report of the occurrence of ankylostomum in this country.

The patient whose case I report is a German carpenter, a native of Oberhausen, near Essen, in the Rhineland, and had been a resident of America seventeen months when he came under observation at the St. Louis City Hospital.

I think there is but little doubt that he brought his parasites with him, as ankylostomiasis is not so rare in the region of the Rhine whence he came. It was at first thought that he had contracted his disease here, having been employed in a brick-works in St. Louis. He claims to have been in perfect health before coming here. He sailed from Bremen, landed in New York, and came direct to St. Louis, arriving May 1, 1892. His first employment was in car-shops, which he left to work in a brick-yard, where he was engaged in digging the clay. After several weeks' work his legs became sore, in consequence of what, from his description, seems to have been a pustular eczema, and he quit work. He began again in a lumber-yard, giving up the latter in a short while, as the labor was too heavy for him; he was then employed in a collar-shop.

During his first summer, and while working in the brick-yard, he suffered with digestive disturbances, ascribing his derangement to the use of ice-water, to which he was unaccustomed. His friends noticed that he began to lose the fresh and the rosy color that he had when he arrived. He felt tired and weak, but continued working, growing paler and weaker, having pains in his stomach and bowels, with variable appetite and frequent diarrheas until June 6, 1893, when he took to his bed, a little more than a year after his arrival and not quite a year from the beginning of his gastro-intestinal symptoms, which have continued up to date. He was treated privately until he entered the hospital at the end of the past September.

Parasites.
(Naked-eye appearance.)

Ova. (Zeiss, DD, oc. 2.)

My attention was called to him as an example of a case of extreme anemia the etiology of which was obscure.

Physical examination was negative, with the exception of pain on pressure just above the umbilicus. The man was extremely pale. He presented not a waxy or greenish or yellowish hue, but a simple pallor. He was not emaciated, the outlines of the body being well rounded, but he was extremely weak. His appetite was fair, and because of frequent severe pains after eating, especially solids, care was necessary in the selection of his diet. The bowels were variable; as a rule, the discharges were rather thin and varying as to frequency, the color usually brownish to black; there was no emesis, and no hemorrhage. There was slight edema of the right ankle. Urinalysis was negative. The blood was very thin—"800,000 reds to the cubic millimeter" was the memorandum in the case-record. I subjected the blood to a careful microscopic examination. No malaria had been suggested as the cause of the anemia. I could find no plasmodia. The blood resembled that of pernicious anemia. There was marked leukocytosis and poikilocytosis, and great variations in size of the red blood-corpuscles. There were many large mononuclear and multinuclear leukocytes, the lymphocytes being in the minority. The α and γ granulations (Ehrlich) were sufficiently numerous to awaken the suspicion of the case being one of myelogenous leukemia.

As intestinal parasites, especially the one under consideration, are frequent causes of extreme anemia, and as the examination of the stools had been overlooked, I secured some of the feces, which were quite fluid, and

the microscope very promptly revealed the presence of large numbers of the ova of the ankylostomum.

I presented the case to the Verein Deutscher Aerzte on October 13th, detailing the case and demonstrating the eggs.

An attempt to develop the parasite from the ova was unsuccessful, but a dose of filix mas furnished large numbers of the parasite, which varied from seven to fifteen millimeters in length, being less than a millimeter in diameter.

I examined quite a number of the worms, but found no males—those found seemed all to be females. Probably the next batch passed may have been made up more exclusively of males. This variation as to the predominance of one sex over the other has often been noted, the severity of the anemia seemingly being the greater when the female worm predominated.

The clinical picture of the case tallies fairly well with the clinical phenomena usually described: Extreme pallor, weakness without emaciation, the body being well-rounded (fat, not edema), some slight rise of temperature, gastro-intestinal disturbance, no kidney-complications, neither enlarged spleen (Völkers reports splenic enlargement in two out of three cases) nor liver.

A number of observers have noted hemoglobinemia, but no leukocytosis. The latter was marked in the case under consideration, as it was in a case reported by Fränkel, in which "the blood was leukemic, and at the autopsy the bones resembled the condition characteristic of myelogenous leukemia." The same was noted in a post-mortem record of Cohnheim (diagnosis: Pernicious Anemia).

It has been frequently urged, and all clinical microscopists and teachers advise, that in all cases of anemia the stools should be subjected to microscopic scrutiny. If the report of this case will awaken a more general interest in clinical microscopy, without which the diagnosis in this instance could certainly not have been made, it will have served its purpose. In looking over the literature I found information in an article in the *Reference Handbook of the Medical Sciences*, article Nematodes, vol. v, page 134, by Charles E. Hackley, to the effect that the diagnosis must be made by the symptoms, as neither the ova nor the parasites had as yet been found in the dejecta, though it was possible that a careful microscopic examination of the stools *might* reveal either. In this case, and so far as I can learn in all cases, ova are plentiful in the stools; the parasite, on the contrary, is rarely or never found except after the use of remedies used for their destruction.

Frequent examinations of the stools are necessary for weeks after a supposed cure, to be certain there are no ova and that the cure is one in reality.

For the privilege of examining and reporting this case I am indebted to Dr. H. Marks, Surgeon-in-charge of the St. Louis City Hospital.

Hospitals Acquire No Lien against a Railroad.—Medical attendance and board furnished by a hospital to an employé of a railroad company, who has been injured and disabled in its service, are not, according to a decision of the United States Circuit Court, "supplies necessary to the operation of the railroad," within the terms of a statute which gives a lien therefor.

A RENAL CALCULUS.

BY RICHARD SLEE, M.D.,
OF SWIFTWATER, PA.

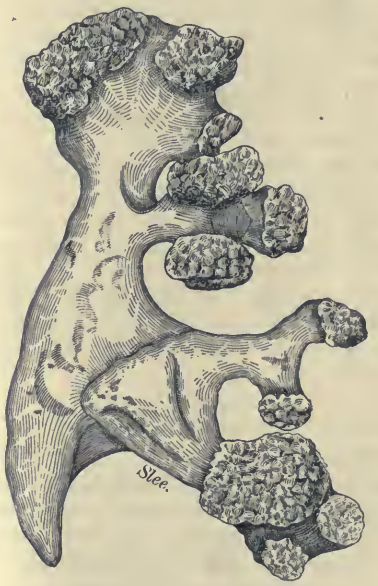
IN conducting post-mortem examinations pathologists frequently expose existing conditions calculated to make the surgeon sigh to think of the justifiable opportunity for surgical work *lost* through the absence in many cases of tangible symptoms.

The subject of this sketch is a fair example of such a case.

An Italian, about forty-five years old, was recently admitted to the Methodist Episcopal Hospital of Brooklyn, and placed in the First Surgical Division under the care of Dr. Louis S. Pilcher.

He was suffering from *old* prostatic and urethral disease. A tight urethral stricture had for many years given him considerable difficulty in micturition. At the time of his admittance he passed all urine through a number of perineal sinuses, and his general condition was exceedingly poor.

The perineum was perforated by a number of sinuses, extending in various directions, with pockets here and there containing urine, débris, and slough.



Extensive curetting was required to remove the sloughing tissues and place the parts in a condition to justify an expectation of repair. Operative interference was, however, a "forlorn hope" in his case, and he died several days later from asthenia.

The post-mortem findings of interest were confined to the genito-urinary tract, which was removed *en masse* for preservation. The urethra was found to be the seat of several strictures; one very low down was tight enough to prevent the passage of a filiform bougie. The prostatic body was entirely destroyed by the sloughing process; the bladder was perforated on its posterior surface near the neck, and through this opening the urine made its escape.

The bladder was greatly dilated, and its walls were

enormously thickened; the mucous membrane bore no resemblance to the normal structure, having large phosfatic masses of deposit scattered here and there over its surface, and being markedly necrotic where it was not the seat of this deposit.

The ureters were much thickened and dilated at all points, permitting the introduction of one's little finger, and presenting the appearance of an exaggerated varicose vein. Each was capable of holding about half a pint of urine.

In the left kidney was found an enormous calculus, from which I made the accompanying drawing (actual size), weighing 350 grains, and composed principally of calcium salts, with a spiral-shaped band of uric acid deposited on the body or the pelvic portion. The body of the calculus is dense in structure, while the branching processes formed in the calices are tufted with large crystals, the whole suggesting in its appearance a sprig of coral.

The horn-like projection at the lower extremity of the drawing was lodged in the upper extremity of the ureter, and the calculus was found in about the position shown with relation to the anterior abdominal walls.

The working portion of the kidney was entirely destroyed, the mass consisting almost entirely of fibrous tissue, which was tucked in and around the irregular surfaces of the stone and was firm enough to retain its shape after removal of the calculus. Some free pus was found in the pockets. The necrotic process, however, was not as active as one would expect from the size, shape, and structure of the calculus.

The left kidney was practically normal, save for a well-marked compensatory hypertrophy.

Renal calculi are by no means rare. This, however, seems rather an unusual one in size and shape, and, I think, worthy of record. Several that I have come across have been almost as large, but the deposits were chiefly confined to the pelvic portion of the kidney, and did not make as perfect a cast of the cavities of the organ as this.

MULTIPLE PAPILLOMATA IN A CHILD:

Tracheotomy at Four Years of Age; Retention of Canula Thirteen Years; Evulsion of Multiple Laryngeal and Pharyngeal Neoplasms; Closure of the Tracheal Fistule by a Cutaneous Flap; Recurrent or Repullulant Growth at the Anterior Commissure of the Glottis.

BY J. SOLIS-COHEN, M.D.,
HONORARY PROFESSOR OF LARYNGOLOGY, JEFFERSON MEDICAL COLLEGE.

THIS instructive and long-time neglected case was sent to my clinic in April, 1892, by Dr. Harter, of Maytown, Pa.

The patient, a girl seventeen years of age, but less fully developed than many a child of fourteen or even less, was completely aphonic, and was wearing a child's tracheotomy-tube.

Her story was that at four years of age, after suffering frequently with what was supposed to be croup, tumors in the larynx were diagnosticated by the late Dr. John Atlee, of Lancaster, Pa., than whom there have rarely been better surgeons. Dr. Atlee performed tracheotomy and inserted a double canula. This appliance was used for eleven years without any withdrawal of the outer tube by her attendants, when it was found to have become corroded. Then a new canula was inserted and this second one had not been removed up to the time the patient was brought to me. On removing it I found it so corroded that I deemed it imprudent to replace it, and therefore substituted another.

Laryngoscopic inspection revealed multiple neoplasms filling the upper portion of the larynx and extending along the laryngeal face of the epiglottis almost to its very tip. There were likewise a few multiple neoplasms at the base of the tongue, and along the pharyngo-epiglottic and glosso-pharyngeal folds.

The patient was admitted to the hospital, where my clinical aids, with some assistance from me, removed in a number of sittings all the morbid growths, chiefly with forceps; about a month being consumed in the procedures, and the voice returning in a satisfactory manner both for conversation and for singing.

After waiting for a few weeks, without noting any evidence of recurrence or repullulation, I removed the canula definitely at the end of June, and sent the patient home with directions to report in October, when my clinical services at the hospital would be resumed.

When she returned there was still no evidence of recurrence. The fistule in the neck, however, was as large as ever, and I determined to close it with a cutaneous flap. So on October 7th, before my clinical class, I dissected out the cicatricial tissue around the fistula, so as to leave an oval section in the integument, with bevelled edges from without inward. A flap of integument was then raised from over the sternum, and so bevelled on the edges that when the flap was turned up, skin-surface inward, its edges would fit into the bevelled seat prepared for it around the fistula, somewhat like a stone is set in a piece of jewelry. The parts were carefully stitched as far around to the pedicle of the flap as possible. The fat of the flap was then snipped away with scissors, and the raw flap was dressed with sulphuric ether so as to dissolve any remaining fat during the healing process. The wound in the tissue from which the flap had been raised, and which had gaped widely by retraction during the fitting of the flap in its new and reversed position, was drawn together with sutures, except a triangular portion superiorly and just beneath the pedicle of the inversion, and which had to be left to heal by granulation.

The flap adhered well and thoroughly to the parts to which it had been stitched, and there was no necessity to release the pedicle to fill in the gap in the healthy tissues. Nature's unaided efforts were sufficient to cause absorption of the exuberant duplicature at the pedicle, and to gradually skin the raw surface of the flap with cicatricial tissue, so that there was no further occasion for professional supervision at the end of a month, when the patient was dismissed with instructions to report at the end of a year, or sooner, should anything untoward occur.

On October 17, 1893, the patient reported at the clinic very much improved in appearance, and with a clear voice of greatly increased volume. She had gained ten pounds in weight. The cicatricial tissue over and around the position of the fistula was in excellent condition, and except for a glossy aspect was not notably distinguishable from normal integument.

On examining the larynx, I detected a small, red, pedunculated pyramidal growth, about the size of a small pea, at the anterior commissure of the glottis and hanging below the vocal bands so that it did not interfere sufficiently with phonation to produce hoarseness. The voice, indeed, was shrill rather than deep. Whether this was a recurrent growth, or a repullulation from fragments left in extracting the growths the year previously, cannot be determined. It might be of either, but was probably of the latter character. It had occasioned no symptoms whatever indicative of laryngeal disorder. This little growth was readily removed with forceps.

MEDICAL PROGRESS.

Exophthalmic Goiter Fatal after Extirpation of the Uterus during Pregnancy for Fibromata.—BROOMALL (*New York Journal of Gynecology and Obstetrics*, vol. iii, No. 11, p. 978) has reported the case of a woman, thirty years old, pregnant for the second time, who presented protrusion of the eyeballs, tachycardia and bronchocele, with insomnia, headache, and dyspnea. Some of the bones, but not the pelvis, displayed evidences of rhachitis. Examination disclosed the presence of many small nodules in the walls of the uterus, and of one large fibroma near the fundus, while the pelvic cavity was occupied by a round, firm body, having its attachment to the cervix, and preventing the recognition of any portion of the fetus *per vaginam*. The pregnancy had advanced to the seventh month. The patient suffered a good deal from attacks of vomiting, accompanied by dyspnea and irregularity and rapidity of action of the heart. In the course of a month her condition had become alarming, all of the symptoms being aggravated, and the general suffering increased by painful uterine contractions. During the development of the lower uterine segment the resistance of the cervical fibroma excited the uterus to painful spasmodic action, with the result of forcing the tumor lower down in the pelvic cavity, and causing complete obstruction to the descent of the fetal head. As the condition of the patient demanded immediate relief, and as delivery through the natural passages was considered out of the question, extirpation of the uterus was decided upon and carried out. The child was asphyxiated, and died after half an hour. During the extraction of the fetus, uterine hemorrhage was prevented by manual compression of the cervix; after delivery, an elastic ligature was substituted for the fingers of an assistant. Later, in the adjustment of the serre-neud, it was found that the cervical fibroma could not be drawn above the constricting cord, and that the pedicle was too thick. As the patient would have been exposed to the danger of infection if the tumor were allowed to remain partially constricted by the serre-neud, or to the danger of hemorrhage if the temporary tourniquet were relaxed sufficiently to permit of the enucleation of the growth, the peritoneal covering was slit below the elastic cord, the cut edges of the peritoneum caught, and the tumor enucleated without much difficulty. The surrounding peritoneum and connective tissue were then drawn above the serre-neud and made part of the stump, which was slender and long enough to be brought out at the lower angle of the abdominal wound. Though the loss of blood was not excessive, and the symptoms of shock not greater than usual after similar operations, the action of the heart was feeble and rapid. The woman did fairly well until the nineteenth day after the operation, when she suddenly became very restless and complained of severe pain in the epigastrium. The pulse was rapid and feeble, and death occurred on the following day. Upon post-mortem examination the abdominal wound was found firmly united, with slight suppuration around the stump, and a few drops of pus in an abdominal stitch-sinus. There was no peritonitis, and only slight adhesion between the omentum and the stump. The kidneys and liver were normal. The heart was large; its walls thinned; the endocardium injected; but there was no valvular defect and no heart-clot. Death is ascribed to the primary disease, exophthalmic goiter.

Hemorrhagic Pachymeningitis, with Focal Epilepsy.—EUSTACE and PARSONS (*Dublin Journal of Medical Science*, November, 1893, p. 369) have reported the case of a man, twenty-eight years old, who for a year had suffered from attacks of petit mal and manifested some symptoms of paretic dementia. His father suffered from paralysis agitans, a sister was hysteric, and an uncle had died of syphilitic general paralysis of the insane. It was certain that the patient was not addicted to alcohol or sexual excess; nor had he contracted syphilis. There was a vague history of a blow upon the head during childhood, but medical attendance was not required, and no scar could be found. On one occasion the patient had attempted to injure his sister with a pruning-knife. The man appeared intensely happy, was garrulous and seemed pleased with his surroundings, and did not appear to find the restraint of asylum-life irksome. He was vain and boastful, but apparently in good physical health. While under observation he had a convulsion in which he turned pale and suddenly fell to the floor, the left arm and leg being more actively moved than the members on the right side. The left side, and particularly the arm and the leg, was bloodless, cold, and paralyzed. The probability of the existence of a tumor affecting the right hemisphere of the brain was discussed, but the signs were not deemed sufficient to warrant operative interference. The convulsive attacks were repeated during the subsequent two years, despite the administration of bromids and other treatment. The patient believed that he could ward off an attack by the use of antipyrin, or by tying a string around his left wrist. He also believed that sitting near a fire or in a very warm room induced an attack. The attack proper was preceded by a premonitory stage, lasting four or five minutes, though sometimes this occurred without being followed by an attack. The left thumb, as a rule, commenced to twitch first. The convulsive stage varied greatly in intensity and duration, lasting from two to fifteen, or even thirty minutes. The pulse during this stage was small and hard, but as soon as the man passed into the comatose stage the pulse became full, rapid, and bounding, increasing from 60 or 70 to 100 or 110, and the frontal arteries stood out like thick cords. In the attack there was conjugate deviation of the eyes to the left. The post-paroxysmal stage lasted from a half-hour to two hours, or even longer. The man's condition fluctuated from time to time, but at the end of two years the

right side of the body became paralyzed following a convulsive seizure, aphasia developing after some subsequent seizures. From now on the condition of the patient became progressively worse. The dementia became more profound; control of the sphincters was lost; the pupils were closely contracted; the reflexes were exaggerated. Finally, bedsores developed, and an attack of pneumonia led to a fatal issue. Upon post-mortem examination an extensive hemorrhagic membrane about three-sixteenths of an inch thick was found covering the whole of the left cerebral hemisphere, with the exception of the base, while the right hemisphere was covered by a similar membrane, though of greater thickness in places, the posterior portion of the frontal and parietal lobes being flattened and softened by the pressure of the membrane.

Changes in the Spinal Cord in the Course of Pernicious Anemia.—In fatal cases of pernicious anemia which during life presented no disorder of the nervous system, MINNICH (*Zeitschr. f. klin. Med.*, B. xxii, H. 1, 2, *Centralb. f. klin. Med.*, 1893, No. 43, p. 914) has found after death changes of two varieties. The one consisted in capillary hemorrhages in the spinal cord, with their sequelæ, miliary scleroses. These hemorrhages are analogous to the retinal hemorrhages that take place under like conditions. The second group of cases were characterized by peculiar areas of softening. Similar changes were also found in cases in which death had resulted from nephritis, icterus gravis, and leukemia. These areas microscopically presented profound changes, which could be traced from the simple swelling of the nerve-fibers to accumulations of disintegrated tissue. It is pointed out that if this variety of softening exist in association with true primary spinal degeneration, it may obscure both the clinical and the pathologic picture. It is further believed to be not impossible that the occurrence of this (hydropic) degeneration, in the course of severe diseases, may furnish the basis, subsequently, for true degenerative processes in the spinal cord. Control-observations showed that the alterations found were not the result of artefacts, or due to post-mortem change.

Curetting of the Trachea for the Relief of Diphtheric Obstruction.—SCUDDER (*Boston Medical and Surgical Journal*, 1893, No. 19, vol. cxxix, p. 465) has reported the case of a boy, four years old, in which tracheotomy was performed early on account of increased difficulty in breathing. All went well until the second day after the operation, when the secretion from the tube became a little sticky and slightly diminished in amount. On the third day there was serious trouble. The secretion became still less, the respiration rapid and labored, and the child cyanosed and exhausted. All of the ordinary measures failing, a dull-wire curet that happened to be at hand was introduced into the wound and gently carried to the bifurcation of the trachea, and all sides of the passage were systematically and thoroughly curetted. In the progress of the operation pieces of membrane, one of which made a complete cast of the circumference of the trachea, were withdrawn through the wound. The hemorrhage was slight. The relief to the dyspnea was immediate. The tube was replaced and the child made an uninterrupted recovery. One or two additional pieces of membrane came away on the following day. The child was well and strong two years later.

THERAPEUTIC NOTES.

Spinal Drainage in Acute Meningitis.—PAGET (*Lancet*, No. 3658, p. 873) has reported a case of acute meningitis in a boy eight years old, attended with vomiting, drowsiness, restlessness, abolition of knee-jerks, retraction of the head, occasional strabismus, dilatation and immobility of the pupils, swelling and blurring of the optic discs, incontinence of the sphincters, and marked wasting, in which the dura mater was freely opened between the fourth and fifth cervical vertebræ, a horsehair drain introduced, and the wound closed around it. The operation gave relief for one day, but death ensued four days after the operation. Upon post-mortem examination accumulations of fluid were found in the middle and posterior cerebral fossæ, and the convolutions were greatly flattened. The third and fourth ventricles contained an excess of fluid. The pia mater at the base of the brain was infiltrated with sero-purulent lymph and showed a few minute tubercles. The opinion is expressed that the general swelling of the brain that existed was the chief cause of death, and the suggestion is made that it might be advisable in a similar case to make a free opening into the vault of the skull after incising the dura of the cervical spine.

Subcutaneous Infusion in Eclampsia Gravidarum.—PORAK (*Lancet*, No. 3658, p. 901) reports the successful treatment of a number of cases of puerperal eclampsia by means of subcutaneous injections of a saline solution. A quart of sterilized water, to which from a dram and a half to two drams of sodium chlorid have been added, and at the temperature of the body, is slowly injected into the buttock by means of a hand apparatus or a fountain syringe, and absorption is facilitated and favored by gentle massage. Of eight cases thus treated recovery took place in six. In one of the cases that terminated fatally the patient was moribund when she came under observation, and the other died at home, whither she had been taken contrary to medical advice.

For Gastric Ulcer.—

"CRANKS."

THE recent assassination of the Mayor of Chicago has renewed public interest in the features of homicidal mania and has led to considerable miscellaneous suggestion on the part of laymen, especially through the press, as to the methods of dealing with such dangers. In all this discussion one may distinguish much evidence of feeling and desire for the administration of commensurate punishment, with but little logical consideration of the subject or even knowledge of the conditions that lead to the acts. The non-medical portions of the community, unfortunately very largely the lawyers and newspaper people, do not appreciate the nature of delusional diseases, do not realize the frequency of instances in which men lose all sense of responsibility, and under which they are regardless of possible harm to themselves. Swift and even cruel methods of punishment may have their value. The court of Judge Lynch may not be without a certain usefulness in a wild section, just as the summary proceedings of a court-martial are universally regarded as befitting an actual state of war, but the majority of people do not understand that measures which appeal to the fears of evil-doers cannot be felt by those who are driven by an overpowering delusion. The murder of GARFIELD aroused the nation to the highest pitch of resentment. At the time of the trial the theory of GUITEAU'S insanity was rejected by most persons, yet at the present time it is generally accepted. The line that separates such deluded persons from the criminals proper is a distinct one and has long been recognized by alienists. The community, however, pays almost no notice to homicidal maniacs until some shining mark is struck down, when a wave of discussion passes across the land, soon subsiding into indifference.

These problems cannot be rationally discussed except from medical standpoints. Until our jurisprudence awakens to the consciousness that these acts are the result of disease, bringing the victim into the domain of irresponsibility, no adequate measures will be secured. Learned judges are not infrequently the most serious obstacles to a scientific consideration of these questions. Precedent goes for much in law, and principles laid down by chief justices generations ago are cited in opposition to the scientific demonstrations of physiology and pathology. In a case tried some years ago in this city a defence of insanity was justly set up, and the trial judge, one of the most learned and just of judges, said, in comment on the statement of an expert, "Well, that is the kind of insanity we hang for in Pennsylvania." This reply evinces the difficulty in utilizing the scientific knowledge now at hand.

It is, however, not merely with the more flagrant cases of delusional mania that a reform is needed. Authorities are too indifferent toward milder forms which may lead to many petty annoyances, crimes of less note, or ultimately to murder. It is not unnatural that, in a community in which freedom is the watchword, every guard should be thrown around the citizen to secure to him his liberty, but an extreme sensitiveness in this respect leads to danger. So great has been the popular feeling on the question of the possibility of confining sane persons in asylums that the machinery of the law is easily invoked to secure the discharge of the moderately insane. Juries frequently adjudge a man sane concerning whom competent expert testimony has demonstrated insanity. Moreover, in such cases the experts are likely to be criticised severely, even abusively, by the newspapers, and hence hesitate to speak as freely and as often as they might. The murderers of GARFIELD and HARRISON belong to a class of persons very numerous, but exhibiting many grades of disease, from violent delusions tending to homicidal acts to mere feelings of distrust of those with whom

they are most nearly associated. Not until all these cases come to be regarded as objects for diagnosis and treatment in the hands of the medical profession as absolutely as any other disease, will they be properly assigned. How absurd would it be to submit to an ordinary jury the determination of the question as to the existence or non-existence of diphtheria, carcinoma, or brain-tumor. In earlier days when mankind believed in demoniac possession, when the nature of insanity was not known, and when great danger existed of the unlawful confinement of persons, we can appreciate the value of the writ of *habeas corpus* and the right to a traverse before a jury, but our knowledge of mental disease is now enriched by scientific methods, and no such dangers can ensue.

The whole question is, therefore, not one for lawyers but for doctors, and it is hoped that in default of uniform methods by the States themselves some means may be found to secure national legislation that may eliminate from our courts methods of procedure that grew out of ignorance. It is also desirable that the community at large shall awaken to the necessity of providing means and methods of restraint for delusional maniacs of all grades and, among other efforts, aim to prevent the propagation of such defective strains.

THE TRANSMISSION OF ENTERIC FEVER BY WATER.

THERE can be no question that the most frequent mode of transmission of enteric fever is through the intermediation of the water-supply. Next in frequency is the milk-supply, but this may ordinarily be included in the first, because there is nothing peculiar to milk itself or its source that should make it a carrier of infection, apart from procedures concerned in its manipulation and distribution. This contamination of milk need not necessarily be a result of premeditated adulteration or dilution, but may take place from the legitimate use of water for purposes of ordinary cleanliness. Besides, the possibility of direct contamination of milk through an infected person must also not be ignored. Other possible channels of communication are infected ice, infected vegetables, and defective sewerage or plumbing.

SEDGWICK and CHAPIN[1] detail an analysis of an epidemic of enteric fever in the city of Springfield, Massachusetts, and SEDGWICK[1] reports the results of an investigation of an epidemic of enteric fever in Somerville, Massachusetts, both of which upon careful inquiry were found to be due to infected milk. In the first instance the cases occurred in one of the best parts of the city from a sanitary point of view, but among families supplied with milk from a common source. Some little difficulty was at first experienced in tracing the ultimate channel of infection, but upon persistent and diligent investigation it was found that some cases of enteric fever had occurred at the dairy whence the suspected milk was derived. It was learned that for purposes of preservation the not quite full cans containing the milk were for a time submerged in a well that there was ample reason to believe had become contaminated by the dejecta from the cases of enteric fever, and it was further found that these cans were not so hermetically closed as to prevent the entrance of water. The number of cases discovered and investigated in this epidemic was 150, and the number of deaths 25. Of the whole number 101 had directly received milk from the incriminated source, while 34 others had access to the same milk.

In the second instance reported it was at once discerned that the cases also occurred particularly among the customers of one milkman. Further investigation disclosed that a son of this man who participated in the handling of the milk-cans, if not of the milk itself, had an attack of enteric fever, at first unrecognized, and throughout a large part of which he had continued at work; and it is reasonably surmised that he in some more or less obvious manner was the medium of infection. Thirty-two cases were traceable to this common cause. Of this number thirty had been supplied with or had access to milk supplied from the suspected source.

These two reports, the essence of which we have here reproduced, illustrate admirably how difficult it sometimes is to trace a source of infection, and they reflect great credit upon those who undertook and carried the investigation to a successful issue.

Many similar reports have been published, and the data are abundant showing the intimate relation between the spread of enteric fever and contamination of the water-supply and of the milk-supply, and we shall only further briefly refer to the report by DABNEY (THE NEWS, December 2, 1893, p. 630) of an epidemic of enteric fever involving fourteen

[1] Boston Medical and Surgical Journal, vol. cxxix, No. 20, p. 485.

[1] Ibid., p. 489.

students in the University of Virginia. These lived in different parts of the institution, but all took their meals at the same hotel, one of the employés of which was found also to be ill with enteric fever. There was nothing about the hotel itself to account for the sickness, but it was learned that a part of the milk-supply was derived from the dairy of the keeper of the hotel, and further investigation disclosed the fact that the udders of the cows from which the milk was obtained were washed with water obtained from a creek into which a sewer emptied at a point above the dairy and, in addition, into which probably the dejecta of a previous case of enteric fever, thrown on the ground and not disinfected, had been washed.

There seem to be but a few words to add, but the importance of these cannot be exaggerated. They are that *if all water and all milk used for personal and domestic purposes were sterilized enteric fever would soon disappear.* An approximation to this desirable end is attainable in a rigid scrutiny of the water-supply and legislative supervision of the milk-supply. The benefits of such protective measures would apply not only to enteric fever but also to scarlatina, to diphtheria, to cholera, perhaps to malaria, and probably to other infectious diseases.

ELECTRIC TRACTION AS A SANITARY MEASURE.

If it be true that misfortunes come unexpected and unbidden, "like a thief in the night," it is also true that blessings may come similarly. We do not always realize the full value of inventions until long after they are in practical operation. It seems that certain recent advances in the mechanical world are already giving evidence of benefits far more extended than was contemplated or expected at their introduction.

Electric traction is no longer an experiment, and we can foresee that it is destined to modify very largely social and commercial relations, especially of rural life. It affords a method of reducing the isolation and fixedness which is so unpleasant a feature of the farm, and which has operated so unfavorably on the mental development of its inhabitants, even according to some statisticians materially increasing the amount of insanity.

At the present time one of the large American cities is undergoing a transformation of its methods of surface transit probably more extensive than has ever occurred in a similar area, and already there is enough accomplished to show that the new conditions will result in unexpected and uncontemplated advantages. The nature of the electric motor is such that the cars operated by it are heavier than the common horse-car; this has necessitated a complete reconstruction of the tramways by the laying of a heavier and firmer rail with neater joints. This will result in firmer movement, even if swifter, and will be less fatiguing on the regular rider. Those who are obliged to ride frequently on common tramways find this fatigue no small inconvenience.

The municipal government has, however, in granting the "trolley" privileges, secured a repaving of the streets, and here has been a material gain to city sanitation. Notably, is the employment of the asphalt surface an advantage. It is, however, to be kept in mind that unless this improvement in the construction of the roadway is supplemented by greater attention to cleaning, the change may be a source of more harm than good. Asphalt and well-laid granite block pavements are practically non-absorbent. Hence, all refuse, especially the manurial refuse, which is so abundant on business streets, must be systematically and promptly removed, or it will become dry and be carried everywhere. Our advancing knowledge of the causation of disease shows us that some of the animals that mankind has for ages subjected to his government are his greatest enemies. There is a well-founded suspicion that the cow is the main distributer of one of the most widely fatal of diseases, and incidentally of other forms, and it is not unlikely that the droppings of horses so liberally supplied on our city streets are sources of contagion and infection as yet unrecognized. Now, the country road built "on Adam's plan, and not MacAdam's," is an absorbent surface; the soil acts as a disinfectant for all decomposing organic matter. To secure, therefore, the benefits of our non-absorbent pavements, they must be cleaned thoroughly and repeatedly, not by sweeping, but by flushing into the sewers every night, or at least by such methods as will insure the complete removal of all dirt without allowing it to be raised in clouds to be inhaled by those passing or to settle on every level surface.

Incidentally, however, the coming of electric traction will relieve us of some of these dangers, for it will materially diminish the number of horses working on the streets, and gives us hope that the day is not far distant when lifeless motors will

do all the work in our cities, whether for business and pleasure, and the horse, with his essentially unclean habits, will be relegated to the open country.

Further are to be noted benefits to the health of the citizen by the advance in his comfort that will result from a swifter, smoother, and more commodious method of transit, better lighted cars, and the abolition of the enormous stables, reeking with the offensive odors of horse-manure, and infested with all manner of vermin. The improved condition of the streets will go far also to prevent the filthy condition of the car floors; and if, in addition, a forcible public sentiment can once operate against the spitters, surface travel will be an approach to enjoyment.

LEAVE THE CODE AS IT IS!

THE MEDICAL NEWS finds it necessary to say a few more words on the Code question in order to make its position clear. We still believe the course outlined by us in various editorials, and especially in the issues of September 17, 1892, and January 28, 1893, to be the best possible permanent solution of the Code question.

Realizing, however, that under existing circumstances this course cannot be successfully entered upon, we now announce ourselves as definitively against revision. We prefer the Code as it is to any amendment suggested publicly or privately, officially or unofficially, that seems to have any prospect of passing.

Except in one particular, the Code does not interfere with the comfort, prosperity, or freedom of any *honest and honorable* physician—for no such physician desires to do anything the Code inhibits. In the one particular referred to—namely consultations with sectarians and quacks—the few honest physicians who find the Code opposed to their sincere judgment, must yield to the will—the just and proper will—of the majority. For reasons unnecessary to repeat, that prohibition must be maintained. There is no discussion of the Code that has not been aroused by its opponents, and if these will cease their unwise agitation there will be nothing to interfere with scientific business at the meeting of the American Medical Association. Let our united efforts, then, be made on behalf of the honor and dignity of the profession as represented in "the Code as it is."

EDITORIAL COMMENTS.

A Few Little Incidents of Foot-ball.—The *Lancet* has long made it a custom to chronicle the inconsiderable mishaps that occur from time to time on the foot-ball field, and Dr. Amidon, of New York, has taken the pains to make a list from the *Lancet's* reports of those that came to the notice of the editor in the year 1892. How many casualties escaped notice cannot be told. In this year twenty-three deaths occurred in England that were directly traceable to foot-ball. Those indirect ones that occurred subsequently, or that will occur, are left for future historians. Here is Dr. Amidon's little list of the English accidents requiring hospital treatment:

Nature of Injury.	No. of Cases.
Concussion of brain	3
Injury to the head	1
Injury to the nose	1
Fracture of the nose	1
Fracture of the jaw	1
Fracture of the collar-bone	20
Dislocation of arm	1
Compound fracture of arm	3
Fracture of arm	5
Bad fracture of left arm	2
Serious injury to arm	1
Compound fracture of the elbow	1
Fracture of left wrist	1
Fracture of ribs	3
Severe sprain of thigh muscles	1
Fracture of thigh	3
Injury to leg	1
Fracture of leg	29
Bad fracture of leg	1
Compound fracture of leg	5
Fracture of knee-cap	1
Severe injury to knee-cap	2
Fracture of ankle	3
Dislocation of ankle	1
Sprained ankle, muscles, and tendons severely wrenched	1
Severe injury to foot	1
Fracture of spine	1
Serious injury to spine	1
Serious injury in groin	1
Severe internal injuries	2
Severe internal injuries, fatal in two days	1
Fatal abdominal injuries	6
Undescribed accidents followed by death	3
Undescribed accident followed by lock-jaw and death	1
Total number of grave injuries	109

For the year 1893 the returns are not yet in. In the *Lancet* of November 18th, there are recorded, as occurring during the preceding week, three cases of fractured leg; one of kick in abdomen, with death; one of concussion of spine; one of fractured clavicle; one of injury and death. This year, therefore, there have been at least twenty-eight deaths in England.

English and American Foot-ball.—Since our last issue at least two more deaths have occurred in this country from foot-ball, bringing the known total for this season up to seven.

It has been said by the enthusiasts that the English game and the American game are as different as croquet and prize-fighting, the inference being that croquet-like foot-ball is the American style of the game. In this way it is hoped the shock of responsibility will be lessened and the fact explained of the relatively lower mortality of the American game. But a moment's dispassionate reflection shows the argument to be a vexatious boome-

rang. There can be no doubt that for every ten games played in the United States there are a hundred played in England. This is a very conservative estimate. It does not need much statistical training to deduce from this fact the obvious result that if the brutal game in England kills only twenty-eight persons, while the croquet-like American game kills seven, then when ten times as many shall play the game here, our croquet-like death-rate will be at least seventy. Moreover, if, as has been averred, the brutal English game is at least ten times as brutal as our game, then, —— but we forbear!

There seems to be some justification for the saying that the difference in method between the two styles of game is that in England the rule is, "If you can't kick the ball, kick the man;" with us it is, "If you can't kick the man, kick the ball."

Of course every one knows that the cause of the greater English mortality is chiefly due to the fact that in England a larger proportion of non-college men play, miners, clerks, the unsound, untrained, everybody. The game itself is essentially the same. The greater risk, injury, and death-rate come to the untrained player. It is often remarked that the deaths do not occur here in our larger college professional teams, and precisely for the same reason. This gives occasion for the saddest thing about this whole controversy, the cold-blooded indifferentism of the foot-ball enthusiast to the injury done the inexpert, unprofessional, plebeian imitators of his example. The wrong done the community is nothing to him. But some of the college authorities still make at least pretense of Christian belief and practice. To them we would commend for rumination a principle enunciated in I. Corinthians, viii, 13.

The Infectiousness of So-called Membranous Croup.—We have on a previous occasion (see THE NEWS, July 23, 1892, p. 100) referred to the intimate relationship, if not actual identity, of so-called membranous croup and diphtheria. Confirmation of the position then taken by us comes in the form of a public announcement by the Health Department of the city of New York. The Chief Inspector of the Division of Pathology, Bacteriology, and Disinfection of the Department, Dr. H. M. Biggs, reports that of thirty-six cases of so-called membranous croup in which a bacteriologic study was made, the bacillus diphtheriæ of Loeffler was found in thirty. In all of the cases "the membrane was either confined entirely to the larynx, or at most only slight deposits existed in the throat, while there was very extensive exudation in the larynx." In six cases no diphtheric bacilli were found. These must, therefore, be considered as instances of catarrhal pseudo-diphtheric inflammation of the larynx, analogous to similar non-diphtheric pseudo-membranous inflammations of the pharynx. Five of the cases in which the bacillus of Loeffler was found were both preceded and followed within a week by other cases of pharyngeal diphtheria in the immediate vicinity; three cases were preceded by cases of true diphtheria; and seven cases were followed by other cases of diphtheria. The remaining fifteen cases were neither preceded nor followed by cases of diphtheria in the immediate vicinity. In accordance with the results of the investigation as here summarized, the Commissioner and Chairman of the Sanitary Committee of the Board of Health of New York City, Dr. Cyrus Edson, requests physicians "to report cases of membranous croup under that name, in the same manner that they report cases of contagious disease. The data already obtained are sufficiently convincing to cause this request to the profession to treat membranous croup as a contagious disease; that is, to advise isolation and disinfection, the same as in a case of diphtheria."

Chronic Nephritis without Albuminuria.—That the mere presence or absence of albumin, and the detection of or failure to detect the presence of tube-casts in urine, are not safe guides in the diagnosis and prognosis of chronic disease of the kidney, degenerative or inflammatory, would seem demonstrated by the results of a careful study detailed by STEWART (*American Journal of the Medical Sciences*, December, 1893, p. 654), who records a group of illustrative cases in which the presence of albumin could not, as a rule, be demonstrated, while tube-casts were only occasionally found. The symptoms to be looked for in cases of this kind are rather heightened arterial tension, with accentuation of the second sound of the heart, and a tendency to cardiac enlargement, diminished secretion of urine, and deficient elimination of nitrogen, headache, vertigo, breathlessness, impaired vision, and retinal changes.

In any case in which insidious changes in the kidneys are suspected and the presence of albumin and tube-casts is not demonstrable by ordinary methods, repeated examinations of the total twenty-four hours' urine should be made. The search for casts may be facilitated by centrifugation. Attention should also be directed to the quantity of urine excreted and the amounts of solids contained, particularly of urea and uric acid. The value of these observations resides in the fact that early recognition of the condition is essential to the attainment of the best therapeutic results.

The Ethics of Foot-ball.—Among the multitude of congratulatory letters received by THE NEWS as to its criticisms of foot-ball there have been a few from men whom we and the world delight to honor, urging that while the physical effect is as pernicious as we have contended, the moral and educational influences of the game are far worse than the physiologic effects, and that to these aspects the most attention should be directed. In reply we can only suggest that as a medical journal our province in this connection is chiefly surgical and hygienic, and that only so far as the moral and educational effects are bound up with, and exercise influence upon, the health of the community and the good of medical education, so far must the physician's criticism and domain extend. Those great guardians of the morals of the community, the lay-newspapers, have their chosen field undisputed. To them may be left the questions of the encouragement of betting, drinking, and general rowdyishness by the public professional games, and their evil influence on social progress and morals. The universities also should have a chance for a word. To them may be left the consideration of the lessons to be derived from whole pages of remarkable reports of the various "Thanksgiving" (*sic*) games as published in the great New York papers of December 1st. It is a most lamentable dis-

grace, this of our educational institutions, for advertising purposes going into the business of public amusement-furnishing, and encouraging public contests that the "sporting editors" of daily papers say are more dangerous and debasing than "glove-contests." It is enough for us that at every game there must be ambulances and a corps of surgeons, nurses, rubbers, etc., in waiting, to emphasize the medical and surgical aspects.

The Relation between the Testicles and the Prostate.—Apropos of the proposal to remove the testicles for the relief of prostatic hypertrophy, REGINALD HARRISON, in a communication to the *British Medical Journal* of September 23, 1893, relates the case of an elderly man with symptoms of increasing urinary obstruction, who, a number of years ago, importuned him to perform castration to prevent further growth of the prostate gland. The proposition was declined, but, by way of compromise, subcutaneous division of the vasa deferentia immediately below the external abdominal ring, where they are to be easily and safely reached, by means of a tenotome, was practised, first upon one side and then upon the other, at an interval of a few days. The further progress of the case is not known, other than that the patient was living and well six or seven years after the operation. If atrophy of the testicles will be followed by atrophy of the prostate, and if division of the vasa deferentia will lead to atrophy of the testicles, there are numerous and obvious reasons why the simple operation should be preferred to actual castration.

In the same connection POWELL (*British Medical Journal*, November 18, 1893, p. 1099) reports the case of a man, sixty-five years old, under treatment for prostatic enlargement, whose right testicle was removed on account of the presence of a neoplastic nodule. The left testicle was small and probably useless. The urinary symptoms soon disappeared, and examination some time later showed that the prostate was much reduced in size.

An Analysis of 1300 Errors of Refraction.—One of the most valuable things in medicine is a philosophic and detailed analysis of a large clinical experience in a specialized line of work. Such a bit of good work comes to us from Dr. W. F. Southard, of San Francisco, entitled *The Modern Eye*. With painstaking care, Dr. Southard has collated the statistics of his refraction-work and deduced therefrom many valuable lessons, mention of which we regret that want of space compels us to forego. The monograph (reprinted from the *Pacific Medical Journal*) is admirably outfitted with tables and charts that will be useful to all ophthalmic surgeons. One of the lessons, old it is true, but most sadly neglected, is the intimate association of low refractive errors with intense reflex disorders. "It would seem that no further argument is needed to show the necessity of correcting every such error."

SELECTION.

SOPHISTICATION OF "ANIMAL EXTRACTS."

To the Editor: In your issue of August 26th you published a communication of mine on Hammond's cerebrin, in which the presence of nitroglycerin was suspected.

The results of my chemical examination of that article, also of a bottle of Hammond's medullin, showed how well founded was that suspicion.

A few weeks later Dr. Hammond made public a reply, the essential part of which is that I could not have analyzed the genuine article, since I failed to find alcohol and boric acid in it.

Such a way to meet the issue was so weak, under the light of my statement of the true object of my investigation, that I was contented to let the matter rest without any further remarks.

Since then I have seen a circular issued by the Columbia Chemical Co., the manufacturers of Dr. Hammond's animal extracts, which says that I failed to find water, alcohol, boric acid, and animal matter in the samples examined by me.

Therefore the trade is warned that unscrupulous dealers get empty bottles of Dr. Hammond's products, and fill them with some dangerous imitation, and palm them off as the real article, out of pure deviltry evidently.

Let us bring back the question on its true ground. I never pretended to publish a complete analysis of Dr. Hammond's cerebrin and medullin, because that was unnecessary.

The only question for me to solve was whether the physiological effects of the two articles are due to some extraneous matter, namely, nitroglycerin, or to some ptomaïn.

A priori, there was a faint possibility that a six months' maceration of brain-matter might be attended with the production of *neurin*, or neurin and *cholin*, possibly *muscarin* also.

Those three alkaloids have decided and powerful physiologic properties, not entirely unlike those of nitroglycerin. The general tests for alkaloids failed to show their presence.

On the other hand, I obtained decided reaction, characteristic of nitroglycerin, or, I added, some other closely allied substance (some nitrite for instance).

Since the publication of my first note, I examined with exactly the same results, another *unbroken package* of cerebrin.

The original bills seen by me, show that the three samples were sold by the Columbia Chemical Co. (New York), to Messrs. Lehn & Fink (New York), who forwarded it to Messrs. Gale & Blocki (Chicago), from whom I received it unopened.

With high regard, M. DELAFONTAINE.

—*The Journal of the American Medical Association.*

Dr. Henry Leffmann, Professor of Chemistry and Toxicology in the Woman's Medical College, Philadelphia, chemist to the State Board of Health of Pennsylvania, Eastern District, a man whose character and scientific reputation are beyond all question, recently examined a sample of cerebrin obtained from the Columbia Chemical Co., of New York, by a well-known drug house, and delivered at his laboratory in the original package, bearing across the label of the three-cornered bottle the *fac-simile* of Dr. Hammond's signature. The quantity of material in a single sample is quite small, but Dr. Leffmann was able to get reactions for boric acid, glycerol, nitrates, and nitrites. He has, therefore, reached the same conclusions as Prof. Delafontaine.

ORIGINAL ARTICLES.

THE TREATMENT OF EXOPHTHALMIC GOITER.[1]

BY J. MADISON TAYLOR, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF CHILDREN IN THE PHILADELPHIA POLYCLINIC, AND IN THE MEDICO-CHIRURGICAL COLLEGE; NEUROLOGIST TO HOWARD HOSPITAL, ETC.

FIVE years ago I wrote a brief paper on the early recognition of exophthalmic goiter and reported a number of cases.[2] Since then other cases have come under my observation, both in my own practice and in that of friends. These I have carefully considered, especially from the standpoint of curability. Most of my original cases are now well, and I shall, in brief, report their present condition and the means that were used to bring about this good result. Others will be referred to as illustrating interesting features.

In looking over the literature of exophthalmic goiter, I notice that there is a growing conviction, which I myself have always felt, that this disorder is a very manageable one. Undoubtedly some cases are not to be made well; certainly a large proportion can be most satisfactorily helped, and many entirely cured. The general measures that I have employed with advantage have chiefly the element of rationality to recommend them. It has been said, and rightly, that those disorders which have recommended for their treatment the largest array of medicines and measures are the ones of which we know least. Certainly a large and contrary lot of remedies are urged for this disorder; some are claimed by their authors to be almost specific; others are backed up by a large array of cases; and yet few, to my mind, are, singly considered, much better than the rest.

In looking over my paper referred to, certain conclusions then formulated seem still to obtain with equal force. The most important measure is the early recognition of the symptoms that in their entirety represent the malady. I am inclined to doubt more strongly than ever that, with early recognition and judicious treatment, the disorder need at any time become so serious in its results as we have been led to believe.

Without discussing the reasons at length, my convictions are that exophthalmic goiter is a vasomotor disturbance, and not related to any specific disease of the thyroid gland. It has not been shown to have any connection with the functions of the thyroid as a trophic organ, or at any rate to depend upon either an increase or a diminution of the normal secretions of that gland.[1] It has happened that all of the symptoms of Graves' disease have come on with great suddenness, in consequence of profound emotion, and in persons with, presumably, normal thyroids, and have again disappeared as abruptly. Unless further evidence shall be adduced to the contrary, I am inclined to regard the disorder as a cardio-vascular erethism,[2] or, to use the term coined by my friend Dr. S. Solis-Cohen, as a "vasomotor ataxia."[3]

In this connection certain tropho-neuroses are of the deepest importance therapeutically. The group of trophic and vascular disturbances associated with enlargement of the thyroid gland, including exophthalmic goiter, myxedema, cretinism, and akromegalia, are receiving a good deal of attention, both as to their pathology and as to their treatment, and from this search-light tendency of medical science much is to be hoped. I would be glad to believe that specific results could be hoped for from the absorption of thyroid juices and similar measures, and myself use these in suitable cases. Meanwhile, my present purpose is to relate such measure of success as has come to me, and indicate the lines upon which it has been obtained, holding in reserve the brilliant possibilities referred to.

I am inclined to agree with Raymond and Serieux,[4] who consider exophthalmic goiter a bulbar neurosis, manifesting itself in an exaggeration and permanence of the physiologic phenomena of emotion, placing the emotional state at the foundation of the disease as a pyschic anomaly, a derangement of vasomotor centers, coinciding with analogous troubles in other centers of the cerebro-spinal axis. There are to be found in this disorder certain associated psychoses, with evidence of hereditary taint, signs of physical degeneration, mal-development of the facial area in the central cortex, vaulted palates, etc., seen in developmental neuroses.

Of the three features that constitute the classic

symptom-group of Graves' disease, it is now admittedly possible for any two to be absent, or at least not constantly recognizable. It is common to find the thyroid enlargement absent; next most common to find exophthalmos not present; and possible, though rare, to find the circulatory disturbance to be practically wanting, in the presence of the ocular and thyroid symptoms.

The most important phenomena of the disease are connected with disturbed circulation. One or another of the more picturesque symptoms may be temporarily absent; not seldom the thyroid irregularly enlarges and collapses; the exophthalmos also comes and goes; but in my experience there is seldom an absence of irregular or easily disturbed vascular conditions. In two cases I have seen the more distressing symptoms quite disappear, but either slight exophthalmos or moderate thyroid enlargement, or both, remained. I have had two ladies under observation for seven and ten years respectively, who are practically well, and in whom the exophthalmos persists; and another who has considered herself well for over a year, but whose thyroid is still noticeably large. The thyroid enlargement seems to me to be the first symptom to definitely disappear, although in the case referred to it has persisted after the subsidence of the other symptoms.

The next most common feature is the relaxed state of the sweat-glands. This seems to be a uniform feature, and remains much the same in most cases. I have seen cases of slight vasomotor ataxia in which flushes came and went; but ordinarily there is a pallid, oleaginous appearance, which persists, giving the skin a macerated look, with rarely any offensive odor. Urination is not commonly disturbed; hemoglobinuria is rarely seen; purpuric areas occasionally appear; and slight hemoptysis and hematemesis may take place; nor is it common to see edema. In one particularly severe case, which terminated in wild insanity, I have noted persistent edema; when it occurs it only appears intermittently.

The temperature fluctuates considerably. In first interviews, which are attended with a certain element of nervous emotion, it is quite common to find the temperature above 100° F. In the same individual a short time afterward, the temperature taken in the mouth may be subnormal. In such cases as I put to bed for systematic rest, a rise of temperature is almost always noted for the first three or four days, followed by a steady falling until the normal is passed, the temperature remaining subnormal for three or four days, and then creeping back to the normal, and remaining at this level, or a little below, for several weeks.

The rapid variation in arterial tension accounts for the intermittent albuminuria, the mild polyuria, and other changes in the renal secretion, as well as for the occasional blood-spitting, together with disturbances of special sense, as roaring in the ears, headache, fluttering of the heart, altered heart-sounds, dyspnea, etc. The tremor that Gowers refers to I have not often seen, except in the form of occasional tremulousness of the lip or tongue, and then mostly under excitement; but a more or less constant vibratile quality in the voice is always suspicious. The sensory disorders are not many, headache being the chief, as in one of the cases here related, in which this persisted throughout life, almost daily, worse in the morning and in certain attitudes, as stooping down, and sometimes suddenly becoming so severe as to cause vomiting.

The Von Graefe lid-symptom seems to be regarded as of less significance among clinicians as time goes on. Sharkey[1] has examined 613 patients of all kinds, and among them found 12 that presented this symptom. He states that in people of good health it can be frequently induced by staring fixedly. It constantly fails to be present in Graves' disease, and its diagnostic significance is small. The electric resistance of the body, too, has failed of its early promise as a useful indication, as hopefully outlined by Norris Wolfenden. It had come to mean little to me long ago, and observers generally now regard it as of small account. H. W. Carduff[2] finds the electric resistance diminished in 15 of 20 cases of exophthalmic goiter, and remarks that the phenomenon is worthless as a diagnostic sign, as it varies with the moisture of the skin. When we consider that the moisture of the skin is almost constantly marked in well-defined instances of exophthalmic goiter, the only wonder is that much significance was ever attached to an alteration in the electric resistance as a symptom.

The order in which the characteristic symptoms appear is not always easy to determine. I am inclined to agree with Jaccoud,[3] who puts it as follows: palpitation, dilatation of arteries, enlargement of thyroid, exophthalmos. A point that seems to me to be useful, though rather a result of the characteristic changes that take place, is the diminished respiratory range or chest-expansion pointed out by Fiske-Bryson.[4] I had noticed that the respiratory movements of sufferers from exophthalmic goiter were almost as much disturbed as the cardio-vascular mechanism; and, purely from the therapeutic standpoint, had been accustomed to urge upon patients the use of forced inspiration. This seems to me a very tranquilizing measure, and one that is a proper part of systematic hygienic measures. In the more recent cases under my observation this limited ex-

[4] Ibid., December 14, 1889.

pansion of the chest has been observed. Bronzing of the skin is not common; uniform changes, as pointed out in my original paper, such as a greasy, macerated-looking skin, are much more likely to be present, possibly as a result of the paretic condition of the surface-vessels. There seems also to be an excessive secretion of skin-oil, recognizable by the touch as well as the appearance.

Stellwag's sign—retraction of the upper eyelid—I have rarely seen.

Charcot has somewhere directed attention to the importance of elevation of the temperature as a diagnostic point. In my experience, such an elevation only persists when the patient is upon his feet and moving about. As I have pointed out elsewhere, when such a one is put to bed, the temperature subsides after a few days and becomes subnormal.

Mackenzie [1] makes the statement that when the clinical picture of exophthalmic goiter is incomplete the disease is rarely fatal; but when the picture is well-marked, the disease is dangerous to life. There are times when death occurs apparently from an overwhelming disturbance of circulatory balance —in short, a death from the disease itself; but it rarely seems to be due to trophic changes referable to the pathology of the thyroid gland.

My conviction is that exophthalmic goiter is much less rare than is generally believed, and that it is also far more amenable to treatment than is usually taught. Unless there coexists serious structural disease, excellent results, in more instances a practical cure, may be looked for if the treatment be persistently and systematically pursued. The results in my own cases have taught me to give a favorable prognosis; and if specific medication with thyroid juices and thyroid removal prove of value, these may add much greater possibilities.

It has been my experience to see several cases not clearly definable as Graves' disease, wherein the symptoms of cardio-vascular erethism were most distressing. These were often superadded to organic disorders and generally complicated with hysteria. The patients responded most promptly to tranquilizing agents directed to the loss of vasomotor balance and, in so far as this feature went, were readily relieved. It is reasonable to assume that from such cases as these, full-blown instances of exophthalmic goiter may and sometimes do arise.

A very important point clinically is that too often the significance of these symptoms is not recognized and treated, as well as that the difficulties in inducing such patients to persist in systematic measures for the long periods required are very great.

The treatment of exophthalmic goiter is modified in various hands by the conception of the physician as to the nature of the condition, whether it be a blood, cardiac, neurotic, or thyroid disorder. It must be also recognized that a person suffering from this trouble is always on a lowered plane of health. The degree of this may be much more serious than would appear on the surface; certainly a modification of the ordinary activities of the patient must be outlined, and under most circumstances very little laborious work allowed. When it is possible, absolute rest in bed is indicated for a time. A diet of the most uniform and tranquillizing kind, such as milk, the regular milk-diet such as Kareli outlined, is usually of use to bring the disturbed circulation as soon as possible on an even plane. This may be amplified by a judiciously selected diet in proportion to the depression of nutrition that may exist.

The diathetic element that may be back of the disorder needs careful consideration; in some of my cases it was found to be lithemia. Along with attention to the diet there must be large care in the treatment of the skin. This may take the form of salt sponge-baths, given by another while the patient is in bed, and finally, as strength improves, taken by himself; a tablespoonful of salt in a basin of water regularly applied on waking in the morning, after some little fluid nourishment; this to be followed by a brisk, rough rub from head to heel; afterward breakfast. When the skin is greatly at fault, this may be repeated before bedtime with advantage, or to supplement the skin-stimulation the dry salt towel may be used more or less often; again, an aromatic vinegar on a damp sponge may be applied to the more leaky parts, as the soles of the feet and the palms of the hands, about the small of the back. This aromatic vinegar can easily be made in any household by taking a pint of good white wine-vinegar and adding a dozen or more of cloves, allspice, and whole peppers, and allowing it to steep. A tablespoonful or more of this applied on a moistened sponge is very comforting and relieves the over-damp skin wonderfully. In giving massage it may be important to use drying powders, such as talc or lycopodium, until the patient can endure the manipulations. A measure recommended by some, notably by J. L. Corning, for giving tone to the skin is hot bathing followed by cold ablution, but for my part I have rarely seen the need of it. During conditions of great restlessness, no doubt this would aid in securing sleep. The hot, salt sea-water baths might be very useful to this end, and I have, indeed, ordered them temporarily in a few instances, with advantage, but my dependence is rather upon the cool salt water, the aromatic vinegar, and systematic surface-rubbing, as well as upon such internal remedies as hyoscin hydrobromate in sufficient doses.

Wool or silk should always be worn next the

[1] London Lancet, September 20, 1891.

skin, inasmuch as the cause of the disorder is often closely related to surface-chill. The frequent changing of the underwear, too, is a minor point of large significance. It is bad enough for the surface-exudations to remain uneliminated, but it is worse to keep them locked in by the clothing. If skin-leakage be extreme, it is important to change the underwear several times a day, employing, if possible, a brisk dry rub each time.

For the over-acting, tumultuous heart, there is nothing so certain to steady its beat and lower its frequency, and generally to tranquillize the whole cardio-vascular mechanism, as ice applied to the precordium. Care is needed, of course, lest some damage be caused by this very powerful agent. Ice-bags over the spinal region, too, exercise some value. In conditions of profound tumult of the heart this is valuable, and many times is useful as a more or less routine measure. Galvanization of the great sympathetic and faradization of the cardiac region are highly prized by a number of observers, but I have never seen them do the wonderful things that Charcot, Rockwolf, and Lewandowski have claimed for them, although I think I have seen them do distinct good in a few cases. I have given faithful trial to the carbazotate of ammonium, as recommended by Hammond[1] and by Boaz,[2] in three cases, with no noticeable result, while the offensiveness of the drug is beyond description.

Many writers say that digitalis will not modify the heart's action. Alone probably not, and yet I have had very good results from digitalis. Strophanthus seems to do better, although physiologically one might not expect it. Spartein sulfate may be even better yet. Many different kinds of vascular tonics are useful in this disorder, and it cannot always be predicated which will do best. The one drug that has served me best of all, and to which I look with great confidence in modifying the discomforts and dangers of this disorder, is hyoscin hydrobromate. This serves to tranquillize the overwrought emotions, puts the economy into a reposeful state, dries the surface over-secretions, oftentimes without causing uncomfortable drying of the throat, relieves the feeling of chilliness by checking surface-moisture, exercises a beneficial effect upon the renal vaso-constrictors, and in many ways may be regarded as a most useful ally. In one case here reported this was the chief agent employed in subduing a headache that had existed for half a lifetime and for which much medication had been endured; to be sure, galvanization of the thyroid was also used, and some general measures directed to the patient's nutrition and relief from laborious occupations enforced. In the case of this poor woman, who was compelled to do a large amount of daily work, to prepare her own food and her husband's, and to sustain and carry on many responsibilities, prompt recovery took place from a condition that had persisted for many long and weary years. I will not say too much about the value of hyoscin hydrobromate, because the notes of my cases show this well enough. Dr. S. Solis-Cohen gets excellent results from picrotoxin.[1]

Certain ones, as Kümmell,[2] have removed the thyroid in cases of exophthalmic goiter, leaving part of the left lobe, with favorable results. It does not seem to me that all of the good attributed to this operation lies in the removal of the thyroid, much of it possibly being the enforced rest and regulation of living. Nevertheless, I should welcome any specific agency, such as the surgical removal of an offending part, or the use of thyroid juices internally, if we could by this means radically negate the effects of errant thyroid activities.

Chevalier[3] maintains that the tachycardia is due to an affection of the nucleus of the vagus, the struma and exophthalmos being dependent upon the tachycardia, and declares the cause of the disease to be an intoxication of the nervous system through by-products of the thyroid. Many tonics might be considered in this connection. Iron is frequently indicated, especially the more digestible forms, as the carbonate, Flint's chalybeate pill, the vegetable salts, the malate, and the old-fashioned and reliable lactate. However, it is needless to go over a list of tonics suited to varying conditions and cases. Nutrient tonics are the best; good diet, very carefully adjusted to the needs of the patient. This at first may, with advantage, consist largely of milk, then enlarged by graduated increments, as the case demands, with aids to digestion, and then malt and cod-liver oil. The mechanical tonics, massage and faradic electricity, are of great value. The entire environment of the individual should be carefully reviewed, emotional disturbances rigidly

[1] Extract from letter of Dr. S. Solis-Cohen: "Concerning my use of picrotoxin in cases of Graves' disease and other forms of vasomotor ataxia, I would remind you that I learned the practice from Prof. Bartholow, having seen the good results in a case of exophthalmic goiter, attended with purpura, treated at the Jefferson Medical College Hospital during my service as Chief Clinical Assistant. I give from one-eightieth grain to one-twentieth grain thrice daily, the indications being found principally in the vascular phenomena of the cutaneous and mucous surfaces and glands; that is to say, sweating, profuse discharge of saliva, coryza, and tendency to heat and redness of the skin, suggest the use of this drug. In cases showing constriction rather than relaxation of vessels, it is less applicable. I have sometimes found the combination of ergot and picrotoxin better than picrotoxin alone; in other cases barium chlorid (one-eighth grain) has been combined with it. . . At the same time I have considerable confidence in picrotoxin as a tonic to the taxic power, or center, in these cases of vasomotor disorder."

excluded, and, when possible, physical and mental strains removed. The isolations of a complete rest-treatment probably offer the very best opportunities of all; and finally, graduated activities in the form of Swedish exercises, systematized outings, and restful life in a dull country-place. The correction of refractive errors of the eye is always of the greatest value.

(To be concluded.)

EFFECT OF CARBON DIOXID, CARBONIC OXID, SULPHURETED HYDROGEN, WATER-GAS AND COAL-GAS ON ANIMAL LIFE.[1]

BY JOSEPH R. WILSON,
OF PHILADELPHIA;
MEMBER OF THE FRANKLIN INSTITUTE.

As the health of every individual is dependent upon the purity of the atmosphere, a knowledge of the effect on animal life of impurities in the air is of the highest importance to the community at large, but of special importance to those who work in coal, silver, lead, copper, or gold mines, or at iron furnaces, coke ovens, etc. In such places impurities often exist, such as

	S. D.
CO_2—"Choke-damp," or carbon dioxid . .	1.529
CO—"White damp," or carbonic oxid . .	0.9678
H_2S—Sulphureted hydrogen, or hydrogen sulphid	0.1912

The statistics compiled by me from the indices of the library of the College of Physicians, Philadelphia, one of the most complete institutions in the world, show that 90 per cent. of the total scientific experiments on the effects of noxious gases on animal life have been made by the Germans and the French, and for the last decade scarcely any experiments have been made by scientists of any nationality, the results obtained by our forefathers being accepted with a credulity seldom encountered in other branches of science. In addition to this, the poverty of information in the standard references on this subject is so great that were any particular knowledge required, it would be necessary to make new experiments. With these facts before me, in grouping the results obtained in experiments with carbon dioxid, carbonic oxid, and sulphureted hydrogen on animal life, the medical fraternity will at least have a condensation of experiments for reference from many authorities, combined with the results of my own experiments. I claim that my experiments are absolutely accurate, as the means employed for mixing the different atmospheres (the Shaw gas-tester) is acknowledged to be as nearly perfect as human agency can make anything, and has been awarded the Elliott Cresson and the Scott Legacy medals for accuracy—the highest awards in the gift of the Franklin Institute. This tester is to gases what weights and scales are to solids.

It is not my intention to go into the constituents of the gases named, there being no necessity for my doing so in this paper. I have simply one object in view: to describe, as the result of recent experiments, the effect produced by them on animal life. The Shaw gas-tester, which I used for mixing my gases in the centesimal proportions desired, is an apparatus simple, convenient, and accurate, consisting of two pumps with pistons attached to a graduated arm, so that one cylinder can be set to pump 10 per cent. of gas and the other 90 per cent. of air, or *vice versa*, or any per cent. to the lowest fraction. It is the only instrument in the world capable of mixing gases accurately, rapidly, and continuously in any per cent. desired, the product of the two cylinders being forced through an injector or mixer before delivery.

The animal under treatment is placed in a bell-shaped glass cylinder sixteen inches high, of four inches diameter at the neck and eight inches at the base. The cylinder is placed horizontally on the table, with the neck toward the operator, and is connected with the instrument at the neck by means of a rubber tube. The animal rests on all fours, facing the operator, with its nose near the aperture through which the gases enter the cylinder from the instrument or mixer.

The end of the bell-shaped glass cylinder is entirely open to the air, so that the mixture of gas and air is discharged and replaced every four seconds by each stroke of the pump, always maintaining a constant mixture, preventing stratification or contamination through the exhalations of the animal. The cylinder, being of glass and perfectly transparent, enables the operator to observe every change in the condition of the animal.

The difference in results obtained by the various authorities has caused me to make the following experiments to satisfy myself, an accurate knowledge on this subject being necessary to the pursuit of my profession, and I am well aware of the great difficulties experienced by my predecessors in making accurate mixtures of gases, owing to the crude appliances for this purpose at their command.

As a prelude to my experiments I will give the results obtained with carbon dioxid by scientists whom we are accustomed to quote:

CARBON DIOXID.

	Per cent.
Sir H. Roscoe's *Chemistry:* Will not support combustion of candle	3 to 6
Dr. A. Smith: Lights extinguished	about 2
Would suffocate	4

Watts' *Dictionary of Chemistry* says: "Animals immersed in it soon die, not only from want of oxygen, but in consequence of a direct poisonous action, violent spasms being sometimes produced; sometimes complete atony of the cerebral faculties."

The *Encyclopedia Britannica*, vol. v, p. 87, says: "Will not burn, neither does it support combustion."

Dr. Karl Friedlander, of Berlin, in experiments on animal life states that "62.8 per cent. killed a rabbit in twenty-seven minutes; 65 per cent. killed a rabbit in forty-five minutes," the higher per cent. in this instance taking longer to kill the rabbit than the lower per cent., showing a wide variation in his tests, which I can only account for by the imperfect appliances at his command for placing definite quantities of gas in the atmosphere, and maintaining a constant mixture of definite proportions. Rabbits, like human beings, have their ailments, and I have found in the course of my experiments that disease, in the shape of a fatty accumulation about the heart, disqualifies the animal entirely for tests of this nature, death resulting in one-tenth of the time necessary to produce the same result in a perfectly healthy animal; but in the foregoing instance the difference in time of immersion in such a high per cent. is not great enough for me to ascribe the difference in effect to any organic disease, but rather to the imperfect mixing of the gases.

In all of my experiments I have found that the smaller the animal the sooner it succumbed to poisonous gases. My first experiments were made with small birds; then I tried mice, after which I bestowed my attention on guinea-pigs, finally selecting the rabbit upon which to conduct the experiments herewith presented.

EXPERIMENTS WITH CARBON DIOXID.

EXPERIMENT No. 1. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 10 per cent. of CO_2 and 90 per cent. of air. After one hour and seven minutes the rabbit gave no indication whatever of being affected, so I released it and allowed it to run with several others of its species, the effect of its treatment, contrary to expectation, being great exhilaration instead of stupefication.

Result. 10 per cent. of CO_2 and 90 per cent. of air; one hour and seven minutes' inhalation—exhilaration.

No. 2. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 25 per cent. of CO_2 and 75 per cent. of air for one hour, at the end of which time the animal showed no indication whatever of being affected, and when released and placed with others exhibited as much liveliness as they.

Result. 25 per cent. of CO_2 and 75 per cent. of air; one hour's inhalation—unaffected.

No. 3. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 50 per cent. of CO_2 and 50 per cent. of air. At the end of two minutes the rabbit showed signs of being affected; at the end of three minutes it commenced to gasp regularly every two seconds; at the end of six minutes the gasps were three seconds apart; ten minutes, the gasps were four seconds; twelve minutes, the gasps were six seconds; fourteen minutes, the gasps were eight seconds; fifteen minutes, the gasps were nine seconds; sixteen minutes, the gasps were ten seconds; seventeen minutes, death ensued.

Result. 50 per cent. of CO_2 and 50 per cent. of air; seventeen minutes' inhalation—death.

No. 4. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 75 per cent. of CO_2 and 25 per cent. of air. At the end of two minutes the rabbit commenced to pant rapidly; three minutes, it became stupefied and gasped every two seconds; five minutes, the gasps were three seconds apart; seven minutes, the gasps were five seconds; eight minutes, the gasps were six seconds; nine minutes, the gasps were ten seconds; ten minutes, death ensued.

Result. 75 per cent. of CO_2 and 25 per cent. of air; ten minutes' inhalation—death.

No. 5. I placed a mouse in a glass cylinder and pumped in an atmosphere of pure CO_2; death was instantaneous.

Result. Pure CO_2; death instantaneous.

No. 6. I placed a mouse in a glass cylinder and pumped in an atmosphere of 25 per cent. of CO_2 and 75 per cent. of air. At the end of three minutes the mouse seemed slightly affected, but kept moving around the cylinder—in this test held vertically. At the end of ten minutes the conditions were unchanged, and I displaced the atmosphere of 25 per cent. CO_2 with pure air. The mouse revived instantaneously on the first inhalation.

Result. 25 per cent. of CO_2 and 75 per cent. of air; ten minutes' inhalation; slightly affected, but recovered instantaneously in the fresh air.

No. 7. I placed a mouse in a glass cylinder and pumped in an atmosphere of 50 per cent. of CO_2 and 50 per cent. of air. At the end of ten seconds the mouse showed great exhilaration; twenty seconds, its activity was greatly reduced; thirty seconds, it became stupefied; thirty-five seconds, gave short gasps; forty-five seconds, the gasps were long and apparently painful; fifty-five seconds, death occurred.

Result. 50 per cent. of CO_2 and 50 per cent. of air; fifty-five seconds' inhalation—death.

Experiments 5, 6 and 7, are only given here to illustrate the fact that the smaller the animal the less the power of resistance to CO_2.

EXPERIMENTS WITH CARBONIC OXID.

The results obtained by scientists whom we are accustomed to quote, on the effect of carbonic oxid on animal life, are first epitomized.

H. Letheby, M.B., M.A., Ph.D., etc. late Professor of Chemistry and Toxicology in the Medical College of the London Hospital, says that 0.5 of 1 per cent. of CO killed small birds in three minutes; 1 per cent. in half the time; 2 per cent. renders guinea-pigs insensible in two minutes. In all cases the effects were the same. The animals showed no signs of pain; they fell insensible and either died at once with a slight flutter, hardly amounting to a convulsion, or gradually slept away as if in profound slumber. The post-mortem examination showed the blood to be a little more deeply red than usual.

Prof. A. R. Leeds says: "The operation of pure CO is so immediate as to prevent the lungs throwing off a single charge received."

Watts' *Dictionary of Chemistry* says: "It is a very poisonous gas, acting chiefly on the nervous system, causing giddiness when inhaled, sometimes acute pain in various parts of the body, and after a while complete asphyxia."

Buck, on *Hygiene and Public Health* says: "It is not so immediately fatal as carbonic acid gas."

The *Enclycopedia Britannica*, vol. v, p. 87, says: "It is an extremely poisonous gas, being capable of displacing the oxygen in the blood, owing to a compound with the hemoglobin with which the oxygen is ordinarily combined."

The *American Encyclopedia*, vol. iii, p. 775, says: "It is more irrespirable and poisonous than carbon dioxid. Its inhalation from furnaces sometimes causes immediate asphyxia to the workmen."

I will now submit the results of my own experiments on the effect of carbonic oxid on animal life, but have to omit several important tests owing to the carelessness of a servant in destroying my notes.

No. 1. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 2 per cent. of CO, and 98 per cent. of air. At the end of ten minutes the posterior extremity of the rabbit became paralyzed; at the end of eighteen minutes the fore-legs became paralyzed, and at the end of twenty minutes the rabbit became semi-comatose; at the end of forty-five minutes its condition had not altered; on being placed in the fresh air it revived sufficiently to maintain its equilibrium.

Result. 2 per cent. of CO and 98 per cent. of air; revived in fresh air after forty-five minutes' inhalation of the gas.

No. 2. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 2.5 per cent. of CO and 97.5 per cent. of air. At the end of five minutes the rabbit became semi-comatose, but on being placed in the pure air, it recovered almost immediately.

Result. 2.5 per cent. of CO, and 97.5 per cent. of air; revived in fresh air after inhalation of the gas five minutes.

No. 3. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 4 per cent. of CO, and 96 per cent. of air. Death resulted in four and one-half minutes.

Result. 4 per cent. of CO and 96 per cent. of air; four and one-half minutes' inhalation; death.

No. 4. I placed a mouse in a glass cylinder and pumped in an atmosphere of 0.2 of 1 per cent. of CO and 99.8 per cent. of air. At the end of six minutes the mouse showed no signs whatever of being affected.

No. 5. I then increased the atmosphere to 0.5 of one per cent. of CO and 99.5 per cent. of air. At the end of five minutes the mouse showed no signs whatever of being affected.

No. 3. I now increased the atmosphere to 1 per cent. of CO and 99 per cent. of air. At the end of thirty minutes, the mouse showed no signs of being affected. I then gave it fresh air for one minute, and increased the atmosphere to 2 per cent. of CO, and the mouse died in ten minutes with a total relaxation of all the muscles.

Result. 2 per cent. of CO and 98 per cent. of air; ten minutes' inhalation; death.

No. 7. I placed a mouse in an atmosphere of 2.5 per cent. of CO and 97.5 per cent. of air, and the mouse died in five minutes.

Result. 2.5 per cent. of CO and 97.5 per cent. of air; five minutes' inhalation; death.

No. 8. I placed a mouse in an atmosphere of 10 per cent. of CO and 90 per cent. of air, death resulting in three minutes.

Result. 10 per cent. of CO, and 90 per cent. of air; three minutes' inhalation, death.

In the absence of the missing tests, I have included experiments Nos. 4, 5, 6, 7, and 8, simply to illustrate the fact that the smaller the animal, the less the power of resistance to CO.

SULPHURETED HYDROGEN.

I note again the results obtained by scientific authorities whom we are accustomed to quote, on the effect of sulphureted hydrogen on animal life.

Watts' *Dictionary of Chemistry*, p. 203, says: "An atmosphere of one-tenth of 1 per cent. of this gas proves fatal to lower animals."

Public Health Reports and Papers, vol. iii, p. 75, 76, says: "It is poisonous, and its action on arterial blood is a common lecture-table experiment."

The *Encyclopedia Britannica*, article Chemistry, vol. v, p. 500, says: "It cannot be breathed with impunity, frequently giving rise to nausea and vertigo, even when much diluted."

The *American Encylopedia*, vol. ix, p. 130, says: "Thenard found that a small bird would die in air containing fifteen one-hundredths of 1 per cent. and a horse in air that contained one-quarter of 1 per cent."

The results of my experiments on the effect of H_2S on animal life are as follows:

No. 1. *a.* I placed a rabbit in a glass cylinder and pumped in an atmosphere of 1 per cent. of H_2S and 99 per cent. of air.

b. I placed another rabbit in another glass cylinder and pumped in an atmosphere of 1 per cent. of H_2S, and 99 per cent of air, simultaneously with No. 1, using two Shaw gas-testers as mixers for the operation, both connected with the same bag of H_2S. Death occurred simultaneously in cylinders Nos. 1 and 2, at the end of one minute, preceded by violent convulsions which lasted about ten seconds.

Result. 1 per cent. of H_2S and 99 per cent. of air; one minute's inhalation; death.

No. 2. *a.* I placed a rabbit in a glass cylinder No. 1, and pumped an atmosphere of 0.5 of 1 per cent. of H_2S and 99.5 per cent of air.

b. I placed another rabbit in a glass cylinder No. 2, and pumped in an atmosphere of 0.5 of 1 per cent of H_2S and 99.5 per cent. of air simultaneously with No. 1, using two Shaw gas-testers as mixers for the operation, both connected with the same bag of H_2S. Death occurred simultaneously in cylinders 1 and 2 at the end of three minutes, preceded by violent convulsions which lasted about fifteen seconds.

Result. 0.5 of 1 per cent. of H_2S and 99.5 per cent. of air; three minutes' inhalation; death.

No. 3. *a.* I placed a rabbit in glass cylinder No. 1 and pumped in an atmosphere of 0.2 of 1 per cent. of H_2S and 99.8 per cent. of air.

b. I placed another rabbit in a glass cylinder No. 2, and pumped in an atmosphere of 0.2 of 1 per cent. of H_2S and 99.8 per cent. of air, simultaneously with No. 1, using two Shaw gas-testers as mixers for the operation, both connected with the same bag of H_2S; death resulted simultaneously in cylinders Nos. 1 and 2 at the end of ten minutes.

Result. 0.2 of 1 per cent. of H_2S and 99.8 per cent. of air; ten minutes' inhalation; death.

No. 4. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 0.1 of 1 per cent. of H_2S, or the 0.001 part, and 99.9 per cent. of air; death resulted in thirty-seven minutes.

Result. 0.1 of 1 per cent. H_2S, or the 0.001 part, and 99.9 per cent. of air; thirty-seven minutes' inhalation; death.

NOTE.—In all of the foregoing tests the rabbits were seized with convulsions from ten to fifteen seconds after immersion in the poisonous atmosphere, which lasted on an average about twelve seconds.

No. 5. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 0.025 of 1 per cent. of H_2S and 99.975 per cent. of air. At the end of two hours the rabbit showed no signs whatever of being affected, so I released it.

Result. 0.025 of 1 per cent. of H_2S and 99.975 of air; two hours' inhalation; unaffected.

EFFECT OF ILLUMINATING OR COAL AND WATER GAS ON ANIMAL LIFE.

The frequent occurrence of accidental deaths from illuminating gas has caused me to make a series of experiments on this subject, with a view to determining just how much risk we run in having a small escape of gas in our bed-rooms, for instance, and the results obtained ought to act as a warning to all who are in any way careless in turning off the stop-cocks before retiring, or who carelessly turn the gas low near a draught, and find it blown out the next morning and the room filled with gas.

No. 1. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 75 per cent. of illuminating gas (water and coal gas) and 25 per cent. of air. The rabbit was immediately seized with violent convulsions and death ensued in two minutes.

Result. 75 per cent. of illuminating gas (water and coal gas) and 25 per cent. of air; two minutes' inhalation; death.

No. 2. I placed a rabbit in a glass cylinder and pumped in 25 per cent. of illuminating gas (water and coal gas) and 75 per cent. of air; on the third inhalation the rabbit was seized with violent convulsions and urinated freely; at the end of one minute the convulsions ceased, and at the end of four minutes death ensued.

Result. 25 per cent. of illuminating gas (water and coal gas) and 75 per cent. of air; four minutes' inhalation; death.

No. 3. I placed a rabbit in a glass cylinder and pumped in 15 per cent. of illuminating gas (water and coal gas) and 85 per cent. of air; without any struggling it sank into a comatose state; at the end of three minutes it struggled feebly; at the end of four minutes urinated, and at the end of six minutes died.

Result. 15 per cent. of illuminating gas (water and coal gas) and 85 per cent. of air; six minutes' inhalation; death.

No. 4. I placed a rabbit in a glass cylinder and pumped in 10 per cent. of illuminating gas (water and coal gas) and 90 per cent. of air; at the end of thirteen minutes the rabbit was seized with a convulsion and died in five seconds.

Result. 10 per cent. of illuminating gas (water and coal gas) and 90 per cent. of air; thirteen minutes' inhalation; death.

No. 5. I placed a rabbit in a glass cylinder and pumped in an atmosphere of 5 per cent. of illuminating gas (water and coal gas) and 95 per cent. of air; at the end of ten minutes the rabbit was seized with severe convulsions, which lasted twenty seconds; at the end of twenty minutes it commenced to gasp, and at the end of thirty minutes death ensued.

Result. 5 per cent. of illuminating gas (water and coal gas) and 95 per cent. of air; thirty minutes' inhalation; death.

I did not analyze the illuminating gas for its constituents, but the gas used was Philadelphia City gas, and I believe that it contains about 30 per cent. of CO.

I have other experiments on hand on CH_4, carbureted hydrogen, or fire-damp; also on the effect of carbon dioxid, or choke-damp, on lights, the results of which it will afford me pleasure to make known in my next paper.

HEALTH-RESORTS OF THE WEST AND SOUTHWEST.[1]

BY H. G. WETHERILL, M.D.,
OF TRENTON, N. J.;
GYNECOLOGIST TO ST. FRANCIS' HOSPITAL.

So much has been said and written of Colorado, New Mexico, Texas, Arizona, and Southern California as places of residence for invalids, that it is not now a pleasant task to add to this too abundant literature; and if it were not for the fact that a visit to the chief points of resort in those States had shown me the fallacy of many of the opinions of my coworkers in the East, this paper would be unnecessary.

The opportunity to observe, compare, and examine into the respective merits of these localities from an impartial standpoint is not given to many active physicians, and the circumstances that have made it necessary for me to spend nearly a year among these resorts should be turned to account.

Too often the climatologist in writing of a certain place becomes an advocate and, perhaps unconsciously, paints a picture that patients find too highly colored, and reports go back to the medical adviser in the East that do not conform to his preconceived notions of what the conditions should be. This is unfortunate, and ultimately injures both the place and the advocate. The plain truth would be better for all.

To start with, absolute perfection of climatic conditions is not to be had anywhere. In the second place it must be borne in mind that tables of mean temperature and relative humidity are statistical records that may be juggled and made to show almost anything. Then again, there are dozens of other things that bear on the welfare and comfort of the health-seeker, and they should all be considered.

The belt of high table-land (a part of the summit plateau) extending along the eastern range of the Rocky Mountains, and in which Cheyenne, Denver, Colorado Springs, and Manitou may be found at the north, and Los Vegas, Trinidad, and Santa Fé farther south, is a favorite place for the assignment of cases of pulmonary tuberculosis.

The altitude varies from about five thousand feet to something over seven thousand feet. The air is invigorating, even stimulating. There are few days on which the sun does not shine, and the dryness is all that the greatest advocate of a dry climate could ask. During the summer months there is a moderate rainfall, but it comes in showers lasting a few hours only, and is followed by sunshine and blue sky. Gray and clouded skies, and day after day of rain such as the Atlantic seaboard is subject to, are unknown; and it is the proud boast of the people of this plateau that they have about three hundred days of sunshine in a year.

The advantages of this territory are then—the altitude, dryness, abundance of sunshine, the peculiarly stimulating and invigorating qualities of the atmosphere, and, I would add, the purifying effects of the occasional high winds, which are so unpleasent while they last and which are so often cited as a great objection.

Other features that present themselves for consideration are the extremes of temperature between day and night and between one day and the next (winter or summer); the dust-storms or sand-storms; the pall of smoke that is inseparably connected with all large towns or cities where there are railroads or factories (for none but bituminous coal is used anywhere in the region considered).

Denver is a very smoky city and in the winter season sends a trail of black clouds for miles out over the prairie. Even Colorado Springs of a winter's morning is overhung and enveloped in its own smoke-product, and the view of it from the plains is far from ideal. I do not desire to convey the impression that these cities are dark and dingy, as are Pittsburg and Chicago—the free circulation of air would prevent that even if the smoke were much thicker. I am speaking of them as health-resorts, and of this condition as existing to an undesirable degree.

Colorado has an admirable winter climate, but from November 1st to March 1st it is not a tropical or semi-tropical climate by any means, and the patient who goes there then expecting to camp out, or wear his summer clothing, makes a great mistake. The nights are always cold—sometimes very cold—and the days are mostly bright, dry, and beautiful, but often very cold also, so that warm winter clothing, and an abundance of it, is needed.

A Philadelphia lawyer was sent to Colorado Springs last fall by one of the ablest physicians of his city, and was told that he could live out of doors, hunt, fish, shoot, etc. Wrapped in his heaviest ulster, and pacing up and down the hotel piazza in the sun to try and keep warm, the man told me that if he had given a legal opinion with as little knowledge of the facts as that he would have been disbarred.

Catarrhal diseases of the respiratory tract are the common and prevailing ailments in Colorado, and new-comers are greatly annoyed for a time with dry nose and throat, induced by the passage of the very dry air over the mucous membrane. Adaptation to the new conditions soon takes place, however.

As to other conditions, it may be said that the society is good, and the people educated and affable to an unusual degree. There is plenty of interest to

[1] Read at the Mercer County District Medical Society, October 10, 1893.

divert one; saddle-horses are abundant, cheap, and good; roads fair, and in some places excellent; food equal to that found anywhere; and stores well stocked for all one's needs, but with prices for board and merchandise about a fourth or sixth higher than in the East. The houses are well built, warm, and comfortable, with ample provision for heating; electric lights and railroads are in all large towns; and first-class transportation, with good dining-car service, is present all over the States and to the East.

For certain well-selected cases Colorado is admirably adapted, but the medical men of the world make a mistake in fancying that all cases of pulmonary tuberculosis will do well in Colorado. Many tuberculous patients are hurried to the grave by a trip to Colorado. In some the disease is arrested for a time, to be accelerated later, while in others the arrest may be complete and permanent. Cases far advanced, very young patients with active disease—in fact, acute cases of tuberculosis do not do well here; indeed, they do not do well anywhere. The best results are had in slow non-febrile, and hemorrhagic cases of a subacute kind, in which there is an apparent effort to resist the disease, and when a degree of immunity may have been established. When valvular heart-lesions exist, or the kidneys are damaged, the patient should not go to Colorado.

Those who go and get the best results spend as much time out of doors as possible, and are guided as to exercise in that rarefied air by a good local medical adviser. Grave mistakes may be made if one yields to the stimulation of the rarefied air, and exercises violently. The effect of the air and altitude has been aptly spoken of as "champagny," and patients must be cautioned to go slowly until they are acclimated.

The climate of Northern New Mexico, in the vicinity of Los Vegas and Santa Fé, is much like that of Colorado Springs. It is, perhaps, not so subject to sudden change, and on the whole is warmer. At Los Vegas there is a good hotel, where one may have all he requires, and Santa Fé is a very curious old town, full of interesting things.

In Southern New Mexico, Western Texas, and in Arizona, all of the conditions are very different from those of Colorado. The elevation is less, the soil is different, the water is for the most part so alkaline as to be very distasteful and disturbing to those not accustomed to it. The rainfall is much less, and the dust is dreadful. The sun is hot, and one very soon feels the enervation and *ennui* of it all. In addition to all this, the hotels in Albuquerque, El Paso, Tucson, Phœnix, and Yuma are bad beyond endurance. The food is wretched, and the people one meets, with a few notable exceptions, are not attractive companions.

There has been a disposition of late, on the part of some Eastern consultants, to send tuberculous patients to this arid country; but their ideas of it were not formed after seeing and carefully investigating its fitness for such cases, or none would be sent there by men of conscience.

A territory that offers no more in comfort, associations, entertainments, or natural advantages than this, and is by reason of its heat, dust, bad water, and poor domiciles so uncomfortable, and is in addition as unhygienic as the filthy habits of the native Mexican and Indian population can make it, is no place for a delicate Eastern invalid with a cultivated taste for many things that have become necessaries of life, and that are here unattainable.

Acquired tuberculosis is very rare, almost unknown, in Colorado. The natives do not have it or acquire it from the many invalids about them. Children of tuberculous persons grow up free from it, intermarry, and rear children who do not acquire it. In Arizona the disease is common and fatal among the native population—the Indians having it in a rapidly fatal form, like that which affects our negro; it not rarely runs a course of only a few weeks or a month or two.

In my opinion, if there is any place on this earth where all the conditions combine to create a field where a tuberculous patient would not do well, that place is Arizona. And when I add to this the mournful tales of actual disappointment and disaster here, I am constrained to beg my co-laborers of the East to cut Arizona from the list, and save their patients trials and discomforts, and themselves remorse. The few cases reported as doing well in Arizona are of a type that would do well anywhere, if they were relieved of care and worry, and could lead an out-of-door life—cases not far advanced, with good resisting powers, and, above all, able to exercise out-of-doors enough to create an appetite that is not critical.

Southern California, in the vicinity of Los Angeles, Pasadena, Riverside, Santa Barbara, or San Bernardino, is a charming State; and San Diego is quite as charming as any of the towns named, and claims a better climate in point of equability of temperature and greater dryness. This claim must be allowed. Here, again, certain invalids do well, for it is possible to be out of doors day after day, and, excepting in the rainy season, it is, any of it, dry enough.

The chief fault to be found with any of these points in Southern California is the same. One falls at once into the lassitude of the semi-tropical atmosphere, and suffers in body and mind from the consequent depression. The dust is bad in the dry season, and the heat of the sun is intense.

Pulmonary tuberculosis is a disease of house-builders, is contagious; it starts in portions of the

lungs least used, and its course is modified by the nutrition and nervous energy of the subject. To combat it, then, it is best to keep out of houses as much as possible (day and night); to avoid contact with tuberculous patients indoors; to "keep out of dust and out of crowds;" to fully expand the air-vesicles of every portion of the lungs many times a day, and best in a rarefied air; to maintain the nutrition by proper exercise and good food, and to remove the person from the cares and worries of business or household. Medicines may be auxiliary to this course, but can do little good when these means are ignored.

California has many conditions favorable to carrying out such treatment, and is no doubt well adapted to the needs of some cases.

Arizona and Western Texas have very unfavorable conditions, while Northern New Mexico, Colorado, and Southern Wyoming offer the very best to be found on this continent, if not on earth. The altitude, dryness, air-currents, sunshine, good-fellowship, and good living make these regions a Mecca to which a certain proportion of the tuberculous patients of the world may go and receive benefit, if they will but go early.

The opportunity is presented for the medical man of the East to exercise rare good judgment in the selection of cases to be sent to Colorado. If he waits till he has exhausted his pharmacopeial resources on a case, and at last sends the patient away to get him off his hands, he must expect no good to come of it. Grasp the situation early; don't temporize or procrastinate; state the *true* condition of things fairly and honestly to the patient or his friends, and make your recommendation with the force and earnestness you would use with any other prescription, when once a painstaking conclusion is reached, and you will not be reproached or feel remorse.

I feel it my duty to add that I believe the curative effect of climate has been vastly overestimated by the great body of medical men, and that a properly directed out-of-door life—rain or shine—will do nearly as much for us under the same conditions of freedom from work and worry as the best climate on earth could do. Returning as I do after a year of health-chasing, to find many of my old patients or acquaintances who have had tuberculosis for years (some as long as thirty), as well, or better, than I left them; to find others apparently well, or with greater improvement at least than I have made, is enough to set one to thinking.

I can recall many cases of the disease, well-advanced, with a history of hemorrhages, etc., that have entirely recovered in New Jersey; and many men of this sort went to the front in 1861, endured all the privations of campaigning, and came home sound and robust, cured by the out-of-door life—some, I regret to say, only to die of a re-development of the disease after a few years of work in the store or office.

Another fallacy is that if one goes West and improves, he must stay there. The truth is, if one improves after a long out-of-door holiday in the West, he cannot expect to go back to his old work and environment, wherever situated, without risk. If he comes back to continue (to a degree at least) the life led West he may hope for good health in the ratio of his approximation to his Western habits.

There are many places within a few hundred miles of New York where Nature is as undisturbed and the atmosphere as pure and free from dust and disease-germs as any that can be found west of the Mississippi. The Adirondacks in New York, the piny regions of New Jersey, or the wilds of Pike County, Pa., offer about all the advantages of Colorado, excepting extreme dryness and great elevation; and it is only under certain circumstances, and for certain well-selected cases, that these are necessary or desirable.

Patients who have not the strength or vitality to lead an out-of-door life in New Jersey will get little or no benefit in Colorado, and need not go to Arizona or California to find conditions no more favorable for their improvement than can be found in the Carolinas, Georgia, or Florida.

The rigors and vagaries of a Northern winter are as well avoided in the Southeast as in the Southwest; the feeble patient is nearer home and friends in case of severe illness or death; he avoids a long and exhausting railroad ride, and is free from the dust and unsanitary conditions of Arizona and the forsaken, far-away, friendless feeling so common in Southern California.

My advice about this whole matter is: keep out of doors, "out of dust and out of crowds;" for the favorable cases (with few exceptions) the place is less important than the kind of life followed; for the unfavorable ones, the nearer home and friends, the better.

An Early Sign of Pneumonia.—Morison (*Lancet*, No. 3656, p. 746), in several cases presenting the general symptoms of pneumonia in the absence of the ordinary physical signs, has observed a jerky expiration over a limited area, in which he subsequently found developed the usual signs of pneumonia. This jerky expiration is believed to be the first physical sign developed, and can be heard soon, if not immediately, after the rigor, before dulness or crepitation appears. The sign is more distinct in children, but has also been observed in adults. It is suggested that the phenomenon may be due either to the primary congestion interfering with the elasticity of the lung or to the better propagation of the heart-beats through a more readily conducting medium than the healthy lung.

ORIGINAL LECTURE.

I. TRAUMATIC EPILEPSY DUE TO FRACTURE OF THE SKULL, TREATED BY EXCISION OF BONE AND NEURECTOMY OF BOTH SUPRA-ORBITAL NERVES.

II. BURROWING ABSCESSES OF THE ABDOMINAL WALL AND PELVIS DUE TO ULCERATIVE APPENDICITIS, TREATED BY REMOVAL OF THE APPENDIX AND DRAINAGE.[1]

BY JOHN B. ROBERTS, A.M., M.D.,
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC AND IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA, AND SURGEON TO THE METHODIST HOSPITAL OF PHILADELPHIA.

THE first case that I shall present to you is a boy, of about twelve years of age, who was kicked in the middle of the forehead by a mule about two years ago, resulting in some form of fracture of the frontal bone. This was treated in the ordinary manner by antiseptic dressings, but no trephining was done, and no special exploration of the wound made. At the end of about six months the boy began to have true epileptic seizures. He bit his tongue and exhibited the ordinary convulsions of an epileptic. Close questioning of the patient has failed to find any other cause for the disease than the injury, and he is very positive that he had no convulsions previously to the time that his head was hurt. You see the scars of the injury and of a former operation, situated above the root of the nose and running horizontally. I find no other cicatrix of the scalp, but notice that the boy flinches when I make pressure over the left supra-orbital nerve. The right supra-orbital nerve is less sensitive, but seems more tender than is normal when such pressure is made over its point of exit from the supra-orbital foramen. The scar itself is also tender. In other respects the boy is healthy.

Dr. Graham, to whom he was brought some months ago, made an incision over the area of the fracture where a depressed scar was located. He found the frontal bone driven in by being bent very much in the manner of a green-stick fracture of the long bones in young children. He removed a narrow strip of depressed bone across the forehead. The epileptic seizures were absent for a time, but gradually returned. The boy comes back to-day to see if anything further can be done for deliverance from his disease. There is no history, so far as we are able to ascertain, of epilepsy in the family.

This, then, is a case of traumatic epilepsy, associated, with fracture of the skull in the frontal region. The question to determine is whether we shall do a secondary bone-operation by cutting down and taking out a portion of the skull, or simply lift up the scalp and endeavor to relieve irritation due to cicatricial pressure upon the supra-orbital nerves that are being pinched. If we make our incisions in the lines of the normal creases of the forehead as I have mapped out on the board, we shall make a less noticeable scar than if the incisions followed other lines. Instead of making a new scar I shall, moreover, make the incision in the position of the old one. I can reach the supra-orbital nerves, I think, by pulling down the flap, without making a vertical incision in the forehead. This will give rise to less disfigurement than if an additional incision is made in an oblique or upward direction.

In the first place, after using chalk for illustrations on the blackboard, or touching anything else, I again sterilize my hands. The finger-nails of the surgeon are one of the most dangerous factors in connection with operations. I may add that I use a saturated solution of potassium permanganate as a disinfecting agent for my hands, and wash them afterward in a saturated solution of oxalic acid in order to get rid of the discoloration made by the potassium permanganate. I have previously effectively used the finger-nail-cleaner and brush with hot water and soap.

As soon as the patient is etherized we shall remove the antiseptic dressing from his shaven head. His bowels have been opened, and the stomach has received no food for a number of hours. The patient, about a half-hour ago, was given a sixth of a grain of morphin and one one-hundred-and-twentieth of a grain of atropin hypodermatically. The amount of ether required during the operation will thus be less, and there will be less bother from accumulation of mucus in the bronchial tubes. By giving the drugs mentioned, one does not have the coughing and spitting due to accumulation of mucus in the bronchial tubes; the recovery from the ether is comfortable, with little vomiting; the patient will probably sleep for two or three hours, and there will be no necessity of giving an anodyne after the operation to relieve pain and soreness.

Although sterilization of the seat of operation has been assured in the wards by the nurses, and the part covered by antiseptic dressings, I usually re-sterilize my patients when they are put on the operating-table, giving the leg, or abdomen, as the case may be, a drenching with mercuric chlorid solution, 1:1000 or 1:2000. I do not suspect my nurses any more than myself, but I am not sure of anything. I have caught myself sometimes doing things entirely unconsciously, which might neutralize my previous efforts to be aseptic. Hence, I may seem hypercritical in my preparation for operation.

In skull-operations I ordinarily put a narrow Esmarch band around the head, which stops bleeding from the scalp; but here I cannot do it, as the incision will be low on the forehead, and I shall have to be satisfied with catching the vessels as they spurt.

I now make an incision across the front of the forehead along the line spoken of, and the assistant catches with hemostatic forceps such vessels as bleed. I can feel through the skin a depression due to the old operation. It is a little above my incision. I made the incision somewhat low because I want to get down to the supra-orbital notches, in order to excise the tender supra-orbital nerves. I can see now the point of the original operation. It is a little more inconvenient when you come to work upon a bone previously operated on, because cicatricial adhesions have taken place, and the parts have been thickened and somewhat displaced. You can see a dent in the bone where the craniectomy was made by the previous operator. It appears that the opening in the skull has actually closed with bone, which is unusual. I shall first take out the nerves. I

[1] A clinical lecture delivered by invitation at Rush Medical College, Chicago.

have cut, as you see, the supra-orbital artery, which is spurting and affords a guide to the notch, which I now show you with the supra-orbital nerve coming out of it. I clear away the tissues about the supra-orbital notch as much as possible, but I find it is hard to keep it in view, because the supra-orbital artery bleeds freely. The supra-orbital nerve in this instance comes through an actual foramen. It is not simply a notch with a band of ligament over it as we often find. I cut out the little piece of bone which makes the lower margin of the foramen in order to enable me to reach the nerve further back. I also nearly always cut out a piece of bone, when I operate on the infra-orbital nerve for trigeminal neuralgia, because if I chisel out the piece of bone completing the opening I can get hold of the nerve further back with forceps and draw it forward and break it off far back. A hemostatic forceps is the best instrument with which to seize this nerve. I have drawn out quite a portion of the nerve and broken it off, and will now scrape out the groove and get every particle of nerve-tissue out of it. The nerve of the other side, which although not so tender, seems to be a little sensitive, must now be exposed. On this side the nerve is not in a foramen, but in a notch. As I cut away the tissues in the notch the orbital fat protrudes, because there was not, as on the other side, a true foramen. I have done all I desire with these two nerves by cutting out a piece of each, and shall next devote my attention to the skull. The depression or groove in the bone is big enough to put my finger in, but it is not very deep, and it extends across the forehead. There is difficulty experienced in raising the periosteum, on account of its adherence to the bony scar due to the previous inflammatory process at the seat of operation. We have now made the area clear of periosteum. The depressed region extends over and crosses the median line of the frontal bone, upon which is the beginning of the superior longitudinal sinus.

Sometimes in opening the skull I use a trephine, and sometimes a chisel. I find that I use a chisel more and more, and the professors connected with this college tell me that they have almost abandoned the trephine. The trephine makes a round hole, whereas with a chisel one can get an opening of any shape that may be desired. The round opening made with the trephine is readily made of any shape by cutting away the edges with the gnawing forceps. In osteoplastic operations on the cranium, when it is desirable to preserve the bony flap and replace it, the chisel is the better instrument. It is here necessary to remove a considerable portion of bone, and I shall not want to replace it, because it is possibly the cause of the trouble by making pressure upon the brain or by irritating the dura. Therefore I shall not save the bone, and a trephine is as good as the chisel. If you expose the brain to remove a tumor or a cortical center for Jacksonian epilepsy, you keep the piece of bone in an antiseptic solution at a temperature of 105°, then replace it afterward, so that the perforation in the skull will be closed with bone. In this case I do not want to do that, because it is necessary to have the brain free from bony pressure.

The frontal bone is comparatively thin, and I have to proceed rather cautiously. If I open into the frontal sinus I may subsequently have to use a smaller trephine to cut through the posterior wall. I presume the two walls are close together, from what Dr. Graham has said. They may be solidified into one. Indeed, the boy is too young to have a well-developed sinus. A disadvantage in the use of the trephine is that if the skull is thicker in one part than in another it cuts unevenly, and you penetrate one side more quickly than the other, and by so doing you may injure the dura. At times therefore I use my segment-trephine, which cuts only along two-thirds of the circle. This instrument is employed after the groove has been started by an ordinary trephine. Here I shall start by perforating the bone with a trephine, gnawing the opening as large as is demanded. This aseptic trephine is one I devised to avoid having a hollow stem and a screw for the center-pin, which are so apt to get full of dirt and grease and become septic. The trephine is simply a cylindrical saw and cuts only in one direction, therefore I make semi-rotations with it in removing the button of bone. It is a good deal harder to get a trephine sharp and keep it so than a chisel, and this is another reason why the chisel is often the better instrument.

I show you the removed disc of bone, with a dent in it on the external aspect, through which the fracture passed. On the inner surface is a thick papule or osteophyte due to a new growth of bone, which pressed down on the dura. This projection of bone was made by the ossification of the fracture on the inner surface, where the vitreous table was more extensively fractured than the external table. This is sufficient to have caused the epilepsy.

A few months ago a patient came under my care who had sustained an injury of the head. He was struck on the temple by a lever or some part of an iron door which was thrown open against him. He was not treated by a physician, and had had nothing specially done for him. A few months after the injury he began to have epilepsy. I found in that case, as in this, a papule of bone like the top of a collar-button, which had been the result of an accentuated or punctured fracture due to the injury; yet the symptoms after injury were so slight that he never suspected that he had a fracture of the skull, and had not shown symptoms sufficient to induce him to apply to a doctor for the original injury. Epilepsy followed, with beginning insanity. That fracture demonstrated the importance of primary trephining in all cases of punctured fracture or fractures due to accentuated violence. A similar distinct process of bone has been pressing on this boy's dura. It will be wise to cut away all depressed bone in this case with the chisel and the gnawing-forceps. Here is found a curious condition: The bone has running directly through it a piece of fibrous tissue attached to the dura mater internally and the soft tissues externally. It is probable that the groove made in the former operation in healing caught some of the pericranium, and thus grasped it in the osseous cicatrix. This tissue is not a part of the dura, for that was not lacerated or incised either by the injury or the first operation. This fibrous partition, however, is attached to the dura, as you perceive, when traction is made on it. Such a condition is conducive to dural irritation leading to epilepsy.

Three things, then, have been found each of which would be sufficient to cause the convulsions, viz., the osteophyte pressing upon the dura, this entanglement of pericranium in the bone-scar, and the supra-orbital

nerves made sensitive by the cicatricial pinching of their branches. The pain in the nerve was, without question, due to the pinching of the pericranium by the gradually closing sides of Dr. Graham's craniectomy. It is remarkable that the opening in the bone should thus be repaired, in such a manner as to bite the soft tissues, as it were. I have taken out the whole area of depressed bone, making an opening across the ferehead about a half-inch wide and about three inches long, and there is no longer pressure on the dura or the brain. The excision of bone is so extensive that there is little probability that the opening will close as it did before. There is now no depressed bone that can give rise to irritation of the dura and be a cause of epilepsy. Hence the boy will be greatly benefited, I believe, and perhaps permanently cured, if treated with bromids, continued for a long time, to break up the convulsive habit. The local physical cause has been removed.

I formerly used threads of catgut for drainage in all of these cases, but recently I have not done so, believing that, if the wound is thoroughly aseptic, the blood-clot will become organized, and there is no danger of suppuration. I am in the habit of closing the wound at once, covering it with iodoform and collodion, and trusting to asepsis and organization of the clot.

When I go out of town to operate I nearly always use capillary drainage. I think it is safer to do so if you have not the patient under your care all of the time. When one operates at home and has his own nurses, he will at once be notified if anything should go wrong. If patients are in the country the after-treatment cannot be followed so closely; and when the nursing is more or less inefficient it is best to use some form of drainage. It is safer for the patient. If you do not put in drainage-threads or a drainage-tube, the wound, however, heals more quickly, because by sealing with gauze, iodoform, and collodion you get immediate union throughout the whole length of the wound. The probability is that in three or four days this patient will be sitting up, and that he will be out of the hospital in two weeks. I put in a few interrupted catgut sutures to bring the parts together, use a few catgut threads for drainage, dust a little iodoform over the wound, and finally apply a large dry dressing. It will be well for us to seal the lower edge of the dressing along the brow with collodion, because it is difficult to keep the edge in contact with the brow by means of bandages without entirely covering his eyes. I thus reinforce the dressing at the lower end, by the application of collodion, to be sure that germs do not gain entrance by the boy trying to see.

NOTE.—The operation-wound healed practically by first intention, though there was a drop or two of purulent secretion about the suture-punctures in the skin. The boy was discharged from the hospital in about three weeks. He had some epileptic seizures after the operation, but they were much less frequent and less severe than for several months before the operation.

BURROWING ABSCESSES OF THE ABDOMINAL WALL AND PELVIS DUE TO ULCERATIVE APPENDICITIS; TREATED BY REMOVAL OF THE APPENDIX AND DRAINAGE.

This young girl, while playing with other children at school last winter, was struck in the right inguinal region with a snowball. She went home, but could not go to school the next day on account of pain, and a physician was finally summoned. The patient continued to have considerable pain, and finally an abscess appeared in the right inguinal region. This was opened by her attendant, but continued to discharge pus, and the girl was brought to the hospital some months later with a discharging sinus at that point, and with the thigh in a flexed position. It was difficult for Dr. Senn to make out whether the case was one of appendicitis that had occurred coincidentally with the injury from the snowball, but unconnected with the injury; or one of appendicitis, due to the blow, going on to suppuration; or one of traumatic hematoma in the tissues of the lower part of the abdomen, which suppurated because of bacterial infection due to proximity to the cecum and vermiform appendix. The abscess was opened, but the appendix was not removed. It is possible, although not probable, that we have here an abscess of a tuberculous nature—that is, a puriform collection arising from tuberculous disease of the vertebræ descending in the sheath of the psoas and iliac muscles.

An interesting point in the case is that when the girl came into the ward the thigh was flexed. That might mislead the surgeon and cause him to think the condition coxitis, or a perinephric abscess, causing spasm of the psoas muscle. It has been said that a good many of the cases of supposed coxitis that recover so rapidly, with perfect motion of the joint, have probably been cases of muscular flexion due to psoas-spasm and the result of a simple perinephric cellulitis. Tuberculous perforation of the acetabulum and the entrance of pus into the cavity of the pelvis might be present and due to progressive coxitis. I do not think that is the case here. Under etherization some weeks ago the leg was readily put in an extended position and kept so for a short time by a gypsum dressing. The flexion was evidently due to the child lying long with the hip bent when the abscess was recent. The deformity is now gone. Near the sinus I feel that within the abdomen there is a hard mass, showing that there is still some inflammatory exudate present. The uterine sound makes one of the nicest probes for entering long sinuses, but it must be used with care. One succeeds better by bending the probe a little at the tip, as it then passes the irregularly tortuous channels better. I shall probe with a good deal of caution. The instrument goes over to the left six or eight inches, and is evidently in the abdominal wall.

Dr. Senn has tried his hydrogen-gas test through the anus, and found no escape of gas, but it is said that injections of fluid thrown into the sinus cause an evacuation of the bowels. I shall enlarge the opening, explore the various tracts, and make provision for thorough drainage. I may accidentally open the peritoneal cavity, but shall try not to do so. If necessary, I shall make an opening posteriorly and establish through-and-through drainage. By cutting down on a grooved director through the hardened tissues of the abdominal wall, I enlarge the opening enough to introduce my finger. I am able to penetrate quite a large cavity, which runs to the left, and feel the intestine as it lies in the abdominal cavity, but separated from my finger. There has been no fecal discharge through this opening; but there is apparent evidence that the opening communicates with the intes-

tine in some indirect way. It is possible that we shall find a small opening leading to some portion of the bowel. Pus has burrowed as far as the median line directly over the bladder, but there is probably no opening into the bladder. There was no evidence of pus in the urine when an examination of the urine was recently made. My finger is now on top of the bladder. The abscess has burrowed over here, and is in the belly-wall in front of the peritoneum, or else the bowel is separated from the cavity of the abscess by an adventitious membrane.

On the left side, where I feel the tip of my finger, I shall make a counter-opening and establish through-and-through drainage. It is necessary to enlarge the wound in order to get more room. We shall establish through-and-through drainage by a tube, after scraping out the cavity and washing away the purulent material. Observe the mass of broken-down granulation-material that escapes from the openings at the two ends of the abscess-pocket. With my finger as a guide, I scrape out the interior of the cavity thoroughly, avoiding the bladder, the position of which I now know, and endeavoring not to break through into the general peritoneal cavity. I feel almost inclined to let well enough alone and not make a search for the appendix, which has probably been the cause of this pathologic condition. If we drain the abscess-cavity thoroughly, it will become shut off from the general peritoneal cavity, and it is possible that the patient will have no further trouble. My incision has exposed coils of intestines near the region of the appendix, but elsewhere the peritoneal cavity is separated from the abscess. This is evidently the cecum that you now see. Notice the characteristic pouched condition which proves the exposed gut to be the large and not the small intestine. One of these longitudinal bands on its wall leads down to the appendix. Here is the base of the appendix. I am now trying to tear the parts loose slowly with my finger, so as to isolate the whole length of the appendix. If I can get to the end of the appendix and find an ulcerative perforation there, we shall have a solution of the case. My finger goes down to a knot of intestine or inflammatory tissue which is tightly adherent to the appendix. There is little doubt that the case is one of appendicitis, with perforation and burrowing of pus. There is a gush of purulent fluid. I shall keep the peritoneal cavity free from this purulent discharge by packing sponges against the intestines. I am working slowly so as not to tear the bowel, near which this abscess is situated. You perceive a fetid odor, and now you see the appendix itself, entirely separated from its adhesions. We have gotten it isolated, but it was difficult to do this without tearing the bowel to which it was adherent. It must be perforated, as it has caused the abscess. I shall tie its mesentery first. I now take the appendix itself and tie it near its base with a silk ligature, and amputate it. Here is the stump of the appendix which I have cut off. I now shove it in so as to invaginate it, and cover it over with peritoneum by sutures of catgut. First I touched the end of the stump with undiluted carbolic acid to disinfect it. Here I show you the perforation in the side of the appendix, which has caused all this mischief. It corresponded with the seat of this abscess and the site of the adhesions and the inflammatory mass about the appendix. Investigation shows that the second abscess-cavity goes down into the true pelvis. I cannot reach the bottom of it. Notice the pus welling up as I take my finger out. I place the patient in the semi-recumbent position so as to throw the pus away from the general peritoneal cavity. We shall protect the peritoneal cavity from infection by gauze packing, and leave the wound open, after thoroughly washing out the cavity with sterilized water. I would like to scrape it if I could, but this would be a somewhat difficult thing to do. I might do harm by making an opening into the vagina or bladder. This second abscess has burrowed down into the pouch of peritoneum between the rectum and the uterus. It is probable that the desire to go to stool, when fluid was forced into the sinus, was due to pressure on the rectum by filling this abscess-pocket with the fluid introduced.

I now simply pack the wound with gauze to keep it open, pass a drainage-tube through the abscess in the belly wall, and apply the ordinary dry dressing. To-morrow the intestines will be shut off from the external wound by plastic exudate. The gauze will then be removed, and a large drainage-tube passed down into the pelvis following the second abscess-pocket opened to-day. If the temperature rises, this tube will be used as a means of flushing the cavity daily with weak antiseptic solutions. It may be necessary to make a counter-opening into the vagina. I hope not.

NOTE.—The patient did well, and some weeks afterward was reported as convalescing nicely.

CLINICAL MEMORANDA.

A CASE OF ACCIDENTAL HEMORRHAGE IN THE FIRST STAGE OF LABOR AT FULL TERM.

BY HENRY H. SMITH, M.D.,
OF RAYTOWN, MO.

As there is some variance among authors as to the symptoms and treatment of the infrequent condition of accidental hemorrhage in the first stage of labor, I report the following case:

On September 11th, I was urgently called to Mrs. R., a robust woman, aged forty-two, in her fourteenth pregnancy, at full term. I found her in a state of collapse, pulseless at the wrist, the extremities icy cold, with great anxiety and restlessness, complaining of blindness and of continuous pain in the lower abdomen. A hasty examination revealed evidence of only slight external hemorrhage, a dilatable os, and a vertex-presentation with the membranes intact. Blood of a dark color and syrupy consistency, giving the characteristic odor of old blood-clots, clung to the examining finger. The womb was greatly distended and bulging into the abdomen; it was rather tense, but still imparted to the hand an inelastic, boggy feel. There were no movements or other signs of life of the fetus.

I at once informed the nurse that the patient was in a very critical state, and called for assistance. My efforts were directed toward reviving the patient. I lowered the head, applied heat to the extremities, and gave hypodermatically spirit of camphor, morphin and atropin, nitro-glycerin, and alcohol, very freely. In twenty minutes I was rewarded by a return of the pulse at the wrist, and in an hour and a half reaction was well established. I adhered to a rule I have always followed in labor, and

gave no ergot until the womb was emptied. The question confronted me from the beginning, whether I should delay or attempt immediate delivery. In the collapsed condition of the patient I believed that the slightest additional hemorrhage meant a disastrous end. Further on, when she had rallied, there were no labor-pains, and consequently there was no promise of contraction and retraction of the womb after delivery. Guided only by the condition before me, I determined to temporize and await developments. The pains in the lower abdomen and lumbar region grew worse and continued without intermission. About three hours after I first saw the patient the physician I had sent for arrived, and after emptying the bladder at his suggestion, we ruptured the membranes and thus brought on feeble labor-pains. The parturient canal was roomy and advancement was due mainly to the expulsive efforts of the mother, rather than to the weak contractions of the uterus. Compression was used over the fundus. In three-quarters of an hour a lifeless child was born, and energetic efforts failed to resuscitate it. The placenta was at once taken away, followed by a basinful of clotted blood. The placental site seemed to have been at the fundus, though the placenta was wholly detached when removed. The wound contracted well, we administered a couple of doses of ergot, and the woman proceeded to a good recovery.

Two weeks before confinement the patient had had a violent fall on the buttocks, which was followed several times, at intervals of a few days, by what she termed "sinking spells"—symptoms of internal hemorrhage—occurring usually at night while she was in bed. Traumatism is considered the most fruitful source of accidental hemorrhage before labor, but in a paper by Dr. Coe, of New York, read before the American Gynecological Society, in 1891, he stated that traumatic injury was the more infrequent origin of hemorrhage during full-term labor, which is the more fatal form.

The readiness with which the circulation regained its volume led me to believe that the collapsed condition was not wholly due to exhaustion from loss of blood, though the hemorrhage was great, as was shown by the débris finally discharged from the womb; it was doubtless in part produced by shock incident to the sudden and extreme over-distention of the uterus. I attributed the absence of labor-pains to loss of contractile power, caused by the abnormal stretching of the uterine muscular fibers.

CHANGES IN REFRACTION AFTER CATARACT-EXTRACTION.

BY CHARLES W. KOLLOCK, M.D.,
OF CHARLESTON, S. C.

ON the 5th of last June I removed a cataract from the left eye of Mr. Y. He was not a strong man, as he suffered considerably at times from indigestion and bleeding piles.

An iridectomy was performed, and the operation was finished without any mishap, except the lodging of a piece of cortical matter in the upper pupillary space. A few careful attempts were made to expel it, when it was seen that the vitreous was protruding, which caused displacement of the edges of the incision. The subsequent healing was slow, but continued without any further complication. The cornea at the incision was somewhat bulged, but the shape gradually improved, so that after the secondary operation had been performed, vision with + 10 D. was 15/70. Twelve days later, with +11+ 2.cyl. ax. 180°, vision was 15/40 and 15/xxx (?). Nearly two months later he came, saying the glasses did not suit. He was again tested, and refused all cylinders; but with +14 D. vision was 20/20 (?), and he read small pica with +16 D. The 14 D. lens was not only best for twenty feet, but for infinite distances.

This case is interesting on account of the various changes that occurred in the corneal surface, which was, of course, more irregular at first from the lack of coaptation of the edges of the incision, but the gradual increase of the strength of the lens to such a degree is unusual.

I have thought that the report of this case would be of interest to those who heard and took part in the discussion of Dr. Jackson's paper in the Ophthalmological Section of the Pan-American Medical Congress.

NEW INSTRUMENT.

AN ESOPHAGEAL STETHOSCOPE: WITH REMARKS ON INTRA-THORACIC AUSCULTATION.[1]

BY SOLOMON SOLIS-COHEN, M.D.,
PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC; ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL, ETC.

THE instrument that I have here is a modification of one suggested by Sir Benjamin Ward Richardson. In the course of that observer's examination of a case of suspected stricture of the esophagus, in which no obstruction was shown by the "water-gurgle" test, and he had concluded to pass the stomach-tube, it occurred to him that, perhaps, if he attached the terminal of his double stethoscope to the stomach-tube he might notice the presence of friction as the tube passed over the stricture, or the absence of friction and of stricture; in this particular case he found no friction and determined that there was no stricture. It then occurred to him that in many cases it might be useful to employ a similar apparatus in listening to the sounds of the heart and possible murmurs in the vessels, as in cases of aneurism, unmodified by transmission through the chest-wall, and that possibly he might be able to hear the sounds of the lungs in the same manner. He also thought that certain sounds generated in the stomach might give information as to the manner in which the gastric functions were being carried on; while the sounds of the abdominal aorta could be heard through the stomach, unmodified by the pressure that on external auscultation is so often a cause of doubt in interpreting the causation of murmurs.

In attempting to repeat Dr. Richardson's observations, I found that there was occasional danger of the regurgitation of fluid through the tube into the ear-pieces. To obviate this objection I have introduced between the stomach-tube and the ear-tube a rubber capsule contain-

[1] Presented to the College of Physicians of Philadelphia, November 1, 1893.

ing a diaphragm of gold-beater's skin, which serves as a barrier and as a resonator. The capsule can be readily taken apart and cleansed, and new diaphragms can be inserted when needed. I exhibit the improved instrument, as skilfully made for me by Messrs. Tiemann & Co., of New York.

The esophageal tube is of soft rubber, No. 27 of the French scale, having a lateral eye near the blunt tip. On the same side as the eye, beginning five inches therefrom and extending up to a distance of nineteen inches, is a series of indentations, one inch apart, which show how far the eye of the instrument is from the patient's teeth. By experiments made outside of the body I have found that the sound heard is transmitted from within a radius of an inch and a half or two inches from the opening in the tube, the sound being most distinct when the eye is in close apposition to the source of sound. I have used the instrument to listen to the sounds of the heart only, not wishing to risk the passage of the tube in cases of thoracic aneurism and not being able to hear through it the lung-sounds.

The most striking difference between the sounds of the heart as heard in the ordinary way and the same sounds as heard through this instrument is the almost uniform quality of the first and second sounds—that is, the sharpness of the second sound, as heard by the ordinary method, is wanting in auscultation by this method. The rhythm is of course the same; the second sound is the shorter, and the pause is easily appreciated. It is possible to separate the two sounds and hear the first sound alone, or the second sound alone, or to hear both. At a distance of from eight to nine inches from the teeth, only the second sound is heard; at ten or eleven inches, both sounds are clearly heard; and at thirteen or fourteen inches only the first sound with, perhaps, an ill-defined second sound. I have not satisfied myself as to my ability to differentiate between the aortic and pulmonary sounds by varying the position of the eye of the tube.

My largest number of observations have been made on persons with healthy hearts, who were under treatment for stomach-troubles, and thus accustomed to passage of the esophageal tube; but I have been able to use the instrument on other patients, with and without cardiac disease; among them two cases in which by the ordinary method of examination I had diagnosticated the existence of mitral obstruction. In one of these two cases mitral obstruction alone was diagnosticated by the ordinary methods of physical examination; and in the other, mitral obstruction and regurgitation. In both cases I failed in each of two examinations to hear the obstructive murmur through the esophageal stethoscope. The regurgitant murmur was heard distinctly, but I could not make out that any part of it was presystolic. I do not know whether there is an acoustic reason for this, or whether it was due to lack of skill with the instrument. I have no doubt of the correctness of the diagnosis.

I have also used the method in one case in which there was doubt as to the coexistence of aortic diastolic and aortic systolic murmurs, but the apparent murmur of regurgitation was not heard through the esophageal stethoscope, whilst the systolic murmur was heard distinctly, and a good closure-sound was heard. This, I think, warranted affirmation of arterial roughening rather than valvular lesion.

While speaking of the use of the tube to clear up the doubt in cases of suspected aneurism, Sir B. W. Richardson remarks that the good sense of the physician must determine whether or not in given instances the method is dangerous, and not to be used.

As to the importance of intra-thoracic auscultation, I cannot as yet speak positively. I do not know how far it will be applicable in cases of doubtful diagnosis—in others it is not needed—or what its exact limitations are. I consider it, however, one of the methods that we may usefully employ among others in making exact observations, and for this reason I have brought the subject before the College for discussion, in the hope that other Fellows may be led to study it.

It is only right to say that two other communications on the subject of intra-thoracic auscultation, one by a German observer, the other by two English observers, have appeared since Dr. Richardson's publication, and apparently as independent studies. Their conclusions are not cited here, as the subject still requires individual and unbiased work.

MEDICAL PROGRESS.

Disease of the Corpora Quadrigemina.—At a recent meeting of the Clinical Society of London, TAYLOR (*Medical Press and Circular*, No. 2845, p. 500) reported the case of a boy, four years old, who four months before coming under observation became ill, would not eat, and presented drooping of the eyelids, followed by gradual loss of strength. For two weeks there had been staggering, the incoördination being increased at the same time as the drooping of the eyelids was worse. The child appeared to be somewhat drowsy and spoke slowly; his gait was markedly ataxic, the feet being thrown forward and suddenly brought down, heels first;

on trying to stand he oscillated forward and backward. He could not touch the tip of his nose with the tip of his forefinger, nor bring the tips of the fingers of the two hands accurately together. The head and neck also oscillated in an antero-posterior direction. There was nearly complete double ophthalmoplegia, including double ptosis, more marked upon the right, and paralysis on both sides of the superior, inferior, and internal recti, and, so far as could be determined, of the superior and inferior oblique. There was some lateral nystagmus. The pupils were slightly and unequally dilated, and reacted to light. There was no optic neuritis and no choroiditis. The child could not see, but no accurate record was made of the powers of vision. After the lapse of a month the child became semi-conscious, swallowing with difficulty, and the arms and legs fell flaccid when lifted from the bed. Loss of consciousness became more profound, the breathing assumed a Cheyne-Stokes character, swallowing became difficult and finally impossible, and death ultimately took place six months after the appearance of the first symptoms. Upon post-mortem examination the cerebellum was found to be perfectly healthy, but the corpora quadrigemina were flattened, broader, and more extensive than normal, and gray and gelatinous in appearance. There was a similar gray substance at the base of the brain, between the crura cerebri and invading them in their inner halves; the third nerves were lost or torn away from their attachments. In the right orbit all of the muscles supplied by the third nerve were atrophied, and the nerve and its branches could not be found. In the left orbit the nerve and its branches were present and the muscles were fairly healthy. The minute investigation of the parts was unsatisfactory, from failure in the preserving methods, but there was no doubt that the corpora quadrigemina and adjacent parts were changed by new growth, probably of a glio-sarcomatous nature.

Epilepsia tarda is the designation that MENDEL (*Deutsche medicin. Wochenschr.*, 1893, No. 45, p. 1108) would apply to epilepsy that appears after the fortieth year of life. From a statistical analysis he has found that the condition is both relatively and absolutely more common among males than among females. Hereditary predisposition plays an important etiologic rôle in this form, as in other forms of epilepsy. The course of epilepsia tarda is in general milder and comparatively less progressive than that of the ordinary form of epilepsy, and the mental condition suffers less, even after prolonged existence of the condition.

Temporary Aphasia following Contusion of the Left Side of the Head.—GAUDOIN (*Indian Medical Record*, vol. v, No. 7, p. 222) has recorded the case of a girl, ten years old, who came under observation in an unconscious condition, and presenting a contusion of the left side of the head, the result of a blow. On the following morning a hematoma about the size of a walnut was found at the site of injury above the left ear. The patient had recovered consciousness, but there was total aphasia. The child answered questions and made known her wants by intelligent signs. In the course of time, however, steady improvement took place, the tumor gradually disappearing and speech returning.

THERAPEUTIC NOTES.

The Treatment of Chronic Gastric Catarrh.—As the result of a thoughtful study of the measured effects of certain therapeutic agents, including lavage, hydrochloric acid, and intra-gastric faradization and galvanization upon the secretory and motor functions of the stomach in cases of chronic catarrh (glandular gastritis), STEWART (*Therapeutic Gazette*, November 15, 1893, p. 744) comes to the conclusion that in the treatment of this condition lavage is of service as a cleanser of the mucosa and as a stimulant to the most important of the gastric functions—the secretory and motor; although for all purposes but the last lavage is decidedly inferior as a remedial agent to the intra-gastric application of electricity. Hydrochloric acid, administered even in full doses, after meals, is of less value as a stimulant to the secretion of the hydrochloric acid of the stomach than as a digestant; even in this capacity it may be of little utility in the total absence of hydrochloric acid from the gastric secretion. Under such circumstances benefit may be derived from its employment in large doses in combination with pepsin. Of the various agents employed in the treatment of gastric catarrh, by virtue of their influence upon the secretion and motility of the stomach, none is comparable with the intelligent daily use of intra-gastric faradism and galvanism.

Loretin—a Substitute for Iodoform.—SCHINZINGER (*Centralblatt für Chirurgie*, 1893, No. 45, p. 984) reports the employment, with satisfaction, in a considerable number of operations, of loretin as a substitute for iodoform. Chemically, the preparation is meta-iodo-orthochinolin-sulfonic acid, and it is claimed that it lacks the disagreeable odor and the toxic properties of iodoform. The body is a yellow, crystalline powder, in appearance suggestive of iodoform, but entirely without odor. It is but slightly soluble in water and in alcohol and practically insoluble in ether and in oils, although with the latter it forms emulsions, and particularly with collodion. As a sulfonic acid, loretin forms metallic oxids; of these the alkaline salts are soluble in water with the production of an orange-red color. A solution of the sodium salt of from 2 to 5 per cent. commends itself for purposes of irrigation or topical application. Careful investigation demonstrated the innocuousness of the preparation and the absence of renal irritation after its use. The drug is also free from irritating action upon the skin. Gauze impregnated with loretin has been employed when indicated.

Benzol for Influenza.—ROBERTSON (*Lancet*, No. 3663, p. 186) relates that he has treated a number of cases of influenza with benzol, with the best results. The drug was administered in doses of five minims every two hours and a half, in the form of an emulsion, in lemonade. As a rule, in about two hours after the first dose the general discomfort had disappeared, and within the first twenty-four hours the temperature was observed to be normal. Convalescence was usually rapid and followed by very little debility. Correspondingly good results were observed in cases of whooping-cough treated with benzol.

THE TREATMENT OF TYPHOID FEVER WITH INJECTIONS OF DEAD BACTERIAL CULTURES.

How many "specific remedies" have been recommended in the treatment of typhoid fever we should be afraid to say. A long series of intestinal antiseptics has been tried, but each of them in turn has been abandoned. At the moment the general opinion seems to be that where it is practicable, as in large hospitals, the cold-bath supplemented by purely symptomatic treatment, gives the best results. But even by this method not much has been gained beyond an amelioration of the general symptoms, and, perhaps, a moderate lowering of the death-rate. The duration of the disease has not been shortened, and it has even been claimed that relapses are more frequent than when the cold baths are not employed.

It is evident, however, that we are not to fail in the therapy of typhoid fever for want of trying, and already another system of treatment has been suggested, and this time from an entirely new, although, perhaps, not an unexpected, quarter. It will be remembered that last year BRIEGER, KITASATO, and WASSERMANN[1] claimed that by growing typhoid bacilli in bouillon made from the thymus of the calf (method of WOOLDRIDGE), a culture free from toxic properties could be obtained. In order to completely annul the toxicity and to kill the bacteria it was found necessary to heat the cultures to 60° C. Starting with this fact, EUGEN FRAENKEL,[1] with the assistance of MANCHOT, has prepared such a sterile liquid and has used it in the treatment of some fifty-seven cases of typhoid fever. The mixture was given by hypodermatic injection, preferably deeply into the muscles of the buttock; in no instance did any untoward local effects follow.

The injections were begun with 0.5 c.cm. of the sterile liquid—a dose which appeared to be quite harmless, even for children. As a rule, this had no visible effect, and on the following day 1.0 c.cm. was injected into the opposite buttock. This dose, unlike the first, gave rise, in the majority of cases, to a marked elevation of the temperature, sometimes accompanied by chilly sensations. On the following day the temperature-curve generally showed a decided fall, which was only temporary in the cases in which the injections were then discontinued. FRAENKEL'S rule was to give an injection every other day, increasing the dose about 1 c.cm. each time. The continuous fever disappeared, and the charts showed marked remissions in the temperature; the intensity of the constitutional symptoms diminished, and complete apyrexia followed in a very few days. With the fall in temperature the activity of the skin was restored, free diuresis was reëstablished, the diarrhea disappeared, and the patient, with an enlarged spleen, and perhaps copious crops of rose-spots, entered into convalescence and soon began to gain in weight. Twelve of these cases were of a grave type; the remaining forty-five were of average severity.

In an equally important communication appearing at the same time, RUMPF[2] reports the results of the treatment of thirty cases of typhoid fever with dead cultures of the bacillus pyocyaneus. Encouraged by the results of FRAENKEL, and stimulated by certain suggestions of BUCHNER,[3] he undertook these experiments in order to ascertain whether or not those general vital processes which, at the

2 "Die Behandlung des Typhus abdominalis mit abgetödteten Culturen des Bacillus pyocyaneus," Deutsche medicinische Wochenschrift, 1893, No. 41, p. 987.

3 "Ueber Bacteriengifte und Gegengifte," Münchener medicinische Wochenschrift, 1893, No. 24.

onset of an affection, are called into play to inhibit the progress of the disease, and to protect the organism against its evil effects, could not be developed and strengthened by the introduction into the body of dead bacteria of kinds other than that setting up the infection. In his first experiments he used dead cultures of the streptococcus pyogenes, but these having no favorable effect he next prepared cultures of the bacillus pyocyaneus in thymus-bouillon, just as FRAENKEL had done with typhoid-bacilli. The action of this "pyocyaneus-bouillon" on the patients was, on the whole, quite as favorable as that observed in the cases treated by FRAENKEL with "typhoid-bouillon." The temperature-curve soon assumed a remittent type, the somnolence and delirium gave way, the functions of the skin and kidneys were restored—all without any appreciable embarrassment of the respiration or circulation.

FRAENKEL and RUMPF claim, and they have had ample opportunity for observation in the large general hospital at Hamburg, that never in their experience with different methods of treating typhoid fever have they before seen such results as were obtained in these cases. In from six to eight days the fever for the most part, and all of the severe phenomena of the disease, had disappeared. The convalescence was prompt, and, as a rule, pursued an uninterrupted course. In cases in which relapses occurred these yielded speedily on the renewal of the injections. All of FRAENKEL'S cases, we think, recovered; of RUMPF'S thirty cases two died—one of intestinal hemorrhage and one of pneumonia. The latter is quite conservative in the matter, being content to leave to many further trials the decision as to the ultimate value of this method of treatment, emphasizing, however, the point which he regards as the most important outcome of the investigation, viz., "that it has now been established that a disease in human beings can be influenced by products of microörganisms wholly different from those which cause the disease."

BUCHNER,[1] in commenting upon this work, expresses his satisfaction with the results, especially with the conclusions of RUMPF, and points out the analogy between FRAENKEL'S work and the treatment of tuberculosis with tuberculin. From a bacteriologic standpoint, typhoid fever has to be looked upon as a fight of several weeks' duration between the animal organism and the typhoid-bacilli in the intestine, mesenteric glands and other organs. On the part of the human body the war is carried on with the aid of an inflammatory (and febrile) reaction, an attempt being made, either through the activity of the leukocytes (?) or through germicidal substances newly formed in the tissues (of the nature of which we are as yet ignorant), to bring about the destruction of the invading bacilli. BUCHNER therefore views the aim of these bacterial injections which we have just described as an effort to render this "curative reaction" more intense and thus more effectual, exactly as was that of the treatment of tuberculosis with tuberculin. Here we have nothing to do with antitoxic influences, or with the production of immunity, nor have these effects (as RUMPF has pointed out) essentially anything to do with "specificity" any more than have those of the tuberculin-reaction, as was shown for the latter two years ago by the fact that it can be set up by the products of bacteria other than tubercle-bacilli. The seat of reaction is, however, determined by the localization of the lesions of the specific disease, apparently because there the tissue-elements are already in an abnormal state of excitation, and can all the more easily be aroused to a still greater activity. Very different substances are capable of calling forth the reaction. We already know that the protein-substances contained in the bodies of different kinds of bacteria can give rise to it, and it is probable that other substances which cause a leukocytosis or a local inflammation can serve the same purpose. It will be necessary, as BUCHNER says, to determine how much, if any, of the effect produced by these injections of FRAENKEL and RUMPF is directly dependent on the extract of thymus which is employed in the preparation of the bouillon, for experiment has shown that the extract exercises almost as powerful a positive chemotactic influence as do the bacterial proteins themselves.

The disastrous consequences of the general rush after tuberculin will, we feel sure, tend to dampen any undue enthusiasm concerning this new departure in the treatment of typhoid fever. We shall this time be willing to await the results of the control-experiments which will undoubtedly soon be inaugurated by investigators in large hospitals, where the preparation by competent bacteriologists of a reliable fluid for injection can be assured. Should the treatment prove to be of value, it is more than likely that, as with tuberculin, many modifications and chemical refinements will have to be worked out

[1] Münchener medicinische Wochenschrift, 1893, No. 43.

before it will be safe to recommend its general employment. In any case, these researches are of the widest interest, and we shall watch attentively for further developments in a similar direction.

PHYSICAL TRAINING VS. ATHLETICISM.

ANTHROPOMETRY and experimental psychology are comparatively new comers among the sciences. The attempt to secure relatively accurate standards of measurement for physical and mental capacities is practically a matter of the last fifteen years, but the new sciences have come to stay, and accurately observed and carefully recorded facts already at hand are sufficiently striking and comprehensive to demand the attention of all those interested in the physical and intellectual improvement of the race. Anthropometry as developed under the system known as *Bertillonage*, established by M. ALPHONSE BERTILLON, has rendered the differential diagnosis of the various physical types of defectives and delinquents as precise as that employed by the medical specialist in the various other fields of human abnormality. Workers such as WUNDT, GALTON, CATTELL, and JASTROW, have furnished us with a basis for the estimation of the departure from or approximation to the mental and nervous *norm* as easy of application and as intelligible to the trained observer as are the readings of the hydrometer, barometer, or other means for estimating relative physical states. Statistics cited by MACDONALD, in his recent essays on Abnormal Man, point to the conclusion that school and college education *per se* has little influence in decreasing crime, insanity, suicide, or other acts based upon perverted mental and physical states, but to the contrary, that crime, university education, and alcoholism manifest a large and corresponding increase.

PROFESSOR JOSIAH ROYCE, of Harvard, in his articles in the *Educational Review*, points out how great a region childhood is for the sprouting and first springing up of the young weeds of future mental disorder, while E. M. HARTWELL, Director of Physical Training in Johns Hopkins University, proposes the term *cachexia scholastica* for the irritable, easily over-wrought, and unsteady nervous system, arrested development and enfeebled powers of assimilation so frequently met with among our young people from ten to thirty years of age. The only inference to be drawn from the startling array of testimony before us as to the inadequacy of mere intellectual education to avert human degeneracy, and from the direct bearing the existing system of instruction has in lowering the healthy or entrophic average, is that more attention must be paid to the building up of a race of men and women sound in body and mind, although perhaps not so precocious intellectually.

We often hear it said that this is the day of young men, and so it seems to be; but what a grotesque and absurd resemblance the average middle-class young man holds to the ideal youth! The measurements of over 15,000 young men show that the youth of London average all of three and a half inches shorter, and eighteen pounds less in weight, than the normally well developed type of the same age. The examiners for admission to West Point find a majority of the applicants unfit physically, and sometimes not one comes up to the standard of an able-bodied soldier.

We may well stop and ask those directing the education of the people what they are providing in the way of physical training toward the development of men and women whose prolonged and healthful lives shall render their increased acuteness of perception a source of personal and public comfort rather than a source of pain, premature old age, and all the evils resulting from physical depression.

The public has been deluded into accepting a false athleticism in place of scientific physical training. Only two or three of our universities have directors of physical training capable of bringing to bear the resources of the physician, the psycho-physicist, and the anthropometric expert. In the majority of instances the physical training of the student is ignored, or placed in charge of a retired sparring-master, rowing-coach, or ex-professional base-ball champion. The great mass of our boys and girls—of whom there are some fifteen millions, more or less, in actual school attendance, averaging, as BLAKIE estimates, forty pupils to each teacher in the land—these boys and girls are being practically neglected physically while being crammed mentally. In the meantime, the fact that over 60 per cent. of our population dwell in cities—an increase of 40 per cent. in the last century—shows that our stock of hardy country lads and lasses, from which to draw men of brawn and women of sound nerves, is rapidly lessening. If the tide of humanity cannot be turned out over the fields, then let us have some intelligent effort

on the part of Boards of Education and College Trustees to provide for the proper conservation of physical energy in our city children rather than the foolish encouragement of a popular fad for so-called athletics, based upon the same instinct that controls the gambler, the pugilist, and the *habitué* of the race-course. Place the physical training in the hands of scientifically qualified directors, allow the exercises to be based upon the needs of the student rather than upon the necessity of putting out a strong base-ball nine or foot-ball team. Do away with some of the present studies, and give at least half an hour a day to properly directed physical exercise. Increase the number of gymnasiums, make the fees nominal, have a personal record kept of each boy and girl, and see that the prescribed exercise is not evaded. An excellent aid in this respect consists in stitching colored worsted to the gymnasium suits over the parts requiring development, thus enabling the attendant to see that each pupil is performing only the required exercise, and inciting the pupil to a real endeavor to get rid of a mark indicating his or her weak point. Let the Directors of Physical Training hold annual conventions, to harmonize and systematize their work. The necessity of scientific physical training is a real one throughout our entire land, and physicians and parents should see to it that the young people for whose healthy development they are responsible should not be deluded and injured by the present semi-professional athleticism which has taken the place of real physical culture in most of our educational institutions, and the influence of which is felt even in the primary schools.

THE FIRST STATE HOSPITAL FOR EPILEPTICS.

THANKSGIVING-DAY was observed with peculiar appropriateness in the little town of Gallipolis, in the southern part of Ohio, for the day marked the opening of the State Hospital for Epileptics, the first of its kind in this country, we believe. We are aware that steps have been taken in Massachusetts, in New York, and in Pennsylvania, looking to the establishment of similar institutions, but, to the best of our knowledge, the hopes of the advocates of such a humane measure have yet to be realized. It would be difficult indeed to conceive of a greater blessing, of a nobler charity, of a truer philanthropy, than the provision of a home and, what is really more important, of healthful and remunerative occupation for a class of the community, the members of which are not so ill as to be unable to lead useful lives, but whose unfortunate condition renders them but temporarily and periodically incapacitated for work, and who thus cannot compete with others; while at the same time they are kept under medical care and observation. In this way these unfortunates are made to yield the greatest degree of usefulness of which they are capable, while they also receive the most scientific and the most humane treatment that can be accorded them. At Gallipolis five cottages have been completed with immediate accommodations for 250 male patients. It is hoped to have four additional cottages ready in the spring, for the reception of 200 female patients. There are, besides, dining-halls, boiler-rooms, and a farm of ten acres. The cottages are two stories high, are built of sandstone, are fireproof, accommodate 50 patients, and cost about $15,000 each. The site is an admirable one in all respects. It is expected at a future date that a second institution will be established in the northern part of the State. Common dining-rooms, except for the sick or infirm, have been provided, from economic motives. The patients will be given useful occupation to the extent that their health will permit. It is proposed to employ most of them during the summer months in truck-farming. It is estimated that the cost per capita will not exceed half that in the State hospitals for the insane. The State of Ohio has set an example that every other State in the United States should speedily follow. There can be no better way of *investing* public moneys.

EDITORIAL COMMENTS.

The Immortal Reading-Notice.—The extent to which the practice of the journalistic disgrace of the sneak reading-notice is carried cannot be known except by editors who look over one or two hundred different journals each week, and thus are enabled to see the same sly, shrewd, compound of lies reprinted *verbatim* as original editorial matter in scores of "medical" serials one after another. The chances are greatly against the ordinary reader, the bamboozled subscriber, or the non-subscribing receiver, knowing that this is fraudulent advice or news, and that it is appearing in many other journals in exactly the same way and in precisely the same words. He only takes one or two such local and venal periodicals, and the deception thus passes unrecognized, until some disgusted editor rails against it. Of late a particularly nauseating mess about "substitution" and the dishonest druggist is made to appear editorially in numberless medical journals, and

the whole end and aim of the rigmarole is a laudation of several proprietary and secret nostrums. Advertiser and editor are sharp enough to change the title in each periodical, but that is all the change except the bribe-money. "A Too Common Affront to the Profession," "Dishonest Druggists," "The Evils of Substitution," and other such are the hypocritic titles of the more hypocritic "ads." In a month or two a new stereotyped form will appear and run its course in the usual manner. We are thinking of making a list of these advertisers and of their slavish journals, and of putting them all in the pillory of publicity. The medical profession should know about these things. The practice is proof positive of the worthlessness of the nostrum thus advertised, the immorality of the advertiser, and the combined worthlessness and immorality of the journal thus prostituting itself.

An Argument for Human Vivisection.—A writer in a Western journal makes a vigorous plea that criminals condemned to death should be first used for vivisection purposes, and especially in the study of cerebral localization and function. One argument adduced is exquisitely humorous, the humor being heightened by the innocent unconsciousness of the quality. The earnest writer thus argues:

Those who would be unfavorably impressed with this method of investigation should take kindly to the information that experiments of this kind on the brain are no more unpleasant to the subject than like impressions aroused during the sojourn of perfect liberty. There is every reason to believe that the stimulus in a large number of instances would be highly pleasing. If, for example, our subject experimented upon was a person who had been repeatedly animated by the ludicrous, upon touching the seat of such impressions the whole circumstance would be reproduced, attended with the same vivacity as the original experience. Painful sensations would not be reproduced unless a certain nucleus of cells was stimulated, and this could be avoided after its exact location was ascertained. To secure coöperation and carry out the operation successfully the condemned would be instructed with the nature of the work.

The childlike conviction that "the ludicrous" and that "pain" have definitely localizable centers, and that all one would have to do in order to spend a life in laughter would be to tickle the ludicrous-center with a galvanic needle is itself one of the most painfully ludicrous conceptions of pseudo-science that we have ever met.

Metabolic Changes following Thyroid Therapy.—We have as yet no adequate knowledge of the processes that take place as a sequence of the administration of preparations of the thyroid gland in the treatment of myxedema. It has been observed in these cases that there occur pronounced metabolic changes, as manifested by elevation of temperature, loss of weight, and increased elimination of urine, as well as of its nitrogenous, phosphorous, and chlorinous elements. VERMEHREN (*Deutsche medicinische Wochenschrift*, 1893, No. 43, p. 1037), of Copenhagen, details the results of some interesting comparative observations, in which he found that in two of three young persons unaffected with myxedema, only increased diuresis followed thyroid treatment; while senile individuals thus treated displayed especially increased nitrogenous metabolism, elevation of temperature, acceleration of pulse, and increased diuresis, comparable to these phenomena as observed in cases of myxedema treated similarly. The inference is that the changes that take place in the myxedematous patient under the influence of thyroid administration likewise occur in old persons subjected to the same treatment. It is further pointed out that this similarity of reaction may be ascribed to changes in the thyroid gland—on the one hand a physiologic obsolescence, and on the other a pathologic atrophy.

Public Health vs. the Law.—In the last *Monthly Bulletin* of the State Board of Health of Iowa we notice a significant opinion from the Attorney-General in relation to the powers of the Board. It appears that the Birmingham local Board of Health condemned as unsanitary the Birmingham School-house and its site, and requested the State Board to investigate their condition. This was done by the civil engineer of the Board, and he pronounced both the building and the site unsanitary and dangerous. Nevertheless, the school-officers proposed to repair the building, and in this connection the attorney gave it as his official opinion that the State Board of Health had *not* the power to prevent this action on the part of the school-authorities.

The opinion is in these words: "The State Board of Health has not the power to make an order requiring a particular school-house to be closed because inimical to the health of children using it."

This is another instance of the absurd, technical ruling of our legal authorities, who consider that the people and their children are made for the law and the courts, and not the law and the courts for the people and their children.

The Solar Cautery as a Remedial Agency.—In the *Pacific Medical Journal*, Dr. A. V. Thayer writes eulogistically of the method of cauterization by means of solar heat. The *Scientific American* says that the method was first suggested by Augustus Barnes, of Southington, Conn., and was patented (we are thankful the man had no medical-title tail to his name!) by him May 28, 1867. One wonders why this method of the destruction of tissues is more agreeable than others in use, but we are assured that it is so. In sunny California the method might be applicable, but what would the surgeons in London, with months of absent sunshine, have to do and to say about it? Perhaps Dr. Thayer would advise sending the patients to California's hospitable shores! Here is a suggestion to the medical philosopher as to the influences of climate on medical and surgical progress. If a great truth, a real discovery, what a change in our office-customs! All surgeons would have to locate their offices as do the photographers, in the glass-roofed upper stories, and all hospitals would have to be much remodelled. In Chicago, with its twenty-two story buildings, this would be a "burning question" indeed.

Bloodless Amputation at the Hip-joint.—In view of the admirable results obtained at the hands of some twenty-five different operators from the employment of the method devised by DR. JOHN A. WYETH, of New York, for the control of hemorrhage in the performance of

amputation at the knee-joint, there would seem to be little to add to the eloquent statistics presented in the article by Dr. Wyeth that appeared in THE NEWS of last week. A procedure that has reduced the mortality of a given operation from 64 per cent. to 22 per cent. is surely deserving of an honorable and a permanent place in the history of practical surgery. The good results to be credited to Wyeth's method are to be found not only in the absolute saving of life in the cases in which operation is undertaken, but also in the indirect saving, in consequence of the performance of operations in cases in which otherwise a fatal result would passively be permitted to take place. American surgery has much to be proud of, and the device of Wyeth will gain it fresh laurels. The procedure must be considered a distinct advance and worthy of more general and extended application.

"*Gasocution.*"—Could anything be more execrable as a word-coinage?—and yet both the word and the thing are seriously proposed. The inquiring reader may guess that the proposal is to execute criminals by gas-asphyxiation instead of by the present methods. In view of the astonishing increase of suicide, would it not be well to consider the possibility of the influence of "gasocuting" and euthanasia generally upon public morals and crime? But there is too much "gaselocution" in the proposition to be very serious about it.

SELECTIONS.

THE POSSIBILITIES AND USES OF ORGANIC EXTRACTS.

BETWEEN such organs as, for example, the brain and the thyroid gland, there are many and great differences. One of these differences is all-important for the present discussion. The thyroid gland is a secretory organ; the brain is not. Without entering into a discussion of the exact nature of the process, concerning which the evidence is not clear, it is sufficient to know that clinical and experimental observations are at one in demonstrating that the thyroid gland manufactures some substance which, by its function in the economy, prevents the occurrence of the symptom-complex termed myxedema or cachexia strumipriva.

The principle is exactly the same as that upon which we administer pepsin or pancreatin to replace the natural pepsin or pancreatin in digestive disorders; the body failing to furnish a certain substance which is necessary to the proper nutrition of all the organs, we supply that lack by administering a similar substance obtained from animals.

It will be observed, moreover, that whatever it may be that is accomplished by the administration of thyroid extract, it is not the cure of disease of the thyroid gland. No one, surely, expects to cure disease of the peptic glands by giving pepsin, or disease of the pancreas by giving pancreatin. Cure can only be obtained by measures which will secure natural reproduction of the missing secretions.

The brain, so far as we know, secretes nothing physical. So far as we know, there is no symptom or symptom-complex which can be attributed to defect in any supposed secretory function of the brain. Consequently, there is nothing in the whole nosology which, on theoretic grounds, the admistration of brain-extract could be expected to remedy. Similarly, the heart, so far as we know, secretes nothing, and there is no symptom or symptom-complex which can be attributed to default of supposed secretory function on the part of the heart. Equally, therefore, there is no ground for the administration of heart-extract to remedy disorder caused by disease of that organ. For, let us remember, the thyroid extract does not cure thyroid disease, the thymus extract does not cure disease of the thymus, the pancreatic extract does not cure disease of the pancreas; and to expect brain-extract to cure brain-disease, or heart-extract to cure heart-disease, is on a par with the science of the Obi-doctor and the practice of the lizard-giving Chinamen.—DR. S. SOLIS-COHEN, in *The Polyclinic.*

SCIENCE AND EXPERIENCE IN MEDICINE.

To the student himself I would say, Cultivate the sciences which lie at the foundation of medicine, for they are to be the key to you that will unlock the treasure-house of the future. They will give to you that sense of satisfaction that arises out of your knowing that you are in the van with progress. Not any the less thereby, but rather the more fitted will you be for professional work when you enter upon it. For this cultivation there is abundance of opportunites in your undergraduate course; and, indeed, the Medical Council has, with a wise foresight, provided that you may pass the fifth year of your course in laboratory work wholly. If, on the other hand, you neglect the sciences, you will be hampered in the appreciation of your work, and the exigencies of a practice will prevent you from overtaking the arrears of knowledge due to that neglect. You may then fully realize your mistake, when regret is of no avail to repair it.

No one, I believe, esteems more highly than I do professional attainments and skill. Nor do I deride experience, for it is not that which makes you satisfied with what has been done, but rather that which stimulates your desire to know more. Perhaps the best view of experience is that given by Tennyson in his poem, "Ulysses." The old hero, who had gone unwillingly with the Greek host, has, after ten long years before Troy and ten years of peril and adventure on the sea, returned to Ithaca, and he is represented as resolving to take up once more the life of change and discovery. I quote one familiar passage because it describes my ideal of the scientific spirit, whether it is to be found in the laboratory or at the bedside, and because it gives to the student of to-day a glimpse of the life that may be his in after-years:

> "I am a part of all that I have met;
> Yet all experience is an arch wherethro'
> Gleams that untravelled world whose margin fades
> Forever and forever when I move.
> How dull it were to pause, to make an end,
> To rust unburnished, not to shine in use!
> As tho' to breathe were life! Life piled on life
> Were all too little, and of one to me
> Little remains; but every hour is saved
> From that eternal silence, something more,
> A bringer of new things; and vile it were

For some three suns to store and hoard myself,
And this gray spirit yearning in desire
To follow knowledge, like a sinking star,
Beyond the utmost bound of human thought."

—PROFESSOR A. B. MACALLUM, Inaugural Lecture University Medical Faculty, Toronto, October 3, 1893.

Dispensary Abuses.—In perusing the discussion on the dispensary system, it is impossible to resist the conviction that most of the dispensaries are badly managed, that there are too many of them for the real needs of the poor, and that the gratuitous services of the physicians are not properly appreciated.—*The New York Medical Record.*

CORRESPONDENCE.

NEW YORK LETTER.

Dupuytren's Contraction—Surgery of the Hand—The Coroner System—Contusion and Rupture of the Ileum—Dispensary Abuses.

To the Editor of THE MEDICAL NEWS,

SIR: Following so close upon the many annual meetings and medical congresses, the closing months of the year are not usually marked by very great activity in medical circles. In this matter of having too many medical societies and meetings we are all agreed, just as we are united in the opinion that the large number of medical journals are more than enough for even a great country like ours; yet new medical societies and new medical periodicals spring up on every hand.

A short time ago the Wesley M. Carpenter Lecture was delivered before the Academy of Medicine by Dr. Robert Abbé. He took for his theme "The Surgery of the Hand," and dwelt at some length on the subject of Dupuytren's contraction, to which, as is well known, he has devoted considerable attention. Mr. William Adams, of England, who is also a well-known authority on this subject, holds to the gouty theory of its causation, whereas Dr. Abbé is the champion of the traumatic theory. Some time ago the latter published an article, based on twenty-five private and fifteen hospital cases, in which he propounded this theory, viz.: that a traumatism of the nerve-ends in the palm, if reflected to the central nervous system, and thence to the part originally hurt, together with a secondary series of reflex symptoms reflected to the corresponding part of the opposite hand, would perfectly account for the clinical phenomena observed. He had never met with gouty concretions in connection with Dupuytren's contraction, and he looked upon the gouty element as a pure assumption. This peculiar contraction attacks by preference the joints of the ring and little fingers, in other words, those most subject to bruises or other traumatism. To clinch the matter still further the lecturer reported a number of cases in which there was a distinct history of a traumatism bearing directly on the development of the symptoms of Dupuytren's contraction. The operative treatment for the relief of this condition is carried out very satisfactorily under cocain-anesthesia, and after the division of the tense bands the wounds are covered with "protective" and damp compresses, and the dressings are kept moist by covering them with gutta-percha tissue. The operation should be completed within twenty minutes, as this seems to be about the length of time an Esmarch bandage can be tolerated. A firm bandage should be applied before the removal of the Esmarch bandage. The first change of dressing is made at the end of twenty-four hours, and the second on the fourth day. Dr. Abbé considers it much better to allow the parts to assume a comfortable position at first, and not be confined on a splint for the first week, rather than to immediately apply a straight splint, as recommended by Mr. Adams. The lecturer then went on to describe the peculiarities of the various other important affections of the hand, such as neuroses, tumors, "trigger-finger," "drop-finger," and the like. He said that sometimes small herniæ of the sheaths of the tendons are found buried in the palm of the hand. They resemble "weeping sinews," but cannot be dissipated by a blow. Although they occasionallydisappear without treatment, such an occurrence is so rare that the surgeon should not be deterred by this from dissecting them out when they cause any trouble. He had had very gratifying results in the treatment of webbed fingers and burns of the hand by a resort to Thiersch's method of skin-grafting. In the case of webbed fingers, split the web, and dissect out any tough part; then carefully apply a long and narrow Thiersch graft up one side and down the other. In one case treated in this way the parts were perfectly healed within three weeks. In some cases of severe burns, such as are produced by the hand being caught in a hot mangle, this method of grafting enables the surgeon to restore the hand to usefulness; for these grafts do not have the same tendency to contract that ordinary scar-tissue possesses. The wonderful results sometimes obtained by replacing nearly severed members had led him to make a series of experiments on animals with a view of devising some method by which the arterial supply might possibly be restored to an amputated limb, so that the limb might be grafted back to its original or to a corresponding stump. These experiments are not yet completed, but he had succeeded in inserting a small piece of glass tube into the femoral artery of a dog and into the aorta of a cat, and at the close of the lecture these animals were exhibited.

The coroner's system has again been the subject of recent investigation, and this time, I am glad to note, the newspapers have called the attention of the general public to the abuses of the coroner's office. It is, of course, the old, old story about an antiquated system, which at the best consumes the public money and gives but little in return. Among the ignorant classes the mere mention of the coroner inspires a feeling of awe and dread, and to those who are better informed as to the duties of the coroner and the value of his services he is still an "awful" person. I do not mean to say that the present coroners are individually any worse than their predecessors, but what is to be expected of a system which is chiefly political, and in which the important work of the deputy coroner is usually let out to the lowest bidder? It is well known that many of the inquests are nothing but farces, and the community is to be congratulated if the "viewing of the body" actually takes place—even from a distance—for it is sometimes only a mental process—a creature of the imagination.

The writer well remembers certain experiences of this kind which he had during his hospital days. For example, a patient who had sustained a dislocation of the knee developed delirium tremens soon after his admission to the hospital, and although appearing one morning in every way better than he had done the previous night, he was found dead only a few minutes after the house-surgeon had left the ward. We were entirely at a loss to account for his death, and the deputy coroner, after trying in vain to elicit some information from me which would give him at least a slender basis of fact on which to make out the certificate of death, admitted frankly that he had no idea what caused the patient's death. Yet in the face of this confession he positively refused to make a post-mortem examination. The attending surgeon, after arguing the matter with the deputy coroner, finally remarked, with indignation: "Well, all that we can do with you fellows is to remember you on election day." This was certainly a truly American way of disposing of the matter, and I sincerely hope the coroner's system in New York will be disposed of in the same way at the Constitutional Convention; but I am constrained to add that in this particular instance the coroner must have been forgotten on election day by the better part of our citizens, for it is not necessary to go back very far in history to learn that he was appointed afterward to a very important and responsible medical position. At another time I remember receiving a document from one of our well-known coroners, ordering me to deliver up the body of a man who had died in the hospital from a fracture of the skull. Although he had received this injury from a collision of a horse-car with his wagon, and there was every probability of there being a suit for damages, the coroner stated in this paper that *he had viewed the body*, and had duly held an inquest in his office before such and such witnesses, and that as a result of this investigation he had come to the conclusion that the person had met his death from fracture of the skull. All this was certified to in spite of the fact that no representative of the coroner's office had appeared at the hospital to make any inquiries there in regard to the deceased, or had viewed the body—even through a telescope.

I have not touched upon the evils or the follies of the coroner's jury, but the foregoing cases, affecting as they do two very prominent representatives of the coroner's office, who have "served the public" (?) for many years, are sufficient to show that, even supposing the system to be a good one—which it is not—its administration in New York City is very bad.

Before leaving this subject, the writer cannot refrain from alluding to the case of the late Colonel Elliott F. Shepard, who died so unexpectedly after etherization. Here there was a grand opportunity for the coroner to do yeoman service to the public by making a post-mortem examination and determining the real cause of death, and so reëstablish the public confidence in ether as an anesthetic; but the coroner, in his superior wisdom, decided that such an examination was not necessary. As a result, a sort of panic seemed to seize the people, and it was very difficult for a time to induce persons to consent to be etherized. This case has been discussed again and again in our medical societies, but all the arguments on this subject lack the force and precision which they would have if a careful post-mortem examination had been made.

At the last meeting of the Society of the Alumni of Bellevue Hospital, the president, Dr. Frederick Holme Wiggin, reported a case which, although chiefly surgical, carries an important lesson for the general physician to bear in mind. The case was one of contusion and rupture of the ileum, with peritonitis, yet without any external wound to indicate to the physician the grave nature of the internal injury. The patient was a colored boy, fifteen years of age, who had been kicked by a horse in the right lumbar region. He vomited a little blood after the accident, and complained of continuous nausea, and when seen some hours later, although suffering slightly from shock, and having an anxious expression, his pulse was 80, and his temperature normal. Owing to a misunderstanding, Dr. Wiggin did not see the patient again until the next evening, when the signs of peritonitis were quite evident. He at once performed celiotomy, followed by enterectomy and circular enterorrhaphy by Maunsell's method. A knuckle of the ileum near the jejunum looked as if it might become gangrenous, and although no perforation could be discovered prior to its removal, this portion of the intestine was resected. The operation was eminently successful, and the patient was shown to the Society. In reporting the case, the author called attention to the fact that he had poured a quantity of a fifteen-volume solution of hydrogen dioxid into the peritoneal cavity, and had allowed it to remain there for a short time, in order to completely disinfect this cavity after the accidental escape of some of the contents of the bowel. The resulting foam was then washed away and the cavity flushed with hot sterilized salt solution (0.6 per cent.) and the abdominal wound closed, leaving the peritoneal cavity full of the salt solution. The object of this was "to lessen shock, to prevent adhesions, to aid in the readjustment of the intestines and omentum to their proper position, and to lessen the danger of septic peritonitis."

In the discussion of this paper, the general opinion among the surgeons seemed to be that Maunsell's method of operating on the intestine was a great step in advance, as it greatly simplified and shortened the operation. Dr. Robert A. Murray called special attention to the fact that many cases end fatally because the profession at large believes that if peritonitis is present, there must be an elevation of temperature and an acceleration of pulse and respiration. This was a very grave mistake; the peritonitis might even be ushered in by a decided fall in the temperature. The peculiar facial expression and the smallness of the pulse were the most important guides in the diagnosis of these cases.

Several other speakers took the same ground, and urged very strongly that the general practitioner should be made acquainted with these facts, as it was he who would ordinarily be called upon to see such cases at a time when operation held out a fair prospect of success. Dr. Matthew D. Field emphasized, by narrating a case, the importance of being on the alert for injury of the intestine or other viscera in cases of traumatism, even when there are no external marks of violence. A man was hurt on the elevated railroad by a "buffer accident," but was able without assistance to walk several blocks, and reach his home, which was several miles distant. He

had no serious symptoms for three days, when he suddenly developed stercoraceous vomiting. After a hasty consultation, the physicians who had been summoned made a diagnosis of intussusception, and proceeded to give him a high enema, whereupon the patient went into collapse and died. The speaker was present at the autopsy, and it was then found that the mesentery had been torn away for nearly half an inch, and that gangrene had resulted in nearly two feet of intestine. The intestine had also been wounded in three other places, but all of these wounds had healed, and the man would have recovered had it not been for the gangrene which followed the tearing of the mesentery. The injection had caused a rupture of one of the wounds in the intestine.

I have so often written about the dispensaries and their abuses that I would not venture to say any more were it not that this is a matter of more than local interest. The latest public ventilation of this topic occurred a few weeks ago at a meeting of the Section on Public Health of the Academy of Medicine. The discussion was opened by Mr. Charles C. Savage, President of the Demilt Dispensary, and Trustee of the Roosevelt Dispensary, who read a paper entitled "Dispensaries, Historically and Locally Considered." The author seemed to think that because free music in the parks and free libraries and free baths did not demoralize the recipients, free medical treatment ought not to be harmful, and an experience of forty years had led him to feel quite sure that dispensary work was the least harmful of the ordinary charities. In closing, he made the astounding statement that the dispensaries having physicians on their boards of managers were among the worst in the city. In the discussion, Dr. H. D. Chapin said the work done in the dispensaries was worthless, from a scientific standpoint. He insisted that those who treat the sick in the dispensaries should have the management of these institutions. Dr. F. W. Jackson firmly believed that good scientific work could be done in dispensaries, and said that the doctor outside had no right to object to the dispensaries, for he had not the energy to get in them. Dr. Joseph Collins saw no more reason for physicians giving their services without compensation than for ministers or lawyers giving theirs. He thought the condition of the medical profession here at present might be aptly compared to that of the American colonists, who suffered from taxation without representation. Among those who also participated in this discussion was a Mr. Cook, a layman, who seemed to think that the more the public could get out of the doctors, or, in fact, out of almost anybody, without paying for it, the better. He said that he had never observed any of the demoralization which some claimed was the result of our dispensaries as at present conducted, but he did know of thousands of people who had been pauperized by doctors.

If this discussion is fairly representative of the present state of public opinion on this subject, this vexed question is evidently far from a satisfactory and proper settlement.

The Biography of Dr. Ephraim McDowell, by his granddaughter, Mrs. Valentine, formerly Mrs. Ridenbaugh, will be furnished to subscribers—we are informed by Mrs. Valentine—so soon as the new edition can be published.

NEWS ITEMS.

Sanitary and Medical Service on Board of Emigrant Ships.—The report of the Committee of the American Public Health Association "On Sanitary and Medical Service on Board of Emigrant Ships" was presented by Medical Director Albert L. Gihon, U.S.N., Chairman, at the session of the twenty-first annual meeting of the Association, held at the Art Institute, Chicago, Ill., Wednesday, October 11, 1893, as follows:

Your Committee beg to report the following concise statement of their views as to the organization of such a sanitary and medical service on board vessels engaged in bringing immigrant passengers to the United States, as the experience and intelligence of this age make a necessity among civilized and enlightened nations.

They are of opinion and advise:

First. As to the location and dimensions of the quarters for emigrant passengers, the number of berths in each, and the provisions for their ventilation and cleansing:

That the preferable location for such quarters is abaft the midship section of the vessel; that single males' quarters shall be distinct from those occupied by women and children, and that if any are forward the midship section, it shall be those for single men;

That there shall never be more than two decks (properly there should be only one) occupied by emigrant passengers' berths, with sixteen feet of superficial space for each adult on the upper berth-deck and twenty feet of such space on the lower berth-deck, with not more than two tiers of berths on each deck, the bottom of the lower tier being not less than eighteen inches above the deck, with not less than thirty inches between the two tiers and between the upper tier and the ceiling of the compartment to allow the occupants of the berths to sit upright;

That no solid partitions or bulkheads shall be placed in any steerage compartment to obstruct light and air;

That the framework of the berths shall be of iron easily removable, that the compartment may be completely emptied and thoroughly cleaned after each passage;

That a steam ventilating apparatus by aspiration shall be introduced into all emigrant vessels; and

That all compartments occupied by passengers and crew shall be lighted by the incandescent electric light by night and day.

Second. As to the location and dimensions of hospitals on board such vessels and the number of sick-berths for which provision should be made:

That the hospitals, or "sick-bays," on board emigrant passenger vessels shall be at the extreme after-part of the upper deck, thoroughly lighted and ventilated, with eighteen feet of superficial space for every fifty passengers, and not less than four sick-berths or hospital-cots for every hundred passengers.

Third. As to the number of medical officers proper for the maximum of emigrant passengers any vessel should be permitted to carry, being the maximum number able to be berthed with regard to health, cleanliness, and comfort:

That there should be one duly qualified medical officer for every two hundred and fifty passengers.

Fourth. As to the professional records which the senior medical officer of every such vessel should be required to keep and his responsibility to the health-authorities of the port of arrival for the truthful and professionally accurate statements of such records:

That the senior medical officer of every such vessel shall be required to keep (1) *a list of sick*, recording in a bound book, in the order of their admission, and on a single line, the name, sex, age, birth-place, date of admission to treatment, date of death or discharge from treatment, disease, and such remarks as may be necessary to enable the inspecting medical officer at the port of arrival to have a clear and complete understanding of the case; and (2) *a medical journal*, in which each medical officer, when there are more than one, shall record the medical history, including the symptoms and treatment of every case, to be approved and signed by the senior medical officer at the close of the day's record; and such list of sick and medical journal shall be submitted to the health-authorities of the port of arrival, and the accuracy of the statements in such records shall be established by oath, and penalties for perjury shall be provided.

Fifth. As to the location and capacity of latrines for emigrant passengers:

That the latrines, shallow troughs with a continuous flow of salt water, shall be on the upper deck under shelter, with two water-closet seats for every fifty passengers, with a proportionate number for women and children, in a separate locality near their own quarters and inaccessible to men.

Sixth. As to the number of attendants provided for such passengers, and their duties as to policing and cleansing emigrants' quarters:

That there shall be not less than one berth-deck attendant for every fifty passengers; female attendants in the same proportion being exclusively assigned to the quarters for women and children;

That the berth-decks shall be thoroughly cleansed every morning by the attendants; never wetted in rainy or damp weather, when they shall be scraped, swept, and freshly sanded, and in pleasant weather washed with hot water and quickly dried, the passengers being sent on deck during the operation;

That the berth-deck attendants shall be on duty night and day in rotation, by regular sea-watches, and the attendants on watch be required to remove the dejecta of sea-sick passengers without delay; and

That benches and mess-tables shall be provided and the passengers' food be distributed by the berth-deck attendants, who shall take away all unused food, and carry the dishes to the pantry.

Seventh. As to additional provisions for the personal health, cleanliness, and comfort of emigrant passengers:

That wash-rooms under cover, with basins supplied with running water, shall be provided on the upper deck, those for men to be separate from those intended for women and children;

That fresh water for drinking purposes shall be provided in each compartment; and

That inexpensive mattresses, pillows, these to be serviceable as life-preservers, and blankets shall be provided for emigrant passengers, the mattresses to be destroyed after each passage, and the pillows and blankets to be steamed and washed before being again used.

While other suggestions as to sanitary provisions might appropriately be made, your Committee feel that these indicated are of such urgent necessity that they should be insisted upon and put into effect without delay.

All which is respectfully submitted:

ALBERT L. GIHON,
Medical Director U. S. Navy, Chairman.
FREDERICK MONTIZAMBERT, M.D., F.R.C.S, D.C.L.,
Supt. Quarantine Station, Grosse Isle, Quebec.
WALTER WYMAN,
Supervising Surgeon-General U. S. M.-H. S.
S. R. OLLIPHANT, M.D.,
President State Board of Health of Louisiana.
WM. T. JENKINS, M.D.,
Health Officer of the Port of New York.

The Pennsylvania State Medical Society will hold its next meeting at Gettysburg, May 15, 16, 17, and 18, 1894. Those desirous of presenting papers are requested to notify, at an early date, the Chairman or any other member of the Committee of Arrangements. Dr. E. E. Montgomery, of Philadelphia, is the Chairman, and the other members of the Committee are: Dr. Isaac C. Gable, of York; Dr. George S. Hull, of Chambersburg; Dr. John C. Davis, of Carlisle; Dr. Henry Stewart, of Gettysburg; Dr. George Rice, of McSherrystown; Dr. E. W. Cashman, of York Springs.

Dr. William Hunt has resigned as one of the visiting surgeons of the Pennsylvania Hospital, and Dr. Richard H. Harte has been elected to fill the vacancy. The Board of Directors of the Hospital has passed a minute expressive of its appreciation of the work of Dr. Hunt, covering a period of thirty years as Attending Surgeon, and of more than forty-three years in various relations with the Hospital.

The Tri-state Medical Journal is the name of a new monthly publication emanating from Keokuk and under the editorial care of Dr. James Moores Ball. Though *Tri-state* in name, it proposes to be unlimited in territory, and promises to be a journal preëminently for young men. It dedicates itself to higher medical education and the advancement of scientific medicine.

The Next Meeting of the American Medical Association will be held at San Francisco, on the first Tuesday in June, 1894, instead of on the first Tuesday in May, in order to permit of a discussion of the Code by the various State Societies that meet just before the meeting of the national Association.

Foot-ball Fatality.—A youth, aged eighteen years, of Normanby, near Middlesborough, has died from injuries sustained on the 11th inst., during a match between Normanby and the Acklem Swifts.—*Lancet*, Nov. 25th.

Dr. Charles Warrington Earle, President of the Chicago Medical Society and one of the founders of the Chicago College of Physicians and Surgeons, died on November 19th, of meningitis.

Correction.—In the first line of the first column of page 478 of THE NEWS of October 28th the dose of trinitrin should have been given as gr. $\frac{1}{50}$ and not as gr. $\frac{1}{5}$.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIII. SATURDAY, DECEMBER 23, 1893. NO. 26.

ORIGINAL ARTICLES.

THE NATURE OF THE GERMICIDAL CONSTITUENT OF BLOOD-SERUM.[1]

BY VICTOR C. VAUGHAN, M.D., PH.D.,
PROFESSOR OF HYGIENE AND DEAN OF THE DEPARTMENTS OF MEDICINE AND SURGERY IN MICHIGAN UNIVERSITY;
AND
CHARLES T. MCCLINTOCK, PH.D.,
INSTRUCTOR IN HYGIENE, ANN ARBOR, MICHIGAN.

As early as 1872, Lewis and D. Cunningham[2] demonstrated the fact that bacteria injected into the circulation rapidly disappear. In the blood of twelve animals that had been treated with such injections, bacteria could be found after six hours in only seven. Of thirty animals, bacteria were found after twenty-four hours in the blood of only fourteen, and of seventeen animals, bacteria were found in only two when the examination was made from two to seven days after the injection.

In 1874, Traube and Gschiedlen[3] found that arterial blood, taken under antiseptic precautions from a rabbit into the jugular vein of which one and one-half c.c. of a fluid rich in putrefactive germs had been injected forty-eight hours previously, failed to undergo decomposition for months. These investigators attributed the germicidal properties of the blood to its ozonized oxygen. Similar results were obtained by Fodor[4] and by Wysokowicz.[5] The latter accounted for the disappearance of the germs, not by supposing that they were destroyed by the blood, but that they found lodgment in the capillaries.

The first experiments made with extra-vascular blood were conducted by Grohmann[6] under the direction of A. Schmidt in his researches upon the cause of coagulation. It was found that anthrax-bacilli, after being kept in plasma, were less virulent, as was demonstrated by their effect upon rabbits. Grohmann supposed that in some way the bacteria were influenced by the process of coagulation.

[6] Ueber die Einwirkung des zellenfreien Blutplasma auf einige pflanzliche Mikroörganismen, Dorpat, 1884.

In 1877, Fodor[1] made a second contribution to this subject, and in this he combated the retention-theory of Wysokowicz. One minute after the injection of one c.c. of anthrax-culture into the jugular vein, in eight samples of blood, Fodor found only one colony of the bacillus. Then he took the blood from the heart with a sterilized pipet and added anthrax-bacilli to it. This was kept at 38° C., and plates made from time to time showed a rapid diminution in the number of germs; after a time, when the blood had lost its germicidal properties, the number of germs began to increase.

In 1888, Nuttall,[2] working under the direction of Flügge, used defibrinated blood taken from various species of animals, rabbits, mice, pigeons, and sheep, and found that this blood destroyed the bacillus anthracis, bacillus subtilis, bacillus megaterium, and staphylococcus pyogenes aureus, when brought in contact with them. He also confirmed the further finding of Fodor that after a while the blood loses its germicidal properties and becomes a suitable culture-medium in which the germs grow abundantly.

Nissen[3] continued this work under Flügge's direction and reached the following conclusions:

(1) The addition of small quantities of sterilized salt-solution or bouillon to the blood does not destroy its germicidal properties.

(2) Cholera-germs and Eberth's bacilli are easily destroyed by fresh blood.

(3) For a given volume of blood there is a maximum amount of bacilli which can be destroyed.

(4) Blood whose coagulability has been destroyed by the injection of peptone is still germicidal.

(5) Blood in which coagulation is prevented by the addition of 25 per cent. of magnesium sulfate has its germicidal properties decreased.

(6) Filtered blood-plasma from the horse is germicidal.

Behring[4] has attributed the action of the blood of the white rat on anthrax-bacilli to its great alkalinity. He has made a number of titrations by which he shows that the blood-serum of the white rat is somewhat more alkaline than that of certain animals that are more susceptible to anthrax, such as the rabbit, the guinea-pig, and the cow. His deduction is not justified, because there are many other and

[1] Deutsche medicinische Wochenschrift, 1887.

[2] Zeitschrift f. Hygiene, B. 4. [3] Ibid., B. 6. [4] Ibid., B. 6.

more important points in which these animals differ more markedly from the white rat than in slight differences in the alkalinity of the blood-serum. Had he shown that the blood of the adult rat, which is not susceptible to anthrax, is more alkaline than that of the young rat, which is susceptible, his argument would have been more plausible; but even then it would not have deserved the dignity of positive evidence.

In 1890, Buchner,[1] aided by Voit, Sittmann, and Orthenberger, made a most valuable contribution to our knowledge of the germicidal properties of blood. The results of this work are stated as follows:

1. The germicidal action of blood is not due to phagocytes, because it is not influenced by the alternate freezing and thawing of the blood, by which the leukocytes of the rabbit are destroyed.

2. The germicidal properties of the cell-free serum must be due to its soluble constituents.

3. Neither neutralization of the serum, nor the addition of pepsin, nor the removal of carbon-dioxid gas, nor treatment with oxygen has any effect upon the germicidal properties of the blood.

4. Dialysis of the serum against water destroys its activity, while dialysis against 0.75 per cent. salt-solution does not. In the diffusate there is no germicidal substance. The loss by dialysis with water must be due to the withdrawal of the inorganic salts of the serum.

5. The same is shown to be the case when the serum is diluted with water and when it is diluted with the salt-solution. In the former instance the germicidal action is destroyed, while in the latter it is not.

6. The inorganic salts have in and of themselves no germicidal action. They are active only in so far as they affect the normal properties of the albuminates of the serum. The germicidal properties of the serum reside in its albuminous constituents.

7. The difference in the effects of the active serum and that which has been heated to 55° C. is due to the altered condition of the albuminate. The difference may possibly be a chemical one (due to changes within the molecule) or it may be due to alterations in mycelial structure. The albuminous bodies act upon the bacteria only when the former are in active state.

We wish at this point to call attention to an inconsistency between the results obtained by Buchner and the conclusions that he draws. In experiment No. 45 he renders the serum slightly acid and adds 0.1 gram of pepsin to each five c. c. of serum (showing by a side experiment that this pepsin actively digests coagulated egg-albumin in neutral solution) and finds that the digestive action of the pepsin does not lessen the germicidal properties of the serum. In fact he states this in his conclusions, but his ultimate opinion, and the one held by him in his latest contribution, is that the germicidal constituent of the blood is the serum-albumin. How much serum-albumin remains in blood-serum after it has been thoroughly digested with pepsin? He could scarcely have chosen a more positive method of demonstrating that the germicidal constituent is not serum-albumin. Either his pepsin was not active, and on this supposition his experiment is without value, or the active constituent of blood-serum is a substance that is not destroyed or materially altered by peptic digestion. We know that the peptones not only have no germicidal properties, but that they belong to that class of proteids that is most favorable to the growth and development of germs. We recognize this fact when we add peptones to the various artificial media on which we cultivate germs. However we shall return to this subject. At present we shall proceed with the literature of the subject.

The successful researches of Buchner led many other investigators to enter this field of experimentation, and some of them have made valuable contributions to our knowledge of the germicidal action of the blood under varying conditions, but so far as the nature of the germicidal constituent is concerned but little or no progress has been made. Prudden[1] found that ascitic and hydrocele fluids restrain the development of certain germs. Rovighi[2] reported that the germicidal action of the blood is increased in febrile conditions. Pekelharing[3] enclosed anthrax-spores in bits of parchment and introduced them under the skin of rabbits. Thus treated, the spores soon lost their virulence and finally their capability of growth. The destruction of these spores could not have been due to phagocytes, which did not penetrate the parchment, but must have been caused by soluble poisons. Behring and Nissen[4] found that the serum of the white rat, the dog, and the rabbit destroys anthrax-bacilli, while serum obtained from the mouse, sheep, guinea-pig, chicken, pigeon, and frog, has no such action. It will be observed from this that there is no constant relation between the germicidal action of the blood of animals of different species and their susceptibility to the disease caused by the germ. Thus, the rabbit is highly susceptible to anthrax, notwithstanding the fact that its blood destroys large numbers of these germs. On the other hand, the chicken is immune to anthrax from the moment when it comes from the shell, and yet the bacillus anthracis grows luxuriantly in the extra-vascular blood of the chick.

This demonstrates that there is a great difference between the action of extra-vascular blood and that circulating in the body, constantly fed, and in case of need, altered in composition by certain glands.

Halliburton has prepared from the lymphatic glands a globulin which he designates as cell-globulin β, and which agrees with fibrin-ferment in inducing coagulation in plasma. Hankin[1] has tested the germicidal properties of this cell-globulin. His experiments have been conducted in the following manner: The lymphatic glands (in later experiments the spleen also) of a dog, or of a cat, are freed as much as possible from fat and connective tissue, then finally divided and extracted with dilute solution of sodium sulfate (one part of a saturated solution to nine parts of water). The cell-globulin passes into solution, while the other proteids are but sparingly soluble. After twenty-four hours, the fluid is filtered and mixed with an excess of alcohol. The voluminous precipitate containing the cell-globulin is collected on a filter and washed with absolute alcohol. For use, a part is dissolved in water, and a small quantity of a bouillon-culture of the anthrax bacillus is added. From time to time plate-cultures are made, along with control-plates, and in this way the germicidal properties of the substance are demonstrated. Hankin closes this contribution with the following conclusions:

1. Halliburton's cell-globulin β has marked germicidal properties.

2. In this respect it differs from fibrin-ferment.

3. The germicidal properties of this substance seem to be identical with those of serum as described by Buchner, Nissen, and Nuttall.

4. The active properties of the serum are probably due to this or to an allied body.

Bitter[2] has repeated the experiments of Hankin, but fails to confirm them. Bitter states that he has followed Hankin's directions exactly. However this may be, it is certain that the spleen contains a germicidal substance, but whether it can be extracted by the method of Hankin or not we do not know. That the germicidal constituent of the spleen is identical with Halliburton's cell-globulin β or with any other globulin, we very much doubt. It certainly is a nuclein, and it is altogether possible that Hankin obtained traces of this nuclein in his extracts. In this case the extract would show, or fail to show, germicidal properties according to the relative amounts of nuclein and other substances present. The less globulin and the more nuclein present the more marked would the germicidal effect be.

Christmas[3] has prepared a germicidal substance from the spleen and other organs by the following method:

The animal is killed with ether, opened under antiseptic precautions and the organ removed, cut into fine pieces, covered with fifty cubic centimeters of glycerin and allowed to stand for twenty-four hours, and then filtered. The filtrate is precipitated with five times its volume of alcohol, and this fluid is immediately decanted. The precipitate is washed with absolute alcohol in order to remove the glycerin. Then the traces of alcohol are removed by pressure and the precipitate dissolved in twenty-five cubic centimeters of distilled water. Through this solution air is driven for some hours in order to destroy the traces of alcohol. Then the fluid is filtered and its germicidal action tested.

Bitter has also examined this method, and the impartial reader must see that he has not done so with fairness. However, this fact renders the work all the more valuable because his results confirm the statements of Christmas. Bitter killed his animals by venesection, and, in some cases at least, prepared the substance in unsterilized vessels; but even when this was done the solution was germ-free and manifested marked germicidal properties. Bitter finally finds a difference between this substance and the germicidal constituent of blood-serum; the latter, he states, is certainly destroyed by a temperature of 65°, while the solution of Christmas, after having been heated to this temperature, is still capable of destroying from 35,000 to 40,000 typhoid-bacilli within four hours. Buchner,[1] in his latest contribution to the subject has the following to say in condemnation of Christmas:

"A method given by Christmas for the preparation of germicidal solutions from the organs of normal rabbits has also been tested by Bitter. Germicidal solutions were indeed obtained, which, however, differed materially from active serum, for in three experiments, notwithstanding heating to 65° C., the germicidal action remained."

It is altogether possible that the more powerful action of the solution made by Christmas is due to the fact that it contained the germicidal substances in more nearly a chemically pure condition than they exist in blood-serum. It is also highly probable that the arrest of the germicidal activity of blood-serum by a temperature of 55° C. is not due to the destruction of its germicidal constituent, but is due to the action of the heat on other constituents of the fluid.

Some attempts have been made to determine the nature of the germicidal constituent by the action of precipitating reagents on the proteids of blood-serum. In his latest contribution, Buchner states that he has not been able to obtain a germicidal solution

[1] Centralblatt f. Bakteriologie, B. 9.
[2] Zeitschrift f. Hygiene, B. 12.
[3] Annales de l'Institut Pasteur, t. v.

[1] Archiv f. Hygiene, B. 17.

by precipitating all the proteids with absolute alcohol, freeing the precipitate from alcohol, drying it, and then redissolving. He does not give the methods employed in freeing the precipitate from alcohol, the temperature or the conditions under which it was dried, or the nature of the menstruum by which resolution was effected. In the absence of these needed details, his conclusion that alcohol destroys the germicidal substance must remain open to question. On the other hand, Christmas states that when the proteids are precipitated with alcohol and the precipitate dissolved in a volume of water equal to that of the original serum, the solution thus obtained has a more powerful germicidal action than the serum. Bitter in an experimental review of the statement of Christmas gives the following detailed account of one experiment:

"Ten cubic centimeters of serum were poured into fifty cubic centimeters of alcohol (strength of alcohol not given), stirred, and the precipitate immediately separated from the alcohol by filtration. (He fails to state whether or not sterilized filter-paper was used.) The precipitate was freed from alcohol by pressure between folds of filter-paper (again he fails to state whether or not this paper was sterilized), then dried at 37° C., and mixed with ten cubic centimeters of sterilized distilled water. On being allowed to stand for a short time at 37° C., nearly all of the precipitate was redissolved. The solution was then separated from the deposit by filtration (through unsterilized filter paper?) and tested."

It can scarcely be a matter of surprise that Bitter found germs nearly always present in the solution obtained in this careless manner. However, he did find that the germs present did not develop when the solution was kept at 37° C., and, moreover, that germs added to this solution were destroyed. Bitter concludes that in truth anthrax and typhoid bacilli are destroyed by "precipitated serum," but not so energetically as by normal serum.

Emmerich, Tsuboi, Steinmetz, and Löw[1] have made interesting and valuable contributions relating to the effect of precipitation of the proteids upon the germicidal action of blood-serum. An active serum was dialyzed in a sterilized parchment-paper tube against water for from twelve to eighteen hours. By the expiration of that time the serum-globulin, becoming insoluble on account of the withdrawal of inorganic salts, was deposited. The dialyzer was dried with sterilized filter paper and the globulin-free serum was precipitated with several volumes of alcohol. The precipitate was collected on a sterilized "falten-filter" and the alcohol removed from the precipitate by sterilized porous plates and filter-paper. The precipitate was then finely divided, dried for half an hour in vacuo at 36° C., then rubbed up in a sterilized mortar and dissolved in sterilized water, to which salt-solution had been added. In the solution thus prepared germs did not show, after from three to four hours, either a marked increase or decrease, but when the solution was heated to 100° C., allowed to cool, and then inoculated with germs, the increase was four-hundred-fold within four hours. It was next found that, if instead of water, a 0.05 per cent. aqueous solution of potassic hydrate was employed in dissolving the alcoholic precipitate in the globulin-free serum, this solution possessed all the germicidal strength of the original serum. The same was found to be true of dilute alkaline solutions of the alcohol precipitate in serum from which the globulin had not been removed. The dilute alkali was shown not to have any germicidal action in and of itself. From these experiments the investigators mentioned conclude that the germicidal constituent of blood-serum is an alkaline compound of serum-albumin. They also found that heating the serum-albumin alkaline solution to 65° C., or higher, destroyed its germicidal action, and they explain this effect of heat on blood-serum and on their artificial solution by supposing that the high temperature breaks up the combination of the alkali with the serum-albumin. Furthermore, they found that a serum that had been rendered inactive by a temperature of 55° C. could be regenerated in part at least by the addition of the small amount of alkali mentioned.

Since Fodor[1] and Zuntz[2] have shown that freshly-drawn blood rapidly decreases in alkalinity on standing *in vitro*, an explanation of the fact that blood-serum rapidly loses its germicidal properties naturally suggests itself. Emmerich and his co-workers confirm their belief in this theory by demonstrating that blood-serum that has been rendered very feebly acid (0.67 part of sulphuric acid per mille) has no germicidal action, but furnishes a good culture-medium.

The foregoing investigations are very valuable, inasmuch as they show the important rôle that the small amount of alkali plays in the germicidal action of blood-serum. This had, indeed, already been demonstrated by Fodor[3] by a quite different line of investigation. This experimenter found that the resistance of rabbits to anthrax is markedly increased by the administration, by the stomach or subcutaneously, of sodium phosfate, carbonate, or bicarbonate, or of potassium carbonate.

Löw concludes that the introduction of the alkali into the albumin-molecule increases its liability, and he cites examples from organic chemistry in support of this view.

[1] Centralblatt f. Bakteriologie, B. 12.

[1] Centralblatt f. Bakteriologie, B. vii.
[2] Centralblatt f. med. Wissenschaft, 1867.
[3] Centralblatt f. Bakteriologie, B vii.

There are some additional points of interest in the theory of Emmerich and his assistants. As has been stated, they believe that the serum-albumin is the germicide, but they think it highly probable that only a comparatively small part of the albumin is active, and this small part, they suppose, originates in the albumin of the daily food, which is converted into lymph-cells, and by the disintegration of these it passes into solution in the blood. They admit, however, that there are some reasons for believing, with Buchner, that the whole of the serum-albumin is active. They state that it is possible, *but highly improbable*, that the germicidal substance is not the serum-albumin, but some substance that is precipitated along with this by alcohol and other agents.

We hope to show that the germicidal agent is not serum-albumin and that this "highly improbable" substance does exist.

In a short and somewhat unsatisfactory review of the report of Emmerich and his co-workers, Buchner[1] devotes himself to a consideration of the question of the regeneration of serum rendered inactive by heating to 55° C. on the addition of an alkali. He details one experiment made by himself on this point. The experiment confirms the work of Emmerich, but Buchner offers an interpretation that is wholly theoretic and by no means convincing. He finds that the regenerated serum, when heated to 60° C., still has a retarding effect upon the growth of germs, and he argues from this that the germicidal action of the "regenerated serum" is (for some unknown reason) due to its being less suited to the growth of bacteria. No one knows better than Buchner the influence of various chemical substances on the temperature at which an active serum is converted into an inactive form, and yet he overlooks altogether the possible effect of increased alkalinity on this conversion. Had he heated the regenerated serum to 100° C. he would then have found that it forms a very fertile culture-medium.

Hankin[2] has recently published a paper that is more valuable in its suggestions than in its experimental details. He suggests that the germicidal substance is a special secretion of the eosinophile granular cells. The granular matter in these cells is, according to his theory, the antecedent of the germicidal substance.

There are many other minor contributions to this subject, but those mentioned contain all the essential points, and there is no necessity for a further review of the literature. It is true that Aronson[3] has very recently announced to the Berlin Medical Society that he has isolated a powerful antitoxin from the blood-serum of animals rendered immune to diphtheria, and that with this substance he has cured guinea-pigs infected with this disease. Following the example of another illustrious German investigator, he refuses to tell how this curative substance is prepared. It is needless to say that this manner of dealing with scientific investigations has not as yet found favor with the unsophisticated profession in the new world.

From a careful and critical study of the investigations that have been briefly reviewed, we have come to the following conclusions:

1. The serum-albumin is not the germicidal substance in blood-serum. As has been stated, either this must be true or the experiment by which Buchner demonstrated that an active pepsin does not destroy the germicidal action of blood-serum must have been an error; because peptic digestion readily and completely converts serum-albumin into peptones, and we know that peptones are especially favorable to bacterial growth.

2. The germicidal substance must belong to the proteids. Otherwise it would be difficult to explain the fact that a temperature of 55° C. renders blood-serum inactive.

3. The only proteid likely to be present in blood-serum and which is not destroyed by peptic digestion is nuclein.

Having reached these conclusions, the following questions naturally present themselves:

1. Is there a nuclein in blood-serum?

2. Has this nuclein, if there be one, germicidal properties?

These questions we have attempted to answer.

Dogs and rabbits were the animals from which the serum was obtained. Healthy animals that had not previously undergone any experimentation were selected. The animal was firmly fixed in a holder, the carotid was laid bare under antiseptic precautions. A ligature and a small clamp were applied to the artery about two inches apart, the former distad, and the latter centrad. Then a slit in the artery was made with a sterilized knife, and a small sterilized glass canula, with sterilized and dried rubber tube leading into a sterilized Erlenmayer flask, was introduced into the artery and held in place by another ligature. Then the clamp was removed and the blood flowed into the flask. In each case the animal was bled to death. The flask containing the blood was placed in the ice-chest and allowed to remain for twenty-four hours. By the expiration of this time, a wine-colored serum had separated. This serum was poured into a second sterilized flask and about ten volumes of a mixture of equal parts of absolute alcohol and ether were added. This produced a voluminous precipitate that was nearly white. This was allowed to stand

[1] Centralblatt f. Bakteriologie, B. xii. [2] Ibid.
[3] Berliner klin. Wochenschrift, 1893.

twenty-four hours, and in some cases much longer, the alcohol and ether twice, or more often, during the time, being decanted and replaced by equal volumes. Then the supernatant fluid was decanted and an equal volume of a 0.2 per cent. solution of hydrochloric acid containing active pepsin was added, and the flask placed in an incubator at 38° C. and the digestion was continued until the fluid failed to respond to the biuret test for peptones. Each time this test was made the fluid was decanted from the undigested portion and replaced by an equal volume of fresh digestive fluid. In some instances the flask containing this fluid was allowed to stand in the incubator for several days. This was not necessary in order to complete the digestion, but was allowed as a matter of convenience. In all cases the digestion was prompt and proceeded to a certain point, when it ceased altogether. The undigested portion was small in amount and grayish in color. This was collected on a small sterilized filter and washed first with 0.2 per cent. solution of hydrochloric acid, and then with alcohol. After the washing with alcohol, the filter was allowed to stand exposed to the air for half an hour or longer in order that all of the alcohol might pass through or evaporate. The precipitate was then dissolved in a sterilized solution of potassic hydrate. The strength of this alkaline solution usually employed was 0.12 per cent. Usually this solution contained in addition to the alkali 0.6 per cent. of sodium chlorid. In some instances a solution containing 1.2 grams of potassic hydrate, 6 grams of sodium chlorid, and 1 gram each of sodium bicarbonate and disodium hydrogen phosfate to one liter of water was employed as a solvent. The solution was filtered through a Chamberland tube and received in a sterilized flask.

The solution thus obtained was perfectly clear, colorless, and did not respond to the biuret test. The addition of strong nitric acid produced a cloudiness, which dissolved on the further addition of the acid. This acid solution did not become yellow on being heated, but did so after the addition of ammonia.

We have now answered the first question. Blood-serum contains a nuclein. We hope to investigate at some time in the future the relation between this nuclein and fibrin-ferment.

The origin of the nuclein found now for the first time in blood-serum is an interesting question. Does it come from the disintegration of the polynuclear cells, or shall we regard certain white blood-corpuscles as unicellular organs whose function it is to secrete this nuclein?

In proceeding to determine whether or not this nuclein has germicidal properties, the solution was distributed in sterilized test-tubes, five c.c. being placed in each tube. It should be stated that in dissolving the nuclein, the volume of the solvent employed was in all cases the same as that of the blood-serum from which the nuclein was obtained. These tubes were inoculated with different germs and plates made at varying intervals of time, in order to test the germicidal action. One and the same platinum loop was used in the preparation of each plate.

EXPERIMENT I.

A nuclein-tube was inoculated with the bacillus of *Asiatic cholera*, and plates made from this gave the following results:

Time,	Immediately	5 min.	15 min.	30 min.	1 hr.	1½ hr.	22 hrs.
No. of colonies,	2100	43	54	71	90	115	1200

That the alkali in which this nuclein was dissolved did not cause the decrease in the number of germs is shown by the subsequent increase.

EXPERIMENT II.

Staphylococcus pyogenes aureus.

Time,	Immediately	1 hr.	4 hrs.	7 hrs.	24 hrs.
No. of colonies,	4000	1720	1050	810	0

EXPERIMENT III.

Anthrax bacillus without spores.

Time,	Immediately	1 hr.	4 hrs.	7 hrs.	24 hrs.
No. of colonies,	100	43	10	1	0

EXPERIMENT IV.

Cholera-germ.

Time,	Immediately	1 hr.	4 hrs.	7 hrs.	24 hrs.
No. of colonies,	470	45	1	0	410

It may be stated that the final increase in the number of cholera-germs occurred both in the nuclein-solution prepared from the serum of the rabbit and that prepared from the serum of the dog.

EXPERIMENT V.

Staphylococcus pyogenes aureus.

Time,	Immediately	1 hr.	5 hrs.	19 hrs.	24 hrs.
No. of colonies,	Countless	22,000	12,525	155	0

EXPERIMENT VI.

Anthrax-bacillus without spores.

Time,	Immediately	1 hr.	5 hrs.	19 hrs.	24 hrs.
No. of colonies,	1120	165	0	0	0

All of the foregoing experiments were made with the solution of nuclein in sterilized water containing 0.12 per cent. potassic hydrate and 0 6 per cent. of sodium chlorid. The following were made in the other solution mentioned. It may be stated that the culture of the aureus experimented with retained its vitality for days in water containing 0.5 per cent. of potassic hydrate.

EXPERIMENT VII.

Staphylococcus pyogenes aureus.

Time,	Immediately	1 hr.	4 hrs.	7 hrs.	24 hrs.
No. of colonies,	5000	2500	1600	1200	0

EXPERIMENT VIII.

Anthrax-bacillus without spores.

Time,	Immediately	1 hr.	4 hrs.	7 hrs.	24 hrs.
No. of colonies,	43	7	0	0	0

EXPERIMENT IX.

Cholera-bacillus.

Time,	Immediately	1 hr.	4 hrs.	7 hrs.	24 hrs.
No. of colonies,	350	105	150	42	0

EXPERIMENT X.

Staphylococcus pyogenes aureus.

Time,	Immediately	1 hr.	5 hrs.	19 hrs.	24 hrs.
No. of colonies,	Countless	25,000	5525	65	500

EXPERIMENT XI.

Anthrax-bacillus without spores.

Time,	Immediately	1 hr.	5 hrs.	19 hrs.	24 hrs.
No. of colonies,	430	0	0	0	0

We have made many other tests of the germicidal action of the nuclein obtained from blood-serum, but as all of them gave practically the same results, further repetition is unnecessary.

We have also made many experiments on the effect of heat and other agents on the germicidal action of this nuclein, but we prefer to report these later, as we have obtained some unexpected results. Suffice it to say that while boiling destroys the germicidal action, the temperature to which these solutions may be heated and still show some retarding action on germs has surprised us.

The fact that the germicidal constituent of blood-serum can be isolated has an important practical bearing. Blood-serum therapy has proved impracticable on account of the large amount of the fluid which must be injected. Nuclein-therapy now promises to enable us to avoid this difficulty, and possibly the near future may find us using this agent in the treatment of disease. The nuclein may be obtained from an animal rendered immune to diphtheria, and a sufficient quantity of this injected into the blood or under the skin of a child suffering with this disease may effect a cure, but we will not prophecy. The future will tell us what it has in store when the future shall have become the present.

ATONY OF THE STOMACH.[1]

BY JULIUS FRIEDENWALD, A.B., M.D.,
OF BALTIMORE;
ATTENDING PHYSICIAN, MEDICAL DEPARTMENT, CITY HOSPITAL DISPENSARY; VISITING PHYSICIAN, BAY VIEW HOSPITAL, BALTIMORE.

ATONY of the stomach is that condition in which the muscular walls have lost their tonicity, with a resultant motor insufficiency, in consequence of which the stomach is unable to pass its contents into the intestine at the normal rate. Although this condition has long been recognized, it has not received sufficient study, and great confusion still exists concerning its significance. By some authors it is classified as a purely nervous disorder; by others as a form of gastrectasia; some pass it by in a cursory manner.

Kussmaul[1] was among the first to make a distinction between atony and dilatation. He showed that in gastrectasia due to stenosis of the pylorus or of the duodenum, vomiting is very frequent during the entire course of the disease, and is a characteristic sign, while in atony it rarely occurs. Oser[2] attempts to distinguish between dilatation and atony, and states that in actual dilatations lavage is of great benefit, but that in atony it is of little service. Naunyn[3] lays stress on fermentation in dilatation of the stomach, and shows that in muscular insufficiency fermentation is usually produced. Minor forms without fermentation, he believes, should be excluded from the chapter of true gastrectasia. Germain Sée[4] likewise distinguishes clinically between dilatation and atony. Von Pfungen[5] has published a monograph devoted to this subject. He distinguishes the condition not only from gastric neuroses but also from gastrectasia.

For clearer views concerning this subject we are much indebted to Boas.[6] In his recent work on *Diseases of the Stomach* he describes this disorder at length, devoting a special chapter to it as a separate pathologic condition. He suggests the name myasthenia (muscle-weakness) as being more appropriate than atony or muscular insufficiency.

As regards causation, atony may be of two kinds —primary and secondary. Primary atony is found in persons who have been in the habit of consuming large quantities of indigestible food; the excessive use of fluids especially predisposes to this disorder; frequently, however, no such cause is assignable. Atony may be secondary to many other diseases, such as those of the brain and cord, typhoid fever, anemia, tuberculosis, and diseases of the gastro-intestinal tract, such as gastroptosis, enteroptosis, chronic gastritis, and nervous dyspepsia. Cholelithiasis is not an infrequent cause (Boas[7]). I have found gastric atony of rather frequent occurrence in diabetes. According to Peyer,[8] it is often found as a neurosis second-

ary to disease of the generative organs in males. Bamberger[1] finds it frequently congenital, and according to Zweifel[2] it is not uncommon in children, due, as he believes, in many cases to improper feeding. Kundrat[3] also finds it in children, and especially among those that have been subjected to many attacks of gastro-intestinal catarrh. Pfungen has shown that atony of the stomach often originates during the period of puberty; it is not improbable that the precocious appetite of this age, leading to the consumption of much indigestible food, is the cause of this disturbance. For the same reason it is not uncommon after typhoid fever. Pfungen[4] relates such a case in a woman in whom atony of the stomach was directly attributable to an attack of typhoid fever. No age seems to be exempt from the disorder, and it appears with equal frequency in males and females.

As to symptoms, most patients complain of a loss of appetite, though in rare instances the appetite may be fully maintained, at least in the first stages. When the condition is secondary to nervous disorders the appetite may even be increased (Peyer[5]). A feeling of pressure or fulness comes on, usually during or after meals, and this is especially marked after the ingestion of fluids. In light forms the distress reaches its height immediately after meals, and gradually passes off during the next hour, to be again aggravated by the smallest amount of food. In severer forms it may be so great as to continue with intensity for hours after meals, and become still more aggravated by the following meal. This feeling of pressure is accompanied by heartburn, pyrosis, eructations of gas, and, rarely, by vomiting. The quality as well as the quantity of the food ingested is productive of the symptom; fluids are most likely to induce pressure. Constipation is almost a constant symptom, and headache of a dull character is frequently present, and may at times lead to actual vertigo. Nervous symptoms of various kinds may be present, such as palpitation of the heart and indefinite pains, and on this account the disorder is frequently mistaken for neurasthenia.

On physical examination the stomach is found to be enlarged, so that the greater curvature reaches to, or below, the level of the umbilicus. Peristaltic and anti-peristaltic movements of the walls of the stomach may occasionally become visible. With but small quantities of fluid in the stomach (from 250 to 300 c.c.) a splashing sound may be produced by quick movements of the patient, or by a series of quick shocks with the fingers upon the abdomen. The boundary of the greater curvature of the stomach may be determined by marking the limit of this splashing, and sometimes when the stomach is dislocated downward, the lesser curvature also. The boundary of the greater curvature may likewise be located by percussion; especially is the method of Dehio[1] to be recommended: he allows a quarter of a liter of water to be swallowed, and the position of the greater curvature obtained by the limit of flatness against the tympanitic transverse colon; by drinking more water the curvature sinks until it reaches the umbilicus. In normal conditions it does not reach beyond this line. In atony, however, with but little fluid it sinks quickly below this limit.

Still more reliable is the method by expansion of the stomach with gas, which may be accomplished by the old method of Frerichs. Carbon-dioxid gas is produced by the ingestion of a teaspoonful of sodium bicarbonate dissolved in a small quantity of water, followed quickly by the ingestion of the same quantity of tartaric acid in water. But it is simpler and better to introduce air into the stomach through the stomach-tube by means of an ordinary double bulb of a spray apparatus. On percussion the stomach will be found to reach to, or below, the umbilicus.

In atony, the stomach is not only enlarged, but its motor function is also markedly impaired, and it does not propel its food into the intestine at the normal rate. The propulsive force of the stomach may be measured by the salol test of Ewald and Sievers.[2] Fifteen grains of salol are swallowed during a meal, and the urine is tested for salicyluric acid at half-hour intervals, beginning one-half hour thereafter, and continuing until the response occurs. Usually salicyluric acid appears in the urine in from forty to sixty minutes after ingestion. It is easily recognized by the violet color produced by the addition of a few drops of a solution of neutral ferric chlorid. The modification of this method by Huber[3] may be employed; according to this the urine is tested for salicyluric acid twenty-four hours after its ingestion, the reaction normally disappearing after this period. In patients suffering with enfeebled motor activity of the stomach, as in cases of atony or gastrectasia, the reaction lasts much longer. Of greater value is the test-dinner of Leube, consist-

ing of a plate of soup (400 c.c.), scraped beef (60 grams), a piece of white bread (50 grams), and a glass of water (200 c.c.). Under normal conditions the stomach will be found empty in from six to seven hours. Should particles of food be still present after this time the motor function of the stomach is much impaired.

A most important test is the condition of the stomach before the ingestion of food (Boas[1]). If the contents of the stomach be expressed in the morning before the ingestion of food, the stomach will be found entirely empty and free of all food-remains. This is not so in cases of gastrectasia, in which greater or smaller quantities of food will be found. Boas has devised still another test, which I have found of great service. The test-supper of Boas consists of white bread with butter, cold meat, and a large cup of tea. In atonic conditions the stomach will be empty the next morning, but in gastrectasia it still contains food-remains at that time.

The examination of the gastric contents is of great importance. The expression one hour after an Ewald test-breakfast[2] shows large quantities of solid contents, not separating into the characteristic three-layered fluid of gastrectasia,[3] or containing yeast-spores or sarcinæ.

Upon chemic examination the contents show in most cases a normal proportion of hydrochloric acid, pepsin, and casein ferments. According to Boas,[4] at the very beginning of atony of the stomach, through constant mechanic irritation of the food upon the walls of the stomach, an increased acid-production results; in fact the irritation may be so great that even hypersecretion may be produced. A case of this kind has come under my observation. In other cases there may be a condition of subacidity.

The symptoms of atony of the stomach are well illustrated by the following two cases:

Case I.—F. B., barkeeper, thirty-eight years of age, with a good family history, had malaria three years ago, and since then has enjoyed good health. Some months ago the patient was taken "with heaviness in the stomach after eating." The heaviness was soon followed by a sense of severe pressure and fulness after meals. Loss of appetite, nausea, headache, and constipation were also marked. Vomiting has never been present. This disorder has gradually increased in severity, until small quantities of fluids now cause great pressure and inconvenience. The man is rather badly nourished, his mucous membranes are pale, the pulse weak, the tongue coated. The heart and lungs are normal, and the liver and spleen are not enlarged. The stomach is tender to pressure along the line of the linea alba, from the ensiform cartilage to the umbilicus. The greater curvature of the stomach is four centimeters below the umbilicus. By quick shocks a splashing sound can be elicited at this point. Upon swallowing a very small quantity of fluid the splashing becomes much more distinct. By inflation of the stomach with air the lesser curvature is found in normal position, while the greater curvature is four centimeters below the umbilicus. The salol-test shows marked retardation of the motion of the stomach. Seven hours after a Leube test-dinner the stomach still contains large quantities of food. Several examinations of the contents of the stomach before the ingestion of food in the morning show no remains of food. This is likewise the case when a Boas test-supper has been taken the previous evening.

The examination of the gastric contents one hour after an Ewald test-breakfast shows large quantities of food remaining, with an acidity of 70; free hydrochloric acid, 0.17 per cent., and no lactic acid. The urine is normal in quantity, containing neither sugar nor albumin.

Case II.—M. W., a colored washerwoman, twenty-three years of age, a widow, with a good family history, had smallpox when a child, and has since been in good health. Fifteen months ago the patient was seized, directly after meals, with a sense of pressure in the stomach. This was especially severe after dinner; water and fluids are badly borne, and always cause inconvenience. The appetite is usually bad, but at times is increased. Constipation has existed for years.

The patient is a well-nourished woman; the pulse is strong; the tongue coated; the heart and lungs normal; the liver and spleen not palpable. The right kidney is palpable and dislocated to the second degree. The stomach is not tender to pressure. After swallowing but 200 c.c. of water a marked splashing sound can be produced in the region of the stomach, the limit of which is found three finger-breadths below the umbilicus; this is verified by the inflation of air. The stomach is found empty in the morning, Boas' test-supper having been taken the evening before. The examination of the gastric contents after an Ewald breakfast shows large quantities of solid contents, with an acidity of 58, HCl 0.19 per cent. The urine is normal in quantity, and contains neither sugar nor albumin.

Among the frequent complications of atony may be mentioned dislocation of the stomach (gastroptosis), and also of the bowel (enteroptosis), and dislocation of the right kidney. The association of dislocation of the kidney with dilatation of the stomach has been pointed out by Bartels,[1] Müller-Warnecke,[2] and Litten.[3] Litten endeavored to

[1] Boas: Loc. cit., p. 68.

[2] The Ewald test-breakfast consists of an ordinary dry roll and 300 c.c. of water.

[2] An upper brown foam, a yellowish middle layer, and a lower dark slimy layer containing food-particles; bubbles of carbon dioxid can be constantly seen rising to the top.

[4] Boas: Loc. cit., p. 66.

[1] Bartels: Schmidt's Jahrb., Bd. clviii, p. 225.

[2] Warnecke: Berl. klinische Wochenschrift, 1877, No. 30, p. 49.

[3] Litten: Verhand. des Kongr. für innere Med., vi, 1887, p. 223.

demonstrate that dilatation of the stomach may cause the liver to move downward, carrying with it the right kidney. This explanation is accepted by but few. Nothnagel[1] claims that Litten's cases were for the most part cases of atony; though dislocation of the right kidney is quite commonly associated with atony, he maintained that this association is merely a coincidence. It is probable that the atony in these cases is secondary to a gastroptosis. The following case illustrates this condition.

CASE III.—L. O., white, female servant, thirty-two years of age, single, came to the dispensary for treatment. She had been healthy when a child, but for years had suffered with constipation. Four months ago she had taken a large dose of "salts" on two successive nights; for several days this was followed by severe diarrhea, which was checked by medicine, but leaving a great sense of pressure in the region of the stomach, nausea, and heaviness in the epigastrium after eating. These symptoms have been very severe ever since; in the intervals between meals this pressure gradually passes away. In moving in bed at night the patient has noticed a splashing sound in the stomach.

The patient is of small stature, rather anemic, the pulse weak, the heart and lungs normal, the liver and spleen not palpable, the right kidney dislocated; points of tenderness are noted along the linea alba from the ensiform cartilage to the umbilicus; the region of the spleen is also tender to pressure; upon quick shocks with the fingers a splashing sound is heard at a distance of five finger-breadths above and six finger-breadths below the umbilicus. On inflation with air the smaller curvature of the stomach is found five finger-breadths above the umbilicus, and the greater curvature six finger-breadths below. Seven hours after a Leube test-dinner the stomach is found to contain large quantities of food-remains. It does not, however, contain particles of food early in the morning before the ingestion of nourishment; one hour after an Ewald test-breakfast large quantities of solid contents are, however, expressed. The acidity is 60; HCl 0.1 per cent., without lactic acid.

On inflating the colon with air it is found dislocated downward, the upper border of the transverse colon being two finger-breadths below the umbilicus. The urine contains neither sugar nor albumin, and is normal in quantity.

Atony of the intestine is not an infrequent concomitant of atony of the stomach—indeed, both may be present for years, and it may be difficult to tell which is the primary trouble. Of twenty cases of atony of the bowel recently examined by me, fourteen were complicated with atony of the stomach.

Gastric vertigo, the vertigo dyspeptica of Trousseau,[2] which this writer believed to be caused by chronic gastritis, probably depends in most cases upon atony (Boas). I have had a case of this kind under observation for some time.

CASE IV.—M. L., thirty-two years of age, a laborer, of good family history, had been in good health until ten years ago, but since then has had gastric trouble. He has had nausea, headache, great pressure after eating, and constipation. Recently the headache has frequently passed into vertigo, which at times becomes so intense that the man is unable to stand. These attacks of vertigo appear at irregular intervals, days sometimes passing by without them. The patient has become very nervous. The man is a large, well-developed individual, with strong pulse; the tongue is coated; the heart and lungs are normal; the liver and spleen are not palpable; the right kidney is dislocated (second degree); the stomach is tender along the median line from the ensiform cartilage to the umbilicus; a splashing sound reaches a hand's breadth beneath the umbilicus, which marks the location of the greater curvature, as was verified by the inflation of air. The stomach contains large quantities of food-remains one hour after the test-breakfast of Ewald. Acidity 62; HCl 0.149 per cent. The urine is clear, containing neither sugar, albumin, nor casts.

Atony of the stomach must be differentiated from nervous dyspepsia and gastrectasia or (dilatation).

According to Bamberger,[1] the variability and rapid change of symptoms, the presence of other nervous symptoms, the normal and increased appetite, and the absence and rapid disappearance of the gastric disturbance, distinguish nervous dyspepsia from atony. At times a diagnosis becomes very difficult and sometimes impossible. It must not be forgotten that atony is frequently a complication of most nervous disorders.

From gastrectasia, atony is diagnosticated by the absence of food-remains from the stomach in the morning before the ingestion of food; by the absence of the three-layered fluid of gastrectasia, and by the absence of sarcinæ and yeast-spores. There is a marked diminution in the secretion of urine in gastrectasia, but not in atony.

Atony of the stomach is a chronic disorder, and may last for years. It is quite amenable to treatment, and, though the disorder may not be perfectly cured, the patient may be relieved of all suffering. Atony may pass into gastrectasia after years, but this is rather a rare occurrence. Boas[2] has observed but a dozen of such cases.

The treatment of myasthenia depends in general upon its cause. If it is secondary, the treatment must be directed to the primary disorder. The dietetic treatment is highly important. It is necessary that the quantity of fluid taken shall be very

[1] Nothnagel: Verhand. des Kongr. für innere Med., vi, 1887, p. 242.

[2] Boas: loc. cit., p. 67.

small. According to Boas not more than from one to one and a half liters of fluid should be taken daily, though in general larger quantities of milk are contra-indicated; in some cases this food is well borne and proves serviceable. The examination of the acidity of the gastric contents gives us indications for the regulation of the diet. If superacidity exists a meat-diet in general is indicated. To this can be added soft-boiled eggs, with but few vegetables. Butter should be allowed in small quantities. In cases of subacidity the more digestible forms of meat should be allowed in smaller quantities. The vegetable diet may be increased in these cases.

In the treatment of the chronic constipation which accompanies most of these cases, my experience coincides with that of Boas. The use of cathartics is in most cases to be deprecated. The method that I carry out, and that I have seen practised with much success in the polyclinic practice of Dr. Boas,[1] is the proper regulation of the diet. Such substances are given as foods as stimulate the peristalsis of the intestine; for this purpose, Graham bread, fruits, and vegetables are ordered in rather large quantities; to these is added milk-sugar, which may be used twice daily in teaspoonful doses to sweeten coffee or milk, and which thus acts as a purgative.

In other cases of constipation, when the treatment just described proves ineffectual, injections of various kinds may prove beneficial. In three cases I have had excellent results from the use of the oil injections recently recommended by Fleiner.[2]

In atony of the stomach, Boas[3] highly disapproves of the use of lavage. He considers fermentation and decomposition the only indications for this procedure; and inasmuch as these are entirely absent in this disorder, lavage is quite superfluous. In regard to this disorder at least, I am convinced of the truth of this statement.

In two cases in which I have practised this form of treatment, not only was no relief obtained, but the pressure was more marked and persistent than before the treatment was undertaken. Of greater benefit is the use of the stomach-douche, especially in those cases depending upon the various gastric neuroses. Still more beneficial is the use of electricity which may be applied either extra-ventricularly or intra-ventricularly by means of Einhorn's electrode. The best results are obtained by the intra-ventricular method.[4] The tonicity of the muscular walls of the stomach are influenced by the faradic current. Painful conditions are alleviated by the galvanic current, the kathode being used intra-ventricularly, the anode placed upon the fundus of the stomach. To this may be added massage of the abdomen, the effect of which is to increase the peristalsis of the intestine and to strengthen the abdominal walls.

In regard to the medicinal treatment, preparations of strychnin seem to serve the best purpose. Either strychnin sulfate or the extract of nux vomica may be given in pill-form. To allay the feeling of pressure, which is a constant and annoying symptom, the extract of belladonna may be prescribed. When there is a diminished secretion of hydrochloric acid, fifteen-drop doses of dilute hydrochloric acid, given, according to the method of Ewald,[1] several times after meals, is indicated.

In cases of increased acidity, sodium bicarbonate should be ordered after meals. Pfungen recommends this remedy very highly.

THE TREATMENT OF EXOPHTHALMIC GOITER.

BY J. MADISON TAYLOR, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF CHILDREN IN THE PHILADELPHIA POLYCLINIC, AND IN THE MEDICO-CHIRURGICAL COLLEGE;
NEUROLOGIST TO HOWARD HOSPITAL, ETC.

(Concluded from page 677.)

A REVIEW of the cases is herewith appended:[2]

CASE I.—Graves' disease; enlarged thyroid; marked circulatory disturbance; no exophthalmos; dyspnea; convulsions, originally perhaps epileptiform, but later hysteric.

The cause was found to reside in a neurotic tendency, conjoined with repeated exposure to cold, and sitting in wet shoes during work, at the age of nineteen, culminating in a profound attack of exhaustion, nervous chill, rapid heart-beat, and overwhelming sense of suffocation. From this time on the heart was markedly disordered. There were present, together with several hysterical manifestations, repeated hemoptysis, cough, and progressive emaciation. An alarming attack of blood-spitting sent her to a hospital for four weeks, where she was treated for pulmonary tuberculosis. Soon afterward the urine was suppressed for three days, without pain; then a dark, offensive fluid passed, and gradual recovery followed. Finally, another profound over-exertion, five years ago, brought her under my care. The examination then showed a pale, thin, unmarried woman, aged twenty-three; the respiration from 24 to 30; the pulse fairly regular, from 130 to 135; constant cough, throbbing carotids; pupils widely dilated. There was complete mydriasis, but no lesion of the fundus. The heart was laboring; a loud, musical murmur was heard over the base; the apex-beat was

[1] Ewald: Klinik der Verdauungskrankheiten, Berlin, 1893, ii, p. 221.

[2] Journal of the American Medical Association, April 14, 1888.

displaced downward and outward; *bruit de diable* was heard. The thyroid gland was enlarged, especially the right, and conveyed a thrill to the hand; the neck measured 14¾ inches in circumference; the skin was pale and oily-looking; sweating occurred readily, and chilliness caused distress; the legs were edematous; menstruation had been absent for three years; the bowels were constantly loose; the urine was small in amount, bright-red with blood, and had a specific gravity of 1009; no casts; the knee-jerks were excessive.

Treatment was as systematic as the circumstances would permit: carefully regulated feeding and rest; simple, diluent drinks; iron in the form of Basham's mixture and digitalis; hot hip-baths; belladonna-plasters over the excited heart; later, cod-liver oil and bromids with digitalis. In a week the pupils became responsive to light, the cough greatly moderated, the urine was only smoky, and the heart-sounds better defined. Her circumstances at home were exceedingly unfortunate; dominated by a fierce virago of a stepmother, and perpetually under distressing domestic environment. However, in six months the girl seemed practically well. Twice since treatment the pupils have been widely dilated on catching a slight cold, and once only the urine showed albumin again. The menstruation has appeared twice; the pulse has been reduced to 85 or 90 in the erect posture.

The subsequent history of this case I followed throughout three or four years at varying intervals. Electricity was used for a time, but she would not continue it. General measures directed toward improving her health and relieving her troubles, domestic and physical, were satisfactorily pursued, and when the girl passed out of sight, I think by moving to a distant part of the country, she considered herself perfectly well of the original difficulty. The skin-activity returned until nothing was left to mark the original seat here but a slight tendency to leakiness. The pulse maintained a fair equilibrium, the thyroid enlargement had entirely disappeared, and I regard the case as cured, in spite of the very unfavorable attendant circumstances. The woman made a very unfortunate marriage with a man who drank and who abused her. She lived with him for six or eight months, then finally abandoned him, and took up several different kinds of laborious work, maintaining herself comfortably. At last accounts, in the year 1891, she was going to live with relatives in a distant place.

CASE II.—Mrs. H., aged twenty-eight, gave no neurotic history. She had two living children; there was marked exophthalmos, with the presence of Von Graefe's sign; irregular, excitable circulation; steady loss of vigor; slight, though well-defined, thyroid enlargement. She had been under my observation since 1881. The difficulties for which I originally treated her had to do with menstrual derangements and great dyspnea; the pulse varied constantly with the smallest emotional changes, and slight exertion caused it to run up to nearly 200 and produce distressing trouble with the breath. This lady was in comfortable circumstances, but, nevertheless, her responsibilities as a mother could not be entirely ignored—certainly she would not obey directions as I would have liked—nevertheless, I enforced as much of systematic feeding, rest, and other measures as possible. The medicinal measures consisted chiefly of digitalis and ergot, together with iron and other tonics, and in six or eight months there remained only the dusky, oily skin, the eye-symptoms and the lid-symptoms, and a somewhat irregular heart. Relapses occurred now and then, but in the main steady improvement took place, and was greatly increased, I am inclined to think, by carefully adjusted glasses, immediately after which the exophthalmos materially lessened.

It is interesting to mention that although a distinguished obstetrician, whom I had in consultation with this lady, pronounced it impossible for her to bear a living, healthy child again, yet I subsequently delivered her at term of three fine children, each of which she suckled for a full year, and at the time of the report then given there was no heart-trouble and no goiter. This lady has been under my observation ever since. She has grown stronger year by year, and is to-day a more vigorous person than when first married.

CASE III.—Well-marked Graves' disease; extreme nervousness; cardiac distress; exophthalmos; thyroid enlargement.

Mrs. R., aged thirty-six years, married, with one child, at the age of thirty-four seemed in perfect health. She weighed 130 pounds, and was surrounded by every luxury and care. She had sustained no shock or fright and had suffered no exhausting disease. While sitting in perfect health in a theater she suddenly had, from no known cause, a nervous chill, and from that time her disorder rapidly grew. The chills recurred frequently, changing to what she described as waves of feeling up and down the body. On the slightest exertion a sense of constriction in the chest and sweating of the skin would occur. The bowels were loose; the sleep broken, the woman lying awake for hours with a feeling of deadly fear. She had fallen to 110 pounds in weight, and presented a frightened, restless expression. The eyes were slightly prominent; Von Graefe's sign was present in slight degree; the cornea was injected. The voice and hands were tremulous on movement, and there was a general restlessness of manner. The carotids throbbed and the pulse was from 125 to 135 in the recumbent posture. An irregular, loud, musical murmur was heard in the precordia. The skin was bronzed and glistening, the hands and feet chilly. The enlargement of the thyroid was symmetrical, coneying a thrill to the hand. Some improvement followed rest and tonics. After passing from under my observation she fell into the hands of a gynecic surgeon, and, under a slight operation, suddenly sank and died. No autopsy was allowed.

This case is interesting from the sudden, unexplainable onset, there being literally nothing upon which to place the finger, except the sudden chill,

as stated, and the progression of the disease. The nature of the disturbance was not recognized or treated, and my recollection of the case is quite vivid. The family physician had urged "gentle exercise, simple food, and change of scene." I had an opportunity of seeing the woman for only a very short time, while she was under the care of Dr. Weir Mitchell, who endeavored to do what could be done, but for some reason or other she passed over into the hands of the surgeon, as stated. Persistent careful treatment in the right direction would probably have saved this woman for many years of useful, comfortable life.

CASE IV.—Graves' disease; slight exophthalmos; slight thyroid enlargement; irregular cardiac action; delusions; rapid loss of flesh; began a year previously to lose flesh rapidly during a severe dysentery; aged thirty-nine; had had ten children in rapid succession.

The symptoms present were slight delusions; vertigo; prominent eyes; injected corneal vessels; restlessness of expression; tremor of voice and hands; clammy and glistening skin; dyspnea; thyroid enlargement; noisy musical cardiac murmur; no valvular defect; very emotional; albumin and muco-pus in urine. The case was sent to me as convalescent by Dr. Mitchell.

General treatment was pursued, with systematized rest and tonics. The woman gained forty pounds in three months and seemed to be in perfect health, barring a readily disturbed emotional balance and a not yet very vigorous heart. The subsequent history, of which I knew something for many months, was to the effect that this gain was maintained and no relapse occurred to my knowledge, and had it done so, I should almost certainly have known it.

CASE V.—Graves' disease; slight exophthalmos; thyroid enlargement, the neck being fully an inch and a half fuller at the base than normal; slight cardiac disturbance; tremulous voice; recovery; still under observation, and perfectly well.

Miss R., aged twenty-five, presented no neurotic history. One sister has some valvular defect of the heart, but seems now to be fairly well. This patient at ten years of age had enteric fever; at eleven severe dysentery, after which she was long in regaining her health. She had had much headache until the age of nineteen years, when an illness occurred, accompanied by neuralgia in the face and profound prostration. Then she noticed rapid breathing on slight exertion. The eyes were soon remarked as being "curious-looking." She tried to gain strength by exercises in the open air. In March, 1882, she consulted Dr. Seguin, who pronounced the affection Graves' disease and gave an unfavorable prognosis. At that time there was edema of the legs. Digitalis and quiet were ordered. In the following November the woman grew better, after having been partly in bed for several months. In December, 1883, she saw Dr. Gray, of Utica, who also pronounced unfavorably, and relieved an increasing diarrhea. From May, 1881, to May, 1884, the woman menstruated only twice; thereafter irregularly until 1887; since then she has been fairly regular. Her weight was about 135 pounds; the skin was leaky; the lip and voice tremulous; Von Graefe's sign was present in both eyes; the pupils were normal; the corneal vessels were much injected; the woman flushed readily—a rather unusual feature; she was rarely pale; the heart was tumultuous; there was no valvular defect; the pulse intermitted one beat in three or seven; the thyroid enlargement was symmetric; there was well-marked thrill; a loud bruit could be heard in the right neck; there was subjective buzzing in the back of the head, and frequently a throbbing in the back.

The patient was placed upon systematic treatment with regulated living, digitalis, belladonna, tonics—iron, etc.—and attention to the skin, and for periods of from three to six weeks, two or three times applications of galvanism were made to the thyroid and the heart. The urine was found loaded with uric acid, and simple measures directed to this difficulty always produced marked relief. My report of 1888 goes on to say that the improvement was very marked at that time. The eyes had been examined by Dr. de Schweinitz, who found a slight hypermetropic astigmatism, but no lesion of the fundus.

The subsequent history of this case, which is still under my observation, is, I think, interesting, and consists briefly in a pursuance more or less regularly, of the various measures already described, including galvanism two or three times a year, for periods of from a month to six weeks, and until the last year or two. Instead of the belladonna, I found that hyoscin hydrobromate was a much more useful remedy, and as the strength grew I systematized the use of exercise, both for the eyes, the mind, and the body, and the improvement has been uniform and more rapid of late, and now this lady declares herself to be perfectly well, and nearly as strong as most people. The intermittent action of the heart has almost entirely ceased, although the organ is still irritable. I recently listened to her heart, and there was a beat or two omitted in about 250 or 300 beats. Slight exertion did not seem to increase this, although starting her heart into a more rapid activity than perhaps a normal heart would show. This lady can walk up and down hill for five or six miles without distress—indeed, with comfort. She lives an ordinarily useful life of a single woman of comfortable means. The exophthalmos has entirely disappeared. There is still an excessive injection of the corneal vessels, and the skin has almost regained its tone. A very recent letter describes her condition to be that of a perfectly well and thoroughly happy woman.

CASE VI.—A girl of twenty-four, with a decidedly neurotic family history, and whose mother was queer, presented well-marked Graves' disease. The cause seemed to me to be an attack of dysentery three years previously. This was followed by alarming heart-symptoms, vertigo in sitting or walking, profound weakness, dyspnea, extreme nervousness, poor sleep, sweating skin. There was also much intolerable itching, roaring noises in the head, and edema of the legs. In March, 1886, the thyroid

enlargement was observed; in May the exophthalmos; then developed the full picture of injected sclerotic, puffed lids, bloated face, livid, greasy skin; thyroid enlargement in three directions, mostly on the right. The heart-sounds were clear, with a heaving impulse, and a systolic murmur. The pulse was regular but frequent; the bowels were loose; the voice was tremulous. The eyes, carefully refracted by Dr. Hansell, showed some accommodative defects, but no lesion of the fundus. The urine was albuminous. The patient had pronounced delusions. No improvement has taken place up to date.

This young woman would submit to no regular treatment. She was practically insane when seen, and grew exceedingly religious, and tried to become a nun, but the Sisters rejected her. She fell into a condition that I should judge was one of religious melancholia, although I saw little of the case, except from time to time, learning of it chiefly through her sister. The girl is now in an insane asylum.

CASE VII.—A girl of sixteen, and a sister of Case VI, presented thyroid enlargement, with a very irregular heart, no exophthalmos, a leaky skin, chilly extremities, roaring in the ears. The heart-sounds were quick and feeble; a muffled bruit was heard over the right clavicle and through the thyroid, also a marked thrill. The carotids pulsated visibly. The girl's appearance was pale and cadaverous.

This girl was treated as well as the circumstances would allow, her necessities requiring that she should labor daily for her maintenance. She refused to submit to much treatment, which she pursued irregularly, with steady improvement however. I learn that she is now pretty well. The greatest relief was had from hyoscin hydrobromate, which controlled the nervousness and vascular irregularities.

CASE VIII.—Mrs. S., aged forty-six, presented marked exophthalmos, with pronounced thyroid enlargement, and Von Graefe's sign distinctly. Her trouble began five years previously, after a financial shock and an attack of typhoid fever. The latter was followed by an abscess of the abdomen, and this was opened in two places.

The woman was mentally depressed, had diarrhea, roaring in the ears, irregular menstruation, which soon after the beginning of her trouble ceased altogether. She was strongly built; her skin was muddy and dusky; the left eye was exceedingly prominent, the right less so; Von Græfe's sign was present in both eyes; the carotids throbbed; the heart-sounds were clear, and a distinct slight bruit could be heard; the pulse was irregular and frequent. After eight or nine months of treatment, consisting in the administration of digitalis and iron, and large doses of belladonna, the woman was greatly improved. She is still under my observation. I used so much of systematized measures as her circumstances will allow, but this was not much. The vascular disturbances are best controlled by hyoscin hydrobromate, strychnin and other tonics being occasionally used. The chief feature in her case is mental depression, slight melancholia readily setting in after any unfavorable news or distressing circumstances, to which, unfortunately, she is frequently subjected. There was, in addition to the trouble described, a considerable catarrhal disorder of the upper air-passages, which received careful treatment. I have seen this patient within a few days, after her return from a trip to Florida, undertaken for her health, and she now seems in all respects a perfectly vigorous, active woman.

CASE IX.—Mrs. J. S., thirty-nine years old; married sixteen years, with no children; a good family history, and of stationary weight; had had headaches of varying intensity all of her life; she has had no serious illness. Menstruation was regular. She suffered with flatulent dyspepsia and irregular bowels, with loose, frequent, slimy stools. Sleep was only fair, being disturbed by bad dreams. The headaches, which had persisted since childhood, were usually relieved by sleeping, and in the morning were localized to the back of the head. This pain was greatly increased on leaning forward, and if this attitude were persisted in, vomiting would often result. The eyes were never comfortable. The woman could not sew or read at night without greatly increased pain. There was also slight lateral nystagmus. The skin was characteristically flabby; frequent flushes were felt; the countenance was anxious; the tongue tremulous and marked by the teeth; there was a vibratile tremor of the voice; the neck was markedly enlarged on the left side; the heart-sounds were feeble and a musical bruit could be heard. The pulse was from 140 to 150 in the sitting posture; its action was irregular. There was great dyspnea on exertion or excitement.

The treatment consisted in the administration of hyoscin hydrobromate, in small dose, every two or three hours, till the skin became drier. Galvanism was applied to the neck, the mode of living regulated, and more rest enjoined. In a week the headache was less than for many years; in two weeks it was entirely gone. Iron was then given with strychnin. In two months the woman was able to resume her labors, and in six months she was scarcely recognizable.

CASE X.—Mrs. S., twenty-four years; married one year, with no children; as an infant was rather weakly. She had scarlatina at ten years of age, and thereafter had a slight swelling of the neck. Her general health then remained good, and at the age of seventeen she weighed one hundred and twenty-eight pounds, and was so circumstanced as to be compelled to do a large amount of hard work on a farm. This necessitated general and prolonged physical exertion, competent observers estimating it as the work ample for three individuals. This was kept up for two years and the woman then began to run steadily down. To the influence of this excessive labor I think may safely be ascribed the development of the malady. For four years this excessive work was kept up and soon afterward she was married. In December, 1889, she had a sharp attack of influenza, with cerebral and laryngeal symptoms. Subsequently marked dyspnea appeared and persisted. Headaches had been a life-long trouble, but six months before coming under observation she had been properly refracted. The

headaches thereafter almost, but not entirely, disappeared. Menstruation was usually regular.

The woman was tall and spare. There was very slight prominence of the eyeball. The skin had a characteristic pasty, leaky look; the hands and feet sweat readily. The heart was rather irregular in action, and a loud systolic murmur was audible over the aorta and the right clavicle; the pulse was 100 and more in the sitting posture. The tongue was clean; the appetite was capricious. Both lobes of the thyroid gland were enlarged.

Galvanic electricity was employed for a fortnight only. Then hyoscin hydrobromate, $\frac{1}{400}$ gr., was given thrice daily. Rest in bed was enjoined, together with a careful diet. Rapid improvement followed.

At the present writing the woman is in the fifth month of pregnancy, and quite stout and vigorous. The pulse is 85 in the sitting posture. The thyroid enlargement is probably greater than before. Therapeutically, the patient is taking a dry extract of thyroid gland.

CASE XI.—Mrs. N. K. S., thirty-three years old. Her parents are living; her mother suffers with rheumatism, and presents chalky deposits. The family history is otherwise good. The patient is the first child; the labor was normal; she was carefully fed; she had whooping-cough and chicken-pox in infancy, and measles, diphtheria, and pneumonia later. An attack of pink-eye three years ago seems to have injured her myopic eyes. The patient was never robust, convalescing slowly from illnesses. She was always nervous. Two years ago she had a mild attack of chorea. As a schoolgirl she was excitable and easily worried. She menstruated at fifteen, and quite regularly until a year ago; the flow is now rather scanty; six years ago there was amenorrhea, probably from anemia, with swelling of the lymphatic glands on the posterior aspect of the neck. The woman took up teaching seven years ago, and kept it up for five and a half years. Two years ago she had a sharp attack of influenza, which left her in a very nervous condition. She continued teaching, however, for six months, and then was married, about eighteen months ago. She seemed very well then until the spring of 1892, when nervousness set in again, partly as a result of the strain in nursing her ill mother. This caused evil dreams at night, and fear of thunderstorms, etc.; she has been getting gradually more nervous and hysterical; she has never been pregnant.

The patient is a rather small, dark-complexioned woman, the hair streaked with gray, the expression anxious, the eyes prominent, and the pupils responding well to light and in accommodation. She is highly myopic; vision O. D. = 20/CC; O. S. = 20/C. The ophthalmoscopic appearances are not unusual; there is a slight posterior staphyloma. The chest is shallow, the respiratory sounds feeble, the heart irritable. A rapid clanging is audible, but no murmur. A venous hum is heard in the neck, and propagated down the sternum. The thyroid not very large but pulsates visibly; it presents no thrill. The pulse is 100; the skin is very leaky, especially upon the hands, and this condition is aggravated by excitement. The station is good; the gait is irregular. The knee-jerks are exaggerated; there is no clonus. The voice exhibits the characteristic vibratile quality. The treatment consisted in rest in bed; massage; hyoscin hydrobromate, gr. $\frac{1}{400}$, four times daily, and increased as needed.

Two weeks later the headache had almost entirely disappeared; the nausea was much more tranquil; the digestion was good; and she was sleeping quietly. She was then taking $\frac{1}{200}$ hyoscin hydrobromate t. i. d. In the third week the hyoscin was withheld, and a tonic given in the form of elixir of iron, quinin, and strychnin. In the fourth week the woman regarded herself as well; her temperature was normal; she began gradually to sit up. She remained at the hospital forty-three days, and was discharged as cured. She had greatly increased in weight, vigor, and equipoise. The temperature followed the characteristic curve. At the present writing the patient continues well.

PRELIMINARY NOTE ON THE EFFECT OF MASSAGE ON THE BLOOD-COUNT.[1]

BY JOHN K. MITCHELL, M.D.,
OF PHILADELPHIA.

WHILE the manipulations of massage have always been said to increase the circulation and promote the movement of blood, it has never, I think, been definitely ascertained what the exact effect upon the blood itself is. In the examination of some recent cases I have had results so startling and so new that I thought them of sufficient interest to justify brief mention to the College to-night, and in advance of the fuller study on which I have already entered.

In the first case, a patient the subject of a very chronic lead-poisoning from drinking-water, with marked anemia, the blood was examined three times before any massage was practised, and the counts were, respectively, 3,725,000 red corpuscles to the c.mm., 4,000,000, and 4,100,000. The percentage of hemoglobin was always the same—a little over 30. On the fourth day careful massage of the abdomen alone was applied, lasting twenty-five minutes. Ten minutes after the ending of the manipulation I examined the blood, and found the red corpuscles 4,500,000, and the white corpuscles, which had previously not been in excess, as 1 to 85 red. The percentage of hemoglobin was not measurably increased. On the fifth day, after general massage lasting one hour, the count showed 6,500,000 red corpuscles, and the same percentage of hemoglobin.

In the second case, a woman from Mississippi, aged forty-two, with a very pallid appearance, decided malarial cachexia, and slight enlargement of the spleen, the first count, made before massage,

[1] From notes read before the College of Physicians of Philadelphia, December 7, 1893.

was 4,700,000, and the hemoglobin 70 per cent. The white corpuscles on this occasion, two hours and a half after the meal, were in the ratio of 1 to 120 red. After one hour's general massage the number of red corpuscles had increased to almost exactly 7,000,000, and the number of white had a ratio of 1 to 38. No further examinations of this case were made on account of the supervention of the patient's menstrual flow.

The third patient, a healthy adult, had a count before massage of 5,675,000, and 110 per cent. of hemoglobin, with no excess of white corpuscles. After massage the red corpuscles were 7,900,000, and the hemoglobin fully 120 per cent. I could not find in this case that there was any excess of white corpuscles, but I had the opportunity of making but one examination, and did not use the only satisfactory method of counting these corpuscles, *i. e.* by a separate examination with a 5 per cent. solution of acetic acid.

The fourth case was one of suspected early locomotor ataxia in an adult male, who, for some weeks had been in hospital under daily massage treatment and quiet, with good food. He had not been rubbed for three days previous to the examination. His count before massage was 6,575,000 red corpuscles, and hemoglobin 110 per cent. At a second examination, on another day, the count was 7,325,000 red corpuscles. On the same day, after massage, he had 7,340,000, a very small increase, and no increase in the amount of hemoglobin.

The fifth case was in a boy of fourteen, who had transverse myelitis, in course of recovery, and had been daily rubbed for some weeks. His count before massage was 6,900,000, with 90 per cent. of hemoglobin, and after massage 8,100,000, with 100 per cent. full of hemoglobin.

I should add that for several of these examinations I am indebted to the kind assistance of Dr. Charles W. Burr, who used a different instrument than mine. They were all made at about the same hour of the day, and, so far as possible, with similar conditions surrounding the patients—a matter of some importance when we recall the great changes that take place in the number of red and white corpuscles in the veins at different hours of the day and in different relations to meal-times. Bernard, indeed, showed that the total amount of blood was so much increased during digestion that an animal could be bled to a greater extent without injury after feeding than before.

This effect of massage does not seem impossible when one recalls how the bloodvessels look when seen in a frog's foot under the microscope. In the lesser capillaries there appears, every now and then, to be a clogging, and, for a time, the corpuscles scarcely move. When this state is overcome, a like condition is evident in another little vessel. Even in larger vessels, many corpuscles seem not to share in the general movement, and to be temporarily out of the current; the white ones especially cling along the walls, and some of the red ones progress less rapidly than others, or linger for an instant as if they were in an eddy or a side-current; it is probably literally true that there is a "side-current," the serum nearest the walls moving more slowly than that in the central stream. A portion of the blood, therefore—and when the whole capillary system is taken into account, it must be a large portion—is not at all times in active circulation.

It is easy to imagine that the alternate compression and expansion of the veins and arteries during deep massage, and the consequent pumping of blood through them, must push many of the corpuscles that are lingering in the by-ways of the circulation into the full stream of the blood-current, and make a demand upon the various reservoirs and factories of red and white corpuscles for further supplies to take their places.

While, as I said at first, the number of cases is too small to make certain the constancy of this very remarkable change after massage, it seems to me of sufficient importance to justify this imperfect preliminary statement. Even so far as it has gone, it suggests matters of novelty both in physiology and in clinical medicine.

CLINICAL MEMORANDA.

A CASE OF COMPRESSION OF THE BRAIN.

BY A. F. HARRINGTON, A.B., M.D.,
OF WEST POINT, GA.

ON the morning of December 26, 1892, I was called to see a negro man, twenty-seven years of age, who at 8 o'clock of the previous night had been struck above the right ear with a stone. I found the patient suffering with a dull headache; there was a contusion of the soft parts above the ear, but I could detect no fracture or depression of the bone. Some dried blood was found in and around the external auditory meatus. The man was perfectly conscious and got out of bed during my visit to void his urine. The only evidence of any paralysis whatever was a very slight difficulty in phonation, and this was hardly perceptible—a little stammering in articulating certain words. The pulse was 64, the temperature normal.

The symptoms pointed to some compression. The areas localized as supplying the larynx were rather anterior to the external injury to the soft parts, yet the existing partial aphonia led me to believe that hemorrhage from a ruptured artery was causing pressure of the speech-center. Being in doubt as to the advisability of trephining I decided to await further developments, ordering a laxative dose of Epsom salts and potassium bromid to quiet restlessness. For four or five days no further symptoms

arose, but the headache still continued. The patient seemed in better spirits and more contented. During this time, without my permission, the man was moved, sitting up in a buggy, to a house one mile away. I was hurriedly called on the morning of January 2d, to find him apparently unconscious, bathed in a profuse and cold perspiration, having convulsions of one minute's duration, occurring every fifteen minutes. During the intermission all of his muscles were tense, the pulse soft, and 125 per minute. The pupils were unequal in size, and irresponsive to light. There was total aphonia, and deglutition was impossible. These symptoms had suddenly made their appearance about 12 o'clock of the previous night, and had rapidly increased in severity. The convulsions occurred more and more frequently, were severer and of longer duration. The man died at 3 o'clock of the same day.

Upon removing the top of the skull, postmortem, I found the inner table fractured at the site of the injury, and a blood-clot two inches in diameter extended forward and upward. All of the meninges were congested. The clot was directly under the bone. The outer table of the skull was perfectly intact.

My sole object in reporting this case is to illustrate the folly of waiting in head-injuries, when symptoms of compression, however slight, exist. I did not operate at once, because I thought the symptoms did not warrant such a radical procedure; when last called no operation was undertaken because the patient was moribund. Whenever there is any compression the symptoms will increase in severity. We cannot expect amelioration unless the cause is removed, and only an operation can do this. Lifting a depressed bone and removing a clot are all that is needed. With antisepsis and due skill the brain can be operated on with impunity. Why then should we allow the formation of a clot to continue until the brain-resistance is overpowered? The surrounding bony wall can never give way—the delicate brain must. Then why not consider *any symptom* of compression an indication for the immediate use of the trephine?

THE TREATMENT OF BLEPHARITIS MARGINALIS BY HYDROGEN DIOXID.

BY S. C. AYRES, M.D.,
OF CINCINNATI, OHIO.

THE treatment of blepharitis marginalis is often unsatisfactory and disappointing. Relapses frequently occur, and remedies seem to lose their effect, and at times even to act unfavorably. It is true that much of our success depends on the faithfulness of the patient or of his parents in carrying out the treatment at home. Much also depends on the physical condition of the patient, and this should always receive careful attention. Anomalies of refraction seem to play an important rôle in perpetuating the disease, and these also should be carefully corrected. But aside from these considerations, the treatment is often prolonged, taxing the patience of the physician as well as of the client.

The remedies prescribed for the relief of this disease are numerous, and all have met with more or less success. During the past year I have used with great satisfaction hydrogen dioxid in the treatment of this disease. I was led to its use by some experiments in cases with suppurating rings around the cilia. After removing the crusts and applying the dioxid, there was a bubbling and boiling effect for a while, which soon subsided, leaving the ulcerated surface whitened, as if a solution of silver nitrate had been used upon it. The application was almost painless, and the lid was left clean and free from pus or scales.

These experiments were followed by a general adoption of this method in nearly all cases, but especially in those with ulcerations along the lid-margin. My experience in a large number of cases justifies me in recommending this treatment, so that others may give it a trial. The manner of its application is as follows: The larger crusts should first be removed or scraped off, after having been softened by tepid water. Then a little cotton is wrapped tightly around a Japanese tooth-pick, which is dipped into the dioxid in a little dish. The cotton is then swept over the entire edge of the lid. The characteristic bubbling will follow, and the application is repeated until the bubbling ceases. The ulcers will then present a whitish appearance. If care is taken, and the cotton is not too freely saturated, none will come in contact with the conjunctiva. In order to obviate all pain, a few drops of a 4 per cent. solution of cocain can first be instilled into the eye. This treatment should be repeated every day. The remedy is one that any intelligent person can apply at home, and one from which there is no danger. My experience with the use of salves and ointments is somewhat disappointing. They often cause unaccountable irritation, and on this account are unreliable. In the method advised a clean remedy is used, which acts promptly and efficiently. By its chemic action it destroys the germs which cling so closely to the edges of the lids. It is not a cure-all or a specific, but I certainly have had the happiest results from its use.

MEDICAL PROGRESS.

Gastrotomy in a Case of Carcinoma of the Esophagus.—At a recent meeting of the Philadelphia Academy of Surgery, KEEN reported the case of a man, forty-eight years old, in which for thirteen months there had been gradually progressive interference with deglutition, so that at the time the patient came under observation he was able to swallow only liquids. The taking of nourishment was followed by a sense of impediment at a point corresponding to the left sterno-clavicular articulation; then the food would pass with comparative ease until it reached a level corresponding to a point half an inch above the lower extremity of the ensiform cartilage. At the latter point distinct obstruction was felt, and the passage of food was attended with darting pain in the median line posteriorly, below the inferior angles of the scapulæ (though more pronounced upon the left), in the epigastric region and in the precordium. Several slight attacks of hematemesis had occurred, and on one occasion quite a considerable loss of blood had taken place. Forty-eight pounds in weight had been lost during thirteen months. There was no history of traumatism, of the ingestion of corrosive substances, of syphilis or of alcoholism. The passage of an esophageal bougie was attended with resistance at a point ten and

a half inches from the teeth, and absolute obstruction was encountered at a distance of twelve inches. It was decided to perform gastrotomy, and the operation selected was that devised by Witzel.

An incision, four inches long, beginning at the middle line and running to the left, a finger's breadth below the border of the ribs, was made, and the fibers of the rectus muscle were separated by the fingers, but not divided. The stomach was seized with two fingers and brought forward and outside the wound, the margins of which were protected with gauze. A rubber tube, five inches in length (size 25, of the French scale for catheters), was introduced into the stomach and infolded by two rows of Lembert sutures. The opening in the stomach was made toward the cardiac extremity, and the tube lay parallel to the external wound, its external extremity emerging near the median line. Three stitches were now inserted into the walls of the stomach, but not tied until the organ was returned to the abdomen, their needles being left threaded. As soon as the stomach was returned these needles were thrust through the abdominal wall and the stomach was brought up to the margin of the opening. The tube was held in place by a catgut stitch passed through the wall of the stomach and through a part of the wall of the tube without obstructing its caliber. About one inch of the tube was thrust into the stomach. The edges of the abdominal opening were now approximated by silkworm-gut sutures and the ordinary dressing was applied. A clip was placed on the tube to prevent the escape of the contents of the stomach.

The patient made an excellent recovery, without incident, excepting in one respect. On the second day after the operation the dressing became twisted in his movements in bed, and the tube was pulled out of the stomach. In order to replace it, it became necessary to cut three stitches in the external wound. When the tube had been replaced these stitches were re-inserted. Apparently, however, such adhesion had formed that no harm was done by this accident excepting to delay the closure of the wound. After a lapse of six or seven weeks the man began to expectorate some bloody mucus, presumably coming from the ulceration of the carcinoma in the esophagus. He had gained about four pounds in weight. Immediately after the operation he was fed for two days by rectal enemata. Then small amounts of milk were poured into the stomach through the tube. This feeding was gradually increased until the daily food consisted of two quarts of milk, about twenty ounces each of beef, mutton, and chicken broth, and a dozen eggs. This was varied by substituting gruel, thin custard, and other similar food. The man became able to walk about with much comfort. The tube was held in place by a gauze dressing, which in turn was retained by rubber adhesive plaster on each side, laced through eyelet-holes. No escape of the gastric contents took place alongside of the tube.

The patient was still doing well three months after the operation. There was absolutely no leakage whatever.

Changes in the Blood as a Result of Thermic Influences. At a recent meeting of the Royal Society of Physicians of Vienna, WINTERNITZ (*Wiener medicinische Presse*, 1893, No. 47, p. 1858) reported the results of observations upon the changes that take place in the blood as a result of applications of heat and cold. He had previously found that the application of cold was followed by an increase in the number of colorless corpuscles in the blood withdrawn from the finger-tip or the lobe of the ear. Fifty additional cases were studied for the purpose of observing the influence of thermic impressions upon the number of red corpuscles, the amount of hemoglobin and the specific gravity. It was found that the employment of general thermic and mechanical measures (friction in cold packs, douches, baths, and the like) involving the entire surface of the body, was attended with an increase of both red and white corpuscles, as well as of the amount of hemoglobin. The maximum increase of red cells reached almost 2,000,000 per cubic millimeter; while the colorless corpuscles were trebled in number, and the hemoglobin was increased 14 per cent. The maximum increase was not always observed immediately after the manipulations, but often after the lapse of an hour. The colorless corpuscles began to increase in number at a time when the red cells were beginning to diminish. These changes lasted a variable time; a diminution could be observed two hours after they had begun. The change in the number of colorless cells was less constant than that in the number of red cells; the former were in some cases both relatively and absolutely in smaller number. In some cases the increase persisted. Active muscular movement had a similar, but less decided effect. General applications of heat were attended with a diminution in the number of red cells, followed by a moderate increase. Applications of cold to the lower extremities were followed by a diminution in the number of both red and colorless cells, in blood obtained from the finger-tip or ear-lobe, while an increase was observed in the blood of the parts to which the applications were made. It was pointed out as unlikely that the increased number of cellular elements is due to their new formation, but as more probable that preëxisting cells are hastened into the blood stream as the result of the application of cold, in consequence of a stimulating and invigorating influence upon the heart, and vessels, and tissues; so that blood previously stagnant in various parts of the body is sent to the lungs and, with a fresh supply of oxygen, becomes capable of renewed function.

Variations in Weight in Epileptics.—At a recent meeting of the Society of Biology of Paris, FÉRÉ (*Compt.-rend. hebd. des Séances de la Soc. de Biol.*, 1893, No. 32, p. 891) presented an epileptic who illustrated remarkable changes in weight, such as may often be observed in neuropathic and psychopathic subjects. The patient was a man, thirty-six years old, who had been under observation for seven years, having, as a rule, about six major and three minor attacks a month. During this time he had been generously treated with bromids and with borax, but without avail. Within a period of seven weeks this man gained 2.2 pounds in weight. Then he rapidly put on flesh, gaining 36.3 pounds in the subsequent twenty-six days. Then the man began to lose weight, falling off 2.2 pounds in the course of three days. Throughout the observations the conditions of treatment and diet remained the same.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 23, 1893.

MANNABERG'S THEORY OF LAVERAN'S CRESCENTS.

THE recent monograph of MANNABERG on the parasites of malaria (*Die Malaria-Parasiten, etc.*, by DR. JULIUS MANNABERG, Vienna, 1893) forms a very important landmark in the history of malaria, and should materially assist in the study of that disease. The book combines a fairly full and accurate account of the work of previous investigators with the results of original observation in a rich field, and is embellished with a large number of figures, for the most part colored, which, with few exceptions, are superior to most of those hitherto available. The work deserves, therefore, to be in the hands of all who have to do with malarial disease.

One of the most interesting and important chapters in the book is that in which the author details his theory of the nature of the crescentic body, a theory announced by him a year ago, but not widely disseminated. MANNABERG himself says that more research is needed in order to confirm the theory, but already one writer on the relation of protozoa to disease (*British Medical Journal*, October 14, 1893, p. 825) has treated it as one perfectly demonstrated.

To an investigator uncritical acquiescence is a shade worse than absolute silence, especially when a novel statement is involved. Candid criticism, on the other hand, is always welcome, and we propose, therefore, to point out briefly some of the more obvious objections to the theory.

A description of the crescents can be omitted here, but before considering the new theory it is well to say that up to this time only one other can claim wide acceptance. This is the theory entertained by MARCHIAFAVA and CELLI, based on observations by those investigators and their pupils, and published in many articles. For convenience we shall call it the Roman theory. According to this the crescents develop from bodies belonging to the form known as the small plasmodium. Beginning as bodies not distinguishable from others of the same kind—that is, as small ameboid intra-corpuscular forms—they tend at an early stage to grow long and narrow, lying along or near one side of the red corpuscle and finally reaching the crescent shape as found in the blood, usually without, but sometimes with traces of the corpuscle in which they grew. According to the Roman investigators the crescents represent sterile forms and do not produce new bodies. It is true that some early observations of the Roman school seemed to show the occurrence of a sort of gemmation, but in all the later investigations stress is laid upon the sterile nature of the bodies, though it is admitted that complete knowledge is still wanting.

MANNABERG'S theory is that the crescents are *syzygies* or conjugation-forms. Conjugation, complete or partial, is a process common among all classes of the protozoa, though its details have been worked out only in a few instances and are not always uniform. MANNABERG describes it concisely as a process "in which two or more individuals come in contact and become partially or completely fused. In this the structure of the original bodies disappears more or less; especially do the nuclei tend to disappear. Earlier or later a membrane forms around the conjugate body, by which it is encapsulated or encysted. The further change which these conjugate bodies, known to zoölogists as syzygies, undergo is usually sporulation, so that syzygies can be looked on as a sort of sexual propagation of the protozoa."

MANNABERG'S idea that the crescents represent some such body as that just described is based on the following grounds:

"It is well known that a single red blood-corpuscle may contain two or more of the ameboid organisms. These may be separate, or they may lie

by twos, or, less frequently, by fours, close together. Often the adjacent borders of the two bodies cannot be distinctly seen, especially in fresh blood, and especially if, as is usually the case, the pair lie close to the edge of the blood-corpuscle. The bodies under these circumstances are often long drawn out, and lie with their concave edges to the center of the blood-cell. The length of the body and the fact that the chief part of the plasma is at the poles, make the resemblance of such a pair to a crescent very striking, and all that is necessary to complete the picture is a small number of pigment grains."

Notwithstanding these striking facts, says MANNABERG, it would be too rash to assert that the crescents are syzygies, were it not for the existence of other reasons which actually force that view. These reasons are: the limiting membrane of the crescents, their peculiar structure, the formation and arrangement of their pigment, and their segmentation.

These four points MANNABERG elaborates in a manner interesting, but at a length that makes the reproduction of his arguments impossible here.

Enough has been said, however, to show the ingenuity of the theory, and to indicate how plausible it is. From a biologic point of view much more is involved than the origin of the crescent from one or from two ameboid forms, even if it does not appear that the supposititious syzygies undergo sporulation.

Admitting before going further that future investigation may prove the truth of the theory in its entirety or in part, we wish to set out briefly some of the points which should be borne in mind now and during critical observations.

In the first place it seems to us that MANNABERG in two respects lays too much stress on a membrane. Conjugation-forms do not always become encysted; nor is the presence of a membrane evidence that the body having it is conjugate. So far as the membrane of the crescent is concerned it is quite compatible with the view that the bodies are sterile forms, and also with the view long ago expressed by COUNCILMAN that the crescents are a form of "Dauersporen."

Passing by a consideration of the statements regarding the structure and the pigment of the crescents, we wish to say a word concerning the segmentation of the bodies. MANNABERG speaks of sporulation as one of the functions of syzygies, but by segmentation he means a different process, a division in ordinary language, which also occurs in conjugation-forms.

According to MANNABERG, segmentation in the case of the cresents consists in a division in the middle in such a way that "before complete division the two halves hang together like a pair of sausages, a part of the pigment being left in each half." From this MANNABERG draws only the nearest conclusion—that is, that the crescents divide—though he suggests that certain dark granules often found in the dividing crescents have some connection with propagation. This process of division MANNABERG says he has seen "not infrequently," and he further says that GRASSI and FELETTI also mention it. But the reference to the work of the latter is so imperfect that it is impossible to verify it. In a later paper by GRASSI and FELETTI (*Centralblatt für Bakteriologie und Parasitenkunde*, Bd. x, No. 15) the following occurs: "We have at times found figures which almost indicated that the crescents divide transversely, and that then each half divides again. At all events we have so far been able to observe indications only of a reproduction of these bodies." On the whole the work of the observers just named does not harmonize with that of MANNABERG.

So far as the division of the crescents is concerned, as MANNABERG figures and describes it, it does not seem to be more than a mere breaking of the body, which from the peculiar structure of the crescents would seem to be very readily brought about. Regarding this point, however, it should be easy to confirm the observation, and one should look, not for partly divided crescents merely, but for the complete division that MANNABERG describes.

Regarding MANNABERG'S clinical proofs, we have to criticise one point only, namely, the assertion that the new theory explains the relapses that occur in cases with crescents (strictly speaking, with crescents and small plasmodia). Relapses occur in tertian intermittents without crescents, and although, perhaps, not so frequently as in cases with the small plasmodium, neither MANNABERG nor anyone else has claimed that there are essential differences between the relapses of the two forms. The power of the germs of tertian to remain, as it were, latent for a long time in the body is so well known that it would seem necessary to dispose of it before stating that the conjugation theory is necessary to explain relapses of from two to three weeks, as MANNABERG puts them.

If it is ever demonstrated that the crescents are

syzygies, we shall have a good explanation of certain relapses, but argument in the reverse direction is of little value.

It is hoped that the assertions of MANNABERG will call forth renewed investigation in this interesting subject, and especially is it desirable that this country, which offers such favorable material, will take its part in the work. Though we have been, perhaps, led astray by the remarkable figure of the crescentic body, and so have overestimated its importance, its other remarkable characteristics make it well worthy of investigation.

SOCIALISM IN MEDICINE.

NATIONALIZATION and centralization have of late made rapid strides in medicine. The position of the physician as a private person is more and more encroached upon, and it is not an idle speculation or theoretic dream to say that if the present methods continue to increase as they have done in the past, the physician of the future will be an officer of the State or of the city, duly appointed and salaried as such. Little by little the work of attending to the sick is being taken up by the community, whether Federal, State, or municipal in nature, by institutions endowed with public moneys or by private or semi-public corporations. The city officials provide vaccination at the public expense, performing in Philadelphia on an average 11,000 a year, and thrice that number in times of epidemics. The Municipal Hospital of the same city is called upon to admit cases of diphtheria, scarlatina, and measles, and during last year's epidemic 183 cases of diphtheria and 159 cases of scarlatina were treated in its wards. With increased facilities a much larger number will be admitted.

The State already possesses six hospitals of its own, not including the hospitals for the insane. These State hospitals are situated in the coal regions and are supposed to care for the injured miners. If the State attends to the health of injured miners, why not have hospitals for the ironworkers, for railroad employés, and finally for tailors, bakers, and all the rest? All are equally entitled to these privileges. Instead of establishing individual institutions, the State endows those already existing; the last legislature appropriated $200,000 for sixteen Philadelphia hospitals.

There are 35 large hospitals in Philadelphia, having a bed-capacity for 4500 patients, and the total population of these institutions on September 30, 1892, was 2600. The total receipts of 30 of these hospitals, not including the Philadelphia Hospital and the Municipal Hospital, were, for the year 1892, over $1,400,000; the total expenditures for the same period were $1,300,000. Only 20 hospitals received payments from patients, amounting in all to $160,000; for the rest of their expenses they were dependent on public and private charity. Moreover these institutions are in reality not used by the very poor, who must be crowded into the old Philadelphia Hospital. It is chiefly the middle classes that are admitted, many of them belonging to special religious denominations.

Surgery is mostly carried on in institutions. Formerly the young doctor had a chance of being called to attend an accident-case happening in his neighborhood. Many a physician has won his way into a fair practice through the skill shown in such emergencies. But to-day the patrol-wagon or the ambulance is as speedily obtained as the nearest doctor, and the case is whirled off to the hospital. It is treated in the dispensary if a slight case, or sent to the wards or a private room, according as the financial condition of the patient seems to warrant. We have known rich men to pay $25 a week for a private room in a general hospital, and demand extra attention of resident and visiting physicians without ever thinking of remunerating one or the other.

Cases of enteric fever, owing to the more complicated treatment, viz., the Brand method, are more and more coming under hospital supervision, and even the young physician is very likely to send his patients to an institution if he finds it difficult to carry out the details of the treatment at home. There were 2300 cases of typhoid fever reported to the Philadelphia Board of Health in the year 1892; and in THE MEDICAL NEWS of November 25, 1893, Dr. J. C. WILSON reports seventy-four cases treated at the German Hospital in one year. If other large hospitals show similar statistics we deduce that over one-third of all cases of enteric fever are cared for in public institutions.

Specialism is largely attended to by the dispensary clinics. The eye, ear, nose, and throat departments are always crowded, and usually by the better classes. Costly underwear is not infrequently seen in the gynecologic out-patient departments.

The great rivalry existing between the institutions, and the readiness with which the public is willing

to receive something for nothing, whether in need of it or not, make the free dispensary an object of great abuse. The poor, for whose benefit it is supposed to exist, are crowded and tired out by the more leisurely class, who come early and have nothing to lose by waiting. It cannot be doubted that the dispensary greatly injures the family physician, whose advice was formerly asked for and remunerated by a large number who now regularly attend the special clinics. Even obstetrics is becoming institutional, and the eleven lying-in hospitals and schools of Philadelphia attended in 1892 to 1200 confinements.

But not only in practical medicine is this centralization noticed. Scientific experts are in the employ of the Government and State to study disease and how to prevent it, both at home in laboratories and experiment stations and abroad as Government commissioners. If SURGEON-GENERAL STERNBERG's plan of army and navy medical schools succeeds, may it not be followed by a national medical college at Washington, properly endowed by the Government?

If the State now contributes moneys to medical colleges, why shall it not concern itself about the expenditure of such grants, and hence have a voice in the management? It is but one step further to complete control.

But not only will college hospitals be under Government supervision, but likewise all hospitals if they receive financial aid from the public.

The Philadelphia Hospital suffers greatly from want of space, while elegant monumental buildings, erected to glorify some individual, or set of individuals, beg for State aid, and have many of their beds empty. One hospital asked for $200,000 of the State Board of Charities to aid in the erection of a new building—a request very properly refused.

The country physician is likewise beginning to suffer from this centralization. The rich, and even middle class, often go to the nearest city in search of medical, and especially surgical advice. The hospitals usually become their resting-place, but having a letter to the hospital surgeon, the latter usually brings in a bill for his services. One prominent surgeon has stated that were it not for such practice referred to him from the country, he could hardly pay his living expenses.

We see, therefore, that while the family physician first suffered from specialism, both he and the specialist are now suffering from institutionalism and paternalism, and that very soon the only remunerative work in medicine will be that coming from public position, either directly or indirectly. In the meantime the hospital visiting surgeon or physician should demand payment for his services, and if the profession will unite in this demand it must be acceded to, for the hospital cannot exist without the physician.

Private patients should be compelled to pay for medical services, and at clinics and dispensaries some charge for services should be made, except in certain cases. It is as pauperizing to a community to give gratuitous medical service as it is to give free bread.

In every-day practice we are very careful how, by word or deed, we injure the interests of our brethren in the profession. Let us not forget when we become attachés of hospitals that our brother still exists, and that every action of ours countenancing the present indiscriminate methods of squandering medical charities not only greatly injures him, but also pauperizes the recipient and tends to make medicine itself secondary to a board of laymen who receive all the praise and credit.

EDITORIAL COMMENTS.

The Neuritis of Diabetes Mellitus.—Though we do not know the ultimate etiology of diabetes mellitus, the lessons of clinical experience would seem to have demonstrated that the symptoms of the condition are essentially manifestations of a morbid derangement of the bodily metabolism. The obvious inference to be drawn from this assumption is that there is, among other things, either defective disintegration of the saccharine elements of the ingested food, and of those generated within the organism, or excessive production of the latter, perhaps additionally with the retention of certain products of imperfect tissue-change. The seat and the nature of the morbid process are, however, not known. It is true that diabetes mellitus has been observed in association with other morbid processes, such as disease of the nervous system and of the pancreas, but the precise relation between the associated conditions has not been determined. As an indication of the profound consequences to which the derangement of metabolism present in diabetes may lead, beyond the presence of glucose in the urine, we need but point to the coma that determines a fatal issue in a certain proportion of cases. The nutritive depravity is further indicated by the occurrence of various trophic lesions, and by the peculiar susceptibility to tuberculous infection displayed by diabetics. Additional evidence of the circulation in the blood of the toxic products of a perverted metabolism is the occurrence of peripheral neuritis, as manifested by characteristic motor or sensory symptoms. Little attention has been given to this complication, or (perhaps

better) manifestation of diabetes, and not much has been recorded concerning the pathologic changes found in the nervous system after death. In the autumn number of *Brain*, T. DAVIES PRICE makes an interesting contribution to this yet but little traversed field. He reports three cases of diabetes mellitus presenting peripheral neuritis of sensory type, and gives the results of a pathologic study. There were present pains, followed by tingling, numbness, and impaired sensibility, together with ataxia, enfeeblement, followed by abolition of the knee-jerks, but without palsy. In two of the cases perforating ulcers of the feet developed, and in one of these, and in the third, gangrene appeared, leading to fatal termination. In one of the cases the pupillary reactions were enfeebled; in another, a number of otherwise good teeth fell out; one presented lividity, and two an erythematous and edematous condition of the lower extremities. In all three cases there was found, post-mortem, the evidences of parenchymatous inflammation of some of the peripheral nerves, and in one case degenerative changes in the ganglion-cells of the anterior horns of the spinal cord, as well as atheromatous changes in the bloodvessels. We can only interpret these various phenomena to be the result of the presence in the circulation of the toxic products of a deranged metabolism. When we shall have learned more about the influences that induce these morbid derangements we will be in a position to outline a rational therapy or to realize our therapeutic puerility.

Vivisection of Criminals.—No more morbid and shameful perversion of the spirit of experimental investigation has been proposed than DR. J. S. PYLE'S "Plea (*Tri-State Medical Journal*, i, 1, p. 5) for the Appropriation of Criminals (convicts ?) Condemned to Capital Punishment to the Experimental Physiologist." This inhuman fantasy contemplates nothing less than the removal of the laboratory of experimental psychology to the dungeon of the convict, followed by the ardent psychologist and pseudo-surgeon. The convict is assured that his execution is now placed in the friendly hands of the physiologist, representing the medical profession. This death is to be made to add to the knowledge of man, and secure an advance of the curative art. Having been assured that the execution will be devoid of physical pain and the experiences of the gibbet, the convict is anesthetized, and the whole, or part, of the calvarium is removed. The anesthetic is then arrested; and, after any uncomfortable effects which the drug has produced have passed away, and the convict is again in a normal condition, the various "centers" of the brain are "excited," and the convict being in a peaceful and observing frame of mind, recounts his experiences to the stenographer of the occasion, or runs them on to a phonograph. Then the experiments being ended, the hypodermatic needle is used, and the convict sinks into the long sleep under the "stimulation" of the "center" of greatest physical pleasure.

There are men who deny the right of society to take life at all. There are men who are pained at the presence of medical men at executions, and, especially, at the experiments which notoriety-mongers pretend to undertake; but a very much larger class would protest against any law or laws contemplating such an unholy alliance between the laboratory and the dungeon.

The mere suggestion is revolting, and equally unbecoming a medical man and the medical press. The recommendation shows how little the author has considered the standing of the medical profession in the eyes of the community, the rights of man, the conduct of courts, the value of experiments on animals, and the perspective of the needs of life.

The Worst Quack Seeks Medical Authority.—One of the most exasperating and disgusting things about the quack is that in the very same advertisement in which he abuses the medical profession he will in some way claim the sanction or protection of medical science or of reputable medical men. A striking example is furnished by a company hailing from Augusta, Maine, who send out the most astonishing circulars as regards the "cash prizes" gained by their agents, and of the thousands of dollars' worth of "OXIEN" that they are selling. The Company claims the sanction and sails under the certificates of the Mayor, the President of Council, City Solicitor, Postmaster, President of the Board of Aldermen, and all the rest! But in a circular dated November 6, 1893, it is also claimed that the nostrum "is sold under the certificate of the City Physician of Augusta." This struck us as "going too far," and we have before us the letter of the City Physician denying absolutely that he has certified as advertised, or that he knows anything of the cure-all.

As another illustration of the mercantile demands for and uses of "physicians," the following advertisement was clipped from the Philadelphia *Press* of December 11, the year of our Lord, 1893:

"WANTED, A PHYSICIAN to travel with medicine company to lecture; experience not necessary; prefer one who can play organ; a steady, pleasant, and lucrative position offered. Address," etc.

Decrease of Crime in England.—The *Lancet* is responsible for the statement that serious crime is steadily decreasing throughout England. It is pointed out that in the five years ending in 1859, when the population of England and Wales was 19,257,000, the sentences to penal servitude numbered 2589, while in the years from 1885 to 1889, in a population of 27,830,179, the number of sentences was 946. Since the last date named a further decrease has taken place. There has also been a remarkable diminution in the number of young convicts. In 1887 this number was 3.2 per cent. of the total; in 1893 it was but 1.2 per cent. These observations agree with the statement that the diminution in the whole amount of imprisoned criminality is mainly attributable to a decrease in the number of young offenders, the proportion of older delinquents having increased. This result may in great measure be ascribed to the steady growth of a tendency, in the case of young persons, to the discipline of reformatory schools. The wisdom of this course can hardly fail to commend itself. Corrective rather than repressive, it embodies the essence of curative treatment as applied to crime. The substitution of fines for imprisonment, the conditional liberation of first offenders and the abolition in many cases of imprisonment for debt are measures of a like tendency, agreed in their purpose of obviating, as far as possible, the necessary evils of prison-life.

Vascular Pain.—At a recent meeting of the Association of Physicians, of Vienna, NOTHNAGEL (*Wiener medicin. Presse*, 1893, No. 46, p. 1819) made the novel suggestion that many of the vague pains so commonly complained of, and which in the absence of demonstrable lesion are ordinarily designated neuralgic, rheumatic, or myalgic, may be dependent upon a disordered state of the walls of the bloodvessels. Thus, in cases in which the symptoms of aneurism later appear, it has been observed that pain was present before compression or involvement of adjacent structures has taken place or distinctive physical signs are recognizable. It is believed that when headache precedes an apoplectic seizure it is indicative of the occurrence of thrombosis, rather than hemorrhage. It is not established, on the one hand, that cerebral ischemia will give rise to pain, or, on the other hand, that cerebral tissue is sensitive, so that the abnormal sensations are to be attributed to changes in the vascular wall. It has been shown that there is a form of migraine dependent upon vascular spasm, and it may be that many of the peripheral pains, sometimes associated also with formication and impaired sensibility, are dependent upon corresponding local spasm. Demonstration is yet wanting that the bloodvessels have a sensory nervous supply, although Pacinian corpuscles have been found in the adventitia of the larger vessels.

The Four-years' Course of Medical Study.—The Trustees and Faculty of Rush Medical College have given notice to the Secretary of the American Medical College Association that at the next meeting they will introduce a resolution requiring all students who begin their studies in the fall of 1895 to attend four full courses of lectures in the Medical College of not less than six months each, providing that graduates of all literary and scientific colleges of good standing shall be allowed to graduate in three years, and providing that graduates of dental colleges requiring three full years of study may be allowed to graduate in two years; and that graduates of dental and pharmaceutical colleges requiring only two years of study may be allowed to graduate in three years in the medical college.

Good! But the semester should be, "not less than eight or nine months" instead of "not less than six months." It is no kindness to the lobster to put him in cold water and bring the temperature slowly up to the boiling-point. The more speedily and frankly we accept the inevitable, the better.

Blindness in England and Wales.—The agitation directed toward the prevention of ophthalmia neonatorum, in conjunction with the natural advances in medical art, is already bearing good fruit in the reduction in the number of cases of blindness, as indicated by certain statistics quoted in a recent number of the *Lancet*. From these figures it would appear that whilst in 1871 there was in England and Wales one blind person to every 1051, the proportion had in 1891 fallen to one in every 1235. The chief cause of blindness is undoubtedly to be found in ophthalmia neonatorum, and it is probably as a result of the better and earlier treatment of this condition that much of the improvement has taken place. A corresponding improvement is likewise to be observed at other periods of life, and this is to be ascribed to the general advances made in ophthalmic diagnosis and treatment.

Increase of Suicide in France.—A study of the number of suicides in France reveals a most deplorable state of affairs. According to the *Journal Officiel*, during the year 1890 this number reached the formidable figure of 8410 (6576 males and 1834 females). These figures indicate a progressive increase in the number of suicides. In the quinquennial period from 1861 to 1865 the average annual number of suicides was 4661 (12 per 100,000 of the population); while during the period from 1886 to 1890 the average annual number was 8226 (or 21 per 100,000). The proportion of suicides among children under the age of sixteen years has also increased. While in the period from 1871 to 1875 the number was 31, it was in 1886, 62; in 1887, 68; in 1888, 65; in 1889, 77; and in 1890, 80.

SELECTIONS.

SUPERFICIALITY AND SELFISHNESS IN THERAPEUTICS.

"IN the work of the younger members of our profession I see, or at least I think that I see, greater care, patience, and accuracy in observation, a more rigorous fidelity in the record of therapeutical experiments, wiser caution in speculation, graver deliberation in judgment, a growing frankness in the confession of oversights and errors, increasing severity in the siftings and testings of their own conclusions, a readier effacement of the personality in the work, less unseemly eagerness for mere priority of publication, a deepened sense of the responsibilities of premature speech and writing, a rapidly abating bitterness in the conflicts of opposing views, a more robust and manlier spirit of scientific life, and less reluctance in making admission that there is no unconditional truth in the results of our inquiries—no finality in our finished work, no creed in medicine. But the Society has done more than train good workers: it has repressed bad workers. For one competent and conscientious worker there are ten who are incompetent and unconscientious, and who in divers ways hinder our progress and spoil our present possessions. Intolerant of the patient and painful toil of the true worker, acute in power of superficial observation, gifted with a certain showy versatility, quick at catching hold of new ideas, ingenious in guessing, crude in experiment, loose in therapeutic trials, hasty in speculation, strong in dogmatic assertions, accomplished in the transfiguration and use of other men's work, finding what they want wherever they seek it, unhindered by difficulties, facile in speech, ready in writing, thirsty for notice—such men, now, alas! not uncommon in medicine, beget papers so quickly that they can have no necessary relation to time, observation, or thought, and flood our literature with their unworthy if not unveracious lucubrations. The favorite hunting-ground for such men is therapeutics, and their favorite sport is the catching of remedies, the putting of them to new uses, and the setting forth of their successful results. These men discern no difficulties and have no failures; they can illustrate their successes by scores of cases, and explain them by the

most ingenious theories. There is scarcely any limit to the extent and variety of their achievements, and as they flaunt along in the fulness of self-satisfaction they look down with pitying condescension upon those in the straight and narrow way who conscientiously toil with small success in seeking after truth, but who, nevertheless, missing the praise of men, find strength and solace in their favored search."—SIR ANDREW CLARK, in the *Boston Medical and Surgical Journal*, November 16, 1893.

THE DUTY OF THE PUBLIC TO MEDICINE.

IT is interesting to compare the aid extended by the public to theologic and technical education with that granted, for the same purpose, to medicine. According to Dr. Gould, the editor of the Philadelphia MEDICAL NEWS, there is, in the United States, a sum of between seventeen and eighteen millions of dollars invested in theologic education, while there is less than half a million invested in medical education. In Ontario, according to the estimates I have in hand, the figures are, respectively, $2,100,000 and $85,000. The amount invested in technical education in the United States it is difficult to estimate, but it is undoubtedly a vast sum. In this province the amount given to aid agricultural and mechanical instruction and civil engineering reaches the neighborhood of $300,000, and this from the State. It may be urged that whatever is given to hospitals should be considered under the head of medical education; but if it could be shown that they always serve that purpose, the contention would be, in some respects, a valid one. But who will contend that this very indirect aid, if it is that, is the equivalent of that granted to instruction in mining, mechanical and civil engineering, and to agricultural education? When millions are given voluntarily by the people to the support of instruction in the various denominational theologies, the State ought surely to presume to give a fraction of such a sum to aid that which is, in the language of the Marquis of Salisbury, "the most sober, the most absolute, the most positive of all the sciences."—PROFESSOR A. B. MACALLUM, Inaugural Lecture, University Medical Faculty, Toronto, October 3, 1893.

SOCIETY PROCEEDINGS.

THE NEW YORK NEUROLOGICAL SOCIETY.

Stated meeting, held at the New York Academy of Medicine, Tuesday evening, December 5, 1893.

DR. M. ALLEN STARR, PRESIDENT, IN THE CHAIR.

DR. L. STIEGLITZ presented a young man, twenty-four years old, who three years ago developed a swelling in the right sub-maxillary region. This disappeared in about three weeks, and was replaced by atrophic tissue, a scleroderma. About six months ago the patient began to suffer from spasmodic contractions of the right masseter and platysma muscles, which still continue. It was not believed that the scleroderma and the spasmodic muscular contractions were due to a common cause, although it was conceded that such an association was possible. Dr. Stieglitz was rather inclined to think that the contractions were due to reflex irritation.

DR. FREDERICK PETERSON presented a specimen of "Glio-sarcoma of the Basal Ganglia." The case was that of a man, fifty years old, who had been in excellent health, with the exception of occasional attacks of vertigo and slight headache, until June 8, 1893, when he fell to the floor in his office. He had a general convulsion, and was unconscious for ten hours. In two weeks he was well enough to return to his office from his home in New Jersey, and to continue at work for five days, when headache and malaise kept him at home. Four weeks after his first convulsion he had five or six more of short duration, and rather left-sided in character. At this time he presented the following symptoms: Left hemiparesis and hemianesthesia; left hemianopsia; a tendency to somnolence; pupils equal and small; occasional delirium; great frontal headache; pulse from 52 to 60 per minute; respirations slow; slight optic neuritis. The diagnosis of sarcoma or glioma situated deep in the brain, so as to affect the posterior limb of the right internal capsule, was made. An operation was out of the question. The man was unconscious during the last three days of life. At the autopsy, made just five months after the first apparent onset of symptoms, a glio-sarcoma was found, about two inches in diameter, occupying the region of the basal ganglia, especially posteriorly, and projecting upward into the right lateral ventricle, and downward somewhat into the right crus. It was not strictly circumscribed, and there was some infiltration into the adjacent white matter of the brain, with here and there some areas of softened brain-tissue. A secondary tumor, the size of an almond, was found attached to the dura mater on the right side, compressing the cortex in the region of the angular gyrus.

DR. PETERSON also presented the fresh brain from "A Case of Infantile Cerebral Spastic Diplegia." The patient was a female infant, twenty months old, with congenital diplegia; that is, spastic paralysis of all four extremities. The child was subject to convulsions, and had enormously exaggerated knee-jerks and ankle-clonus. Its head was exceedingly small. At the autopsy the skull bones were found to be considerably thickened, and all the sutures and fontanels were closed and united. The dura was very thick. There was no increased amount of sub-dural fluid. Over each hemisphere a large group of convolutions, including especially the motor area, were found wanting. The vacuum caused by this atrophy was filled partly by sub-dural fluid and partly by the bulging of each ventricle; there was no internal hydrocephalus. There was no communication between the ventricles and the exterior of the hemispheres. A microscopic examination of the spinal cord showed degeneration and atrophy in the lateral columns.

DR. PETERSON also presented a specimen of "Chronic Hydrocephalus without a Cerebrum." The case was one of a female infant, eighteen months old. Little could be learned of its early history. It had a large head, with widely-gaping fontanels. The child was blind, and had nystagmus. There was rigidity of all four extremities, occasional convulsions and, toward the last, opisthotonus. The child often cried out at night. Speaking to or moving it caused it to cry out. The pulse was rapid and feeble. The urine contained a trace of albumin. There was no trouble with the bladder or rectal sphinc-

ters. The child could not nurse, and was fed with a dropper. It died suddenly in a convulsion. The temperature never rose above 98° F. while it was under observation. Toward the last the infant vomited occasionally after feeding. At the autopsy, sixty-four ounces of reddish serum were first removed by tapping at the anterior fontanel. The skull was very thin, as was also the dura. The falx cerebri had disappeared. At the base of the brain the basal ganglia stood out prominently, the floor of the lateral ventricles being exposed. The cerebellum appeared to be of normal size. There was a mere vestige of each hemisphere. There was degeneration and atrophy of the lateral columns of the cord.

DR. ALFRED WIENER reported "A Case of Subacute Unilateral Bulbar Palsy, with Autopsy." The patient was a young man, seventeen years old. The family history was negative with respect to any hereditary nervous trouble. The patient had always been in good health up to two years ago, when he was seized with an attack of perityphlitis, from which he recovered after five weeks of illness. More than two years ago the glands on both sides of the neck in the region of the sterno-cleido-mastoid muscles began to enlarge. In the summer of the following year, 1892, an abscess formed in one of these glands and had to be evacuated. In August, 1892, the glands on the right side, together with a large portion of the sterno-cleido-mastoid muscle, were excised. Those on the left side were removed in the following month, and were found to be tuberculous. The patient rapidly recovered, and nothing unusual was noticed until November, 1892, when it was discovered that his tongue deviated to the right side, and shortly after this he experienced some difficulty in swallowing. He soon became hoarse and coughed with difficulty, and within a space of ten days complete unilateral palsy of the right side of the tongue, soft palate, pharynx, and right recurrent laryngeal nerve developed. There was no disturbance of the respiratory or cardiac organs, or other condition present that should have called attention to an affection of any other cranial or spinal nerves than the ninth, tenth, eleventh, and twelfth. The symptoms remained stationary for a time; then the patient began to grow much weaker, and suddenly, on March 26, 1893, he had an attack of respiratory failure. From this he partially recovered, and then continued in a condition of slight respiratory difficulty. He could hardly speak above a whisper. He had excessive salivation. On April 11th he could barely protrude his tongue beyond the edge of his teeth. His lips remained normal, and could be brought into perfect apposition. The palate and pharynx on the left side remained normal. On April 20th the man had another attack of respiratory failure, which proved fatal.

At the autopsy, made six hours after death, the motor cortex, internal capsule, crura cerebri, and pons were found normal. The nucleus of the twelfth nerve on the right side was much diseased, while that on the left side was diseased to but a slight degree. The nuclei of the ninth, tenth, and eleventh nerves were slightly affected, those on the right side a little more so than those on the left. The respiratory bundle of the right side appeared to be completely degenerated, while on the left, in the region of the hypoglossal nucleus, the lower and anterior portions were diseased. In the region of the ninth nerve a few fibers were affected. The intra-medullary portions of the ninth, tenth, eleventh, and twelfth nerves were less prominent on the right side than on the left. Otherwise everything appeared to be perfectly normal up to the exit of the first cervical nerve from the spinal cord. As regards the nature of the lesion, no tubercle was found, as had been expected, nor were tubercle-bacilli detected on microscopic examination. There was simply an atrophy of the ganglion-cells and fibers which were motor in function.

From a careful consideration of the clinical and pathologic aspects of the case the following conclusions were reached: 1. That the region of the hypoglossal nucleus gives origin to nerve-fibers that supply the tongue, palate, pharynx, and larynx on one side of the body. 2. That the column of nerve-fibers known as the respiratory bundle, consists of fibers from the glosso-pharyngeal, vagus, and vago-accessorium nerves, and that the lower and anterior portion of this column, probably serves as the locality for the vagus and vago-accessorium fibers. 3. That the glosso-pharyngeal nerve seems to control the reflexes of nausea and gagging in the soft palate and pharynx, and also to send some motor filaments to the pharyngeal muscles. These latter filaments take their origin in the hypoglossal nucleus, and ascend in the respiratory column to the nucleus proper, and then make their exit with the glosso-pharyngeal nerve. 4. That the muscles of the soft palate are not innervated by fibers from the seventh nerve.

DR. ROBERT SAFFORD NEWTON read a paper entitled "The Pons-Medulla Flocculus Triangle as a Tumor Site, with Pathologic Findings." He reported the case of a woman, twenty-eight years old, who entered St. Mary's Hospital, July 10, 1893, complaining of constant headache for a fortnight, with morning vomiting and sickness for seven days. There was no history of trauma, and no specific history; the family history was negative. Two days after admission the woman was examined, and apart from a silly manner and a slight drawling in her speech she presented no symptoms. On July 20th the patient became weak and fell to the floor. She muttered to herself during the night and moaned about her head. The pain appeared to be diffuse. She was dull and stupid. Her speech was prolonged and tedious. At this time there was no observable defect of the cranial nerves. The pulse was 45 per minute. The woman had a shuffling walk, with some tendency to go to the right. The superficial reflexes were present, the knee jerk was exaggerated on the right side. On July 22d the patient became quite deaf. The headache was very violent, keeping her awake. On July 24th the patient was very feeble. Deafness was marked, especially in the left ear; there was, however, no tenderness or discharge. The patient stated that she could not see well, but the opthalmoscope showed no marked lesion. Upon standing up, the patient was projected to the right very forcibly. The movement at each trial was accompanied by a look of fear, pallor of the face, dilatation of the pupils and bathing of the surface in cold perspiration.

From this time on the patient failed rapidly; she grew petulant and childish; her appetite remained fairly good; vision became worse; nystagmus was present for one day only; the external rectus was also temporarily

affected. For a short time there was a transient facial tic. The sense of smell was present to the last. Optic neuritis first appeared in the right eye, then in the left, and rapidly progressed to total blindness. The patient also became totally deaf. Her sense of taste was not appreciably affected, although she occasionally complained of a hot, scalding feeling at the back of the tongue and palate. Her pulse was slow from the beginning; toward the last it dropped to as low as ten, twelve, and fourteen beats per minute, and three days before her death it dropped to six beats per minute. There was no anesthesia or implication of the pain-sense, temperature-sense, tactile sense, or muscular sense. She never had any convulsive seizures or paralytic attacks. The weakness steadily progressed; there was loss of control of the sphincters; the respirations became slow and gradually ceased. Just before death the woman was still able to distinguish between whiskey and milk.

The autopsy was made ten hours after death. Upon removing the brain an enormous tumor, with a central projection, was found on the left side. The swelling was somewhat triangular; its apex was under the thalamus and geniculate body, its base crowding the cerebellum off from the medulla, and its side line not quite reaching the middle of the pons. In the central pons-region was a projecting mass, shaped like a thumb. The bulk of the growth was a cyst. The left half of the pons was much softened and the medulla and cerebellum were flattened. The olfactory nerve was intact. The optic nerve was swollen on the left side. The third and fourth nerves were intact. The fifth and sixth also seemed to have remained unchanged. The seventh nerve was on one side of the growth, the eighth on the other. The nuclei of the ninth, tenth, and eleventh nerves were pushed aside by the change in position of the floor of the medulla. The nucleus of the twelfth nerve was involved in the growth. The cyst began at the margin of the fourth ventricle, by a blocking of the channel of communication between the lateral cisternæ of the ventricle and the cavity of the arachnoid.

Dr. Newton referred to the natural spaces or reservoirs of the sub-arachnoid fluid that exist in this portion of the brain, and how easily a cystic growth may be developed there; and also to what an enormous size it may attain and what numerous tissues and parts may be invaded, without necessarily giving rise to any localizing symptoms.

DR. CHARLES L. DANA read a paper entitled "Syringomyelia; Central Glioma of the Spinal Cord, with Spontaneous Central Hemorrhage." He narrated the history of a man who had a central gliomatous tumor in the lower part of the dorsal region of the spinal cord. This tumor progressed slowly for two or three years, causing during that time the symptoms of a transverse myelitis chiefly, although the presence of a spinal tumor was suspected. Among other symptoms there was anesthesia of the right leg, extending up to the twelfth dorsal spine, and involving tactile, thermic, and painful sensations. The left leg was also anesthetic, but to a slighter degree. Just before the man's death a large hemorrhage occurred, which was confined to the center of the spinal cord and which caused exquisite pain, the man, in fact, dying from exhaustion. Upon post-mortem examination a large central hemorrhage, destroying nearly every particle of the spinal cord at the level of the seventh dorsal segment, was found. This hemorrhage extended upward and downward for a distance of about three inches. Around the hemorrhage and above it were evidences of a gliomatous infiltration involving nearly the whole of the transverse area of the cord at that level. Very striking secondary degenerations, ascending and descending, were found. The case was one of glioma of the spinal cord, without the formation of a cavity. Although clinically, and in one sense pathologically, it would be a case of syringomyelia, yet that name cannot strictly be applied to it.

In commenting on this case, Dr. Dana referred to the question of the existence or the non-existence of a pain-tract, and the advisability of searching for it. The psychologists seem to have come to the conclusion that pain is not a sensation, but a form of feeling; that it is not to be classed with the sensations of touch or temperature or heat; that it does not have peripheral end-organs; and that there are no nerves in existence irritation of which alone gives rise to pain; that there is no such thing as a pain-tract; that the attempt to locate such a tract is like the pursuit of a will-o'-wisp. Dr. Dana said that after a very careful study of this question he has been converted to the psychologists' view. If it is claimed that there is a special tract for pain, it can just as well be claimed that there is one for hunger and various other sensations. If there is a special tract for any of the common subjective sensations, there must be special tracts for all.

DR. B. SACHS said that formerly he had held to the view that pain was nothing more than an intensification of the ordinary tactile sense, and in the majority of cases encountered such an explanation would hold good, and under such conditions special pain-tracts should not be looked for. The clinical facts that have been brought out with regard to syringomyelia, however, do not support such a view. Tactile and thermic sense may remain normal, when the pain-sense is entirely lost. The psychologists' view of this question is one that is rather difficult to reconcile with the clinical facts observed in syringomyelia. On the other hand, this disease is very destructive and irregular in course, and for this reason it is rather an unsafe guide in the determination of physiologic functions.

DR. C. A. HERTER said that several years ago he hemisected the spinal cord of a monkey in the mid-dorsal region, and was unable to find in that case any evidence of a loss of sensibility to pain, either on the same side as the lesion, or on the opposite side. He also performed this experiment on an opossum, with a like result. Mott, in his experiments, cut the antero-lateral ascending tract and was unable to find any evidence of loss of sensibility to pain. The results of experiments on animals, of course, cannot be applied directly to man.

DR. LANDON CARTER GRAY said that in the present state of knowledge as regards the exact functions of the various columns of the cord—the columns of Burdach and of Goll, and the so-called column of Gowers and the uncertainty that exists as to the exact demarcation of the latter—no definite conclusions can be arrived at as to the location of the pain-tracts. So far as clinical evidence

goes, there certainly is such a thing as a pain-sense. In hysteria the tactile sense may be preserved, while the pain-sense is entirely lost.

DR. STARR said that the existence of pain-sensations and of a centripetal pain-tract must be admitted. That tract must necessarily pass through the posterior nerve-roots, because painful sensations of a hallucinatory character occur in locomotor ataxia. It must extend for a distance in the central gray matter of the cord. There are now on record over seventy cases of syringomyelia with autopsies. In these cases there has been a decided loss of pain in a certain limb. When the affected limb has been an arm, then the cavity in the cord was in the cervical region, and the pain-sense was preserved on the trunk and in the legs. Therefore these sensations, though they pass for a short distance in the central gray matter of the cord, subsequently pass into the white columns. The central gray matter contains numerous cells, each of which sends its fibers into the antero-lateral columns, and these pass upward. While it is by no means positive that the antero-lateral columns transmit sensations of pain, all of the facts seem to point to the correctness of this view. The column of Lissauer can have nothing to do with the transmission of pain-sensations. It consists only of short fibers, does not increase in size from below upward, and cannot transmit impulses upward for any great distance. The sense of hunger is by no means analogous to the sense of pain. A distinction must be made between a common sensation and a special sensation. In conclusion, Dr. Starr referred to a case reported by Edinger, with autopsy, in which the lesion was found in the parietal region on one side, and in which the symptoms were chiefly those of intense radiating pain on the opposite side of the body.

DR. DANA added that his views regarding the non-existence of a pain-tract were arrived at only after a long and thorough study of the subject. The pain-sense and the touch-sense and the heat-sense, and other forms of sensibility must not be confounded. Pain and touch are entirely different. Pain is a subjective or common sensation. Touch is objective. Pain is much more closely allied to hunger than it is to touch. Pain is not a special sensation, but a modification of it.

CORRESPONDENCE.

EFFECT OF METHOD OF CASTRATION ON ANIMALS.

To the Editor of THE MEDICAL NEWS,

SIR: Dr. Goodell's interesting article on "The Effect of Castration on Woman" (MEDICAL NEWS, December 9, 1893) recalls a theory familiar to some horsemen, who claim that in castrating a horse, a short "cord" destroys the life and spirit of the animal. A long one—*i. e.*, one cut as close as possible to the testicle—is more apt to retain these desirable attributes. In view of Dr. Goodell's experience, it is possible that the idea may have some foundation in fact; the retention of the epididymis or perhaps a small portion of the testicle, may be responsible for the great difference in the bearing and action of some of our roadsters.

Respectfully yours,

GEO. H. RHOADS.

TOBYHANNA, MONROE CO., PA.

NEWS ITEMS.

The Late Dr. William F. Hutchinson.—At a meeting of the Executive Council of the American Electro-Therapeutic Association the following resolutions on the death of Dr. William F. Hutchinson, of Providence, R. I., were unanimously adopted:

WHEREAS, It becomes our painful duty to announce the death of Dr. William F. Hutchinson, one of the Foundation Fellows of the American Electro-Therapeutic Association as well as the First-Vice President of the same; and,

Whereas, In his death we lose a warm and faithful friend, a valued associate, and an accomplished member of the profession; therefore be it

Resolved, That this Association desires to place on record its appreciation of his genial spirit, his active co-operation in the work of the Association and of his deep interest in the scientific questions relative to his chosen profession.

Resolved, That we express our sincere regret and heartfelt sorrow at his death.

Resolved, That we tender to his sorrowing family an expression of our profound sympathy in their great loss.

Resolved, That a copy of these resolutions be sent to the bereaved family, to the medical journals, and that they be spread upon the minutes of the Association.

Correction.—By an inadvertence the word "no" appeared instead of "as" in the fourteenth line from the bottom of the second column of page 662 of THE NEWS of December 9th. The entire sentence should have read: "I subjected the blood to a careful microscopic examination, as malaria had been suggested as the cause of the anemia."

To Succeed LeFort.—Duplay has been given charge of the surgical clinic at the Hôtel-Dieu in succession to the late Prof. Le Fort; and Tillaux has succeeded to the surgical clinic at the Charité.

Professor Rudolf Kaltenbach, director of the Gynecologic Clinic at Halle, died recently.

ORIGINAL ARTICLES.

THE AIMS AND METHODS OF MEDICAL EDUCATION.[1]

BY WILLIAM C. DABNEY, M.D.,
PROFESSOR OF THE PRACTICE OF MEDICINE IN THE UNIVERSITY OF VIRGINIA.

THE ultimate aim of medical education is to fit those who enter upon the study of medicine to prevent and cure disease and to relieve suffering. For the proper accomplishment of this work, several things are necessary:

1. A sufficient development of the faculty of observation and of the reasoning faculty to enable the person to judge of cause and effect, and to draw proper conclusions from ascertained facts.

2. An ability and a willingness to work.

3. A knowledge of the work done by others directly or indirectly connected with medical matters.

4. A just appreciation of the extent and character of the work that they undertake and of the responsibility that they assume.

I propose to consider in this paper the importance of these different subjects, and shall endeavor to show by what methods the mental training and discipline of a medical student may be best accomplished.

Let me say in the beginning, however, that, in considering the requirements of those entering upon the study of medicine, I have in view the great numbers who yearly enter our lecture-rooms with very moderate intellectual capacity, scant literary training, and often the most deplorable ignorance of the gravity of the task and the responsibility on which they are entering. These are the men and women who treat the great masses of our people, and who need, therefore, the best medical education and training which can be given them.

I recognize the fact—so encouraging to all who are interested in higher medical education—that among those entering upon the study of medicine, there is from year to year a larger and larger number whose minds have been broadened and enlightened by preliminary training and who are thoroughly alive to their own responsibility and the needs of humanity; but the medical teacher should always keep in mind the needs and requirements of the *average* medical student, and not of the favored few who by reason of natural ability or superior preliminary training will overcome all obstacles and far outstrip their less favored associates.

I have stated briefly the chief requisites of those entering upon the study and practice of medicine. The next question that presents itself is: What are the best means of attaining these requisites? I shall consider this question under the following headings:

1. The studies calculated to develop the faculty of *observation*.

2. The studies calculated to develop the *reasoning faculties*.

3. The order in which the various branches of medicine should be studied.

4. The time that should be given to laboratory work and lectures each day.

5. The value and importance of didactic lectures and of daily recitations.

6. The objects and methods of clinical instruction.

7. The importance of a high standard of graduation in medical colleges, with especial reference to the character of the work to be done by the graduate in after-life.

1. *The studies calculated to develop the faculty of observation.* No argument would seem to be necessary to show the importance of a habit of careful observation of details in the study and practice of medicine; yet it is surprising to see how many persons, well educated in other respects, are wofully deficient in this. It would take me beyond the scope of this paper to consider, except in the most cursory manner, the means by which the faculty of observation is to be developed before the study of medicine is entered upon. Yet it is a matter of the utmost importance, especially at the present time when so many institutions of learning are arranging the studies in their academic courses, with reference to the subsequent professional studies of the student.

The *academic* studies that seem to me of most importance for this purpose are geology, zoölogy, and botany, especially the last. All of these branches of study necessitate the most careful observation of details, but botany is of especial value because of its intimate connection with bacteriology.

When the study of medicine itself is entered upon, chemistry, anatomy, histology, bacteriology are the studies that necessitate careful observation, and are therefore of the utmost importance, not only on

[1] Read before the Section on Medical Pedagogics of the Pan-American Medical Congress, September 7, 1893.

account of their intrinsic value, but as a means of mental training and discipline as well. There are of course other subjects that necessitate careful observation—indeed, all branches of knowledge do—but those named seem to me the most useful for developing this faculty in the medical student.

2. *The studies calculated to develop the reasoning faculties.* The *academic* studies that are valuable for developing the reasoning faculties and that are of especial value to those who propose to enter upon the study of medicine are physics and logic. I do not mean to exclude mathematics from this list, but I have not named it specifically because, to some extent at least, it is a subject studied by all, and its value for purposes of mental discipline is universally recognized. Nor would I underrate the value of the languages—ancient and modern—not only on account of the wide field that they open up for instruction and entertainment, but because of the broadening influence that they exert upon the mental faculties. I am old-fashioned enough to believe even in the study of Greek, not only for its own sake but for its influence upon the intellectual faculties as well. Still it seems to me that no other academic studies are as useful to develop the reasoning faculties of the student who proposes to enter upon the study of medicine, as those first named—physics and logic.

The medical studies proper that are most useful for this purpose are physiology and pathology viewed in its broader aspect. I shall speak of this more in detail when I come to consider the value of didactic lectures.

3. *The order in which the various branches of medicine should be studied.* There is but little difference of opinion at the present day on this point, and it is almost universally conceded that *some* knowledge at least of chemistry, anatomy, normal histology and phyisology is absolutely necessary before the student can profitably engage in the study of the so-called *practical* branches.

A few colleges, I believe, still expect the student to begin his medical studies with the daily attendance upon lectures on anatomy, chemistry, physiology, materia medica, obstetrics, practice, surgery, and perhaps a number of special subjects, but the number of these schools is growing rapidly less, and it is almost certain that in a short time all medical schools that are worthy of the name will adopt a graded course and give the student some time for study outside of the lecture-room.

4. *The time that should be given to lectures and laboratory work each day.* Not many years ago the students in many, if not most, medical schools were expected to attend lectures from 8 or 9 A.M. till 5 or 6 P.M., with an intermission for dinner of one hour. The dissections were to be made at night. It is hard to conceive how the intellectual faculties of a student could be developed by this process. Mental confusion and physical fatigue would combine to retard rather than aid the development of these faculties. Three hours a day, at most, is all the time, it seems to me, that should be required of the student so far as listening to didactic lectures is concerned; and scarcely any more time should be given to laboratory instruction, if both didactic lectures and laboratory instruction are given on the same day.

From four to six hours more, the time depending on the physical health and mental training of the student, might be profitably spent in carefully reading in some good text-books the subjects of the lectures of the day and comparing what has been seen in the laboratory with the teachings of those who are specially skilled in laboratory work.

I do not speak here of clinical instruction; I shall allude to that briefly a little later on. I need only say just now that it seems to me far better that the undergraduate should see a *few* cases daily and study them *thoroughly*, than that he should have his mind crowded with different subjects, none of which can be properly digested.

5. *The value and importance of didactic lectures and of daily recitations.* There is at present a manifest tendency to do away in great part with the old-fashioned didactic lectures, and to substitute for them laboratory and clinical work on the one hand and the reading of judicious text-books on the other. Nor can it be denied that the change has been of immense value to medical education; but I am firmly convinced that on many branches of medicine didactic lectures, if properly given, are of great value as a means of education—that is, as a means of making men *think* and *reason* for themselves. For example, in the study of the practice of medicine, with all the excellent books on the subject, none can or does explain the connection between morbid anatomy, causes, symptoms, etc., as is done in the didactic lecture, nor can an author emphasize in a text-book the points that may be of especial moment without making the book of inordinate length. I would offer an earnest plea, then, for the retention of didactic lectures as a means of *education*—of teaching men to think—not to the exclusion of other methods, but as a valuable adjuvant thereto.

Then there is another means of instruction which I believe to be of inestimable value, but that unfortunately cannot be thoroughly applied in large medical schools—I mean daily recitations on the subject of the previous lecture. These recitations are a means of instruction to both teacher and pupil; the teacher learns from them what points he has failed to make clear, and the student is taught not only what he had failed to catch before, but

something far more important than that—the necessity for careful and thorough study and preparation. Much as I value the didactic lecture as a means of instruction, or rather of *education*, if I were compelled in my own teaching to abandon it or the daily recitations, I would unhesitatingly discard the didactic lecture, for in the course of the recitations nearly all the explanations needed could be given.

6. *The objects and methods of clinical instruction.* There are two objects to be attained by clinical instruction: the first, which is of great importance to the student, is the *method of conducting the examination* of a patient; and the second is to teach the symptoms and signs of diseased conditions.

For the attainment of these objects it is essential that the student should not only see examinations made by others, but that he should see and hear and feel for himself. It is equally important, too, that the student should understand the significance of what he does see and hear, and for this reason it seems to me far better that the undergraduate at least should see but a few cases a day, and should be required to study them *thoroughly*, both at the bedside and in the text-books.

Another point seems to me of the greatest importance in connection with clinical instruction, namely, that the student should have been thoroughly drilled in the *principles* of medicine before he begins to study cases, so that he can understand the significance of the various symptoms and signs, and their connection with the morbid changes in the body.

For example, how can a student *understand* the passive hyperemia and dropsy of advanced cardiac disease, who knows nothing of the anatomy and physiology of the heart and vessels, and how can he apply the proper treatment unless he has studied the pathology of the process and the action of drugs?

7. *The importance of a high standard of graduation in medical schools, with especial reference to the character of the work to be done by the graduate in after-life.* If I may judge from my own observations and conversations I have had with a number of physicians who are interested in medical education, the importance of a high standard of graduation on the subsequent work of the student is not appreciated as it should be. It goes without saying that a man with very scant knowledge of medicine is not a suitable person to intrust with the health and lives of his fellow-creatures, but it seems to be a common impression that the defects and deficiencies of early training will be corrected by the experience of subsequent practice. Doubtless this in a measure is true; but there is another side to the subject which I believe to be equally true and of vast importance in medical education, namely, that the graduates of a school having a high standard of graduation will have a higher aim and do better work all through life than the graduates of a school having as good or better facilities for instruction, but whose requirements for graduation are relatively low. My attention was first called to this matter in 1885, when the graduates of a number of different schools appeared before me, as a member of the Board of Medical Examiners of Virginia, to undergo their "State examination." It was a matter of profound astonishment to me and to my colleagues on the Board to see the *superficial* character of the answers given to many of the questions by men of good sense, fair general education, and graduates of schools having admirable facilities for instruction, and whose faculties would compare favorably with any in the world.

I well remember the surprise depicted on the faces of some of these young men who were rejected, and the statement made by some of them that they had "never been taught that all these details were necessary in medicine"! The superficial character of the answers sometimes received and accepted may be judged also by the questions asked. I know of an instance, for example, in which in a written examination on anatomy, lasting two or three hours, one of the six questions was, "Describe the alimentary canal and its appendages." Now, how can a young man of average capacity be expected to learn *thoroughness* when the questions given him on examination are of such a character that only the most superficial answers can be given? How can earnest, painstaking, careful, and thorough work be expected of him in after-life when his training has been such as to encourage the reverse, and that training has been received from men of acknowledged ability and experience?

In conclusion, then, I would plead most earnestly for a higher standard of graduation, not only because it necessitates more knowledge of medical matters when the student graduates, but because it gives him a keener sense of the gravity of the duties that he has assumed and of the responsibilities that rest upon him.

A PETRIFIED EYE.[1]

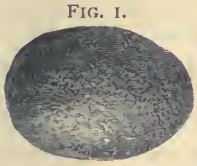
BY JAMES A. LYDSTON, M.D., PH.G.,
FORMERLY PROFESSOR OF INORGANIC AND MEDICAL CHEMISTRY AND LECTURER ON DISEASES OF THE EYE AND EAR, CHICAGO COLLEGE OF PHYSICIANS AND SURGERY; FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.

THROUGH the courtesy of Mr. George B. Davis, of Chicago, I am able to present to the Academy this evening a fossil that I believe presents a typical example of a petrified eye. The fossil was found at the mouth of Knife River, on the north shore of Lake Superior, in 1886, and was first cut by a Chicago lapidary, named Lyman. In order to de-

[1] Read before the Chicago Academy of Medicine, November 10, 1893.

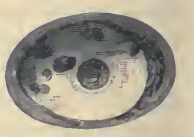
monstrate microscopically the arrangement of its parts, I had a second section made, which shows more clearly the structure of the petrified formation. The eye was first presented to me by Mr. Davis and a reporter for the *Inter-Ocean*, who handed it to me for an opinion. On superficial examination I strongly believed that it was a petrified eye, and so stated at the time, and now, after more exhaustively investigating the subject, I more fully emphasize this opinion. I have submitted it to the critical eyes of some of the most competent and expert lapidaries, and without exception the conclusion of these connoisseurs has been that nothing like it has ever fallen under their observation, and it seems that a single glance will convince even the most skeptical that, aside from the changes consequent upon petrifaction, it most closely approximates the structure of the human eye, and presents many analogous features.

FIG. 1.



Posterior segment of eyeball.

FIG. 2.

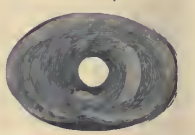


Anterior segment of eyeball.

FIG. 3.

Section showing interior structure.

FIG. 4.



Posterior view of anterior segment, showing lens, etc.

First, we have its outer layer, which conforms to the sclerotic or outer fibrous envelop of the eye, and apparently in keeping therewith we note that it is denser in its vitreous characteristics, and from the fact that its opaqueness renders its illumination impossible, it appears dark under the microscope just as a piece of chalk looks black when held in front of a flame. Lining this we find a somewhat darker pigmented layer composed of circular light and dark striæ, which answers to the choroidal or pigmentary layer of the eye, and we can microscopically outline its several layers, and can even do so macroscopically under intense illumination with reflected light. We cannot define the retina as in its normal state, except its bloodvessels; it is perfectly transparent, and is indistinguishable, and its structure so delicate that it has possibly been obliterated during the petrifactive changes. Furthermore, it is normally so closely approximated to the choroid that fusion would naturally ensue during the process of contraction and shrinkage consequent upon solidification. The vitreous humor or hyaloid body is found in a more or less crystallized form, with here and there darker pigmentary deposits, and prior to the final stages of petrifaction it is probable that the aqueous humor diffused itself throughout the vitreous, thus causing, in combination with the inorganic elements from filtration, a more or less definite crystalloid structure. In regard to the lens, it appears to have been pushed forward into the anterior chamber, and pressed against the iris, and seems to occlude the pupillary opening; in other words, we have here a pretty illustration of occlusio pupillæ. The iris is shown in a somewhat typical manner, and displays itself in a mottled or tesselated form, which is quite noticeable in some irides. Its outlines are distinctly perceptible to the naked eye, and are still more conspicuous when inspected by means of transmitted light and a magnifying lens. We then see at the outer quadrant posteriorly a vacuole or air-chamber, which evidently answers to the junction of the anterior and posterior chambers of the eye, as in cases of displacement of the lens the depth of the anterior chamber is greatly increased. Distinct traces of hematin or oxid of iron are to be seen diffused throughout the anterior portion of the eye, and at the latero-median junction of the iris and sclerotic is found a red discoloration, which, though probably due to a deposition of the oxids of iron and manganese, bears a marked semblance to a hyphemia, or effusion of blood into the anterior chamber.

I have searched the literature in the hope that I might find a similar case recorded, but my efforts have been futile. This, however, does not militate against the soundness of the conclusions reached. It may be argued that such a thing is preposterous in the extreme, but when we recall the fact that in certain pathologic conditions of the human eye we find calcareous deposits, ossification, and other changes, as, for example, in atrophied eyeballs following panophthalmitis, iridocyclitis, and other destructive inflammatory conditions, and we often meet in enucleation with hardened eyeballs closely resembling stone in their general characteristics—so hard, indeed, that it is almost impossible to make sections of them. I would also cite the changes supervening upon amyloid degeneration of the conjunctiva, it being a noteworthy fact that ossification and calcification occur in the later stages of this affection. We also find in cases of cataracta complicata that the lens assumes a calcareous form, and approximates stone in hardness; and still further, in zonular opacity of the cornea we have calcareous depositions.

Now it seems no more difficult that an eye should petrify under the requisite conditions than that other parts of the human body which are just as prone to petrifactive changes should be thus

metamorphosed, and we are aware that in rare instances the flesh, skin, and hair of an animal have been preserved for thousands of years, as in the case of the mammoths entombed within the frozen mud-cliffs of Siberia. In these instances the animal matter has been more or less completely mineralized or petrified.

The first question that naturally presents itself is: How are the remains of animals and plants preserved? The essential conditions are found only in cases in which the organic remains are protected from air and superficial decay—*e. g.*, over the bottom of lake deposits of silt, peat, marl, etc. Stems, branches, and leaves of plants, fruits, or seeds, may be carried into these places, as well as the bodies of land animals, insects, and birds; wild animals venturing on the more treacherous watery parts of a peat-bog are sometimes engulfed. The antiseptic qualities of the peat preserve such remains from decay until the more or less complete metamorphosis characteristic of petrifaction ensues. Hence from European peat-masses many remains of deer and oxen have been exhumed.

The history of the fossil presented to you is of such a nature as to lend all of the requisite conditions for petrifaction, and its characteristics wholly support such an assumption. I regard the fossil as a metamorphosed eye that has suffered a re-arrangement of its constituents, but with sufficient traces remaining to indicate its previous form and structure. The mere presence of water by reason of its universal solvent action necessitates solution of some of the more soluble portions of the eye, and as condensation ensues they may be re-deposited in a new form. This is a possible explanation of the absence of some of the otherwise normal constituents of the eyeball. Most animal formations are derived from the lower grades of the animal kingdom, such as the mollusca, the actinozoa, and the foraminifera; and the explanation of the greater frequency of petrifaction of marine formations lies in the fact of their submarine habitat, their possession of resisting shells; and the mere fact of their food-supply, consisting as it does largely of crustacea and fish, is in itself a factor conducing to a deposition of lime-salts in their several structures, which would favor petrifaction. On the other hand, specimens from the land very seldom find lodgment in subterranean graves, unless they be twigs, leaves, etc., which are doubtless blown or carried by the winds, and, finding a watery grave, that predisposes to petrifactive changes, are accordingly metamorphosed and crystallized. Thus Kirwan says: "North of Quito there is a river that petrifies any kind of wood or leaves. The coral rock, though formed by continuous depositions of polyps, loses by degrees any distinct traces of organic structure, and acquires an internal crystalline structure by water-filtration through its mass, causing a deposition of lime carbonate, etc."

The eye may be that of a predatory animal, whose remains might readily find lodgment in a subterranean cavern, and thence be carried to a watery bed. Thus the British carboniferous rocks have yielded thirteen genera of labyrinthodonts (anthracosaurus, loxomma, ophiderpeton, pholiderpeton, pteroplax, urocordylus, etc.). These were probably fluviatile animals of predaceous habits, subsisting on fish, crustacea, and other organisms of the fresh or salt waters of the coal lagoons, the largest types measuring from seven to eight feet in length.

In conclusion, I will add to the foregoing remarks that the reasons for styling the fossil a petrified eye may be expressed in the following:

1. Its history.
2. Its shape.
3. Its structure (showing as it does such a close analogy to the human eye).
4. Its appearance macroscopically and microscopically.
5. If it is not an eye, what is it?

I submit the question to your scientific minds for consideration.

53 McVICKER'S THEATER BUILDING.

THE RÔLE OF LACTIC ACID IN GASTRIC DIGESTION.[1]

BY ALLEN A. JONES, M.D.,
CLINICAL INSTRUCTOR IN MEDICINE AND INSTRUCTOR IN PRACTICE, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

LACTIC acid is present in the stomach under normal conditions from thirty to forty minutes after a test-meal composed of a roll and water or of chopped lean beef, dry bread, and water. At the expiration of that time lactic acid should entirely disappear from the stomach-contents and free hydrochloric acid alone should prevail. During the first thirty or forty minutes after meals the digestion of starches and albuminoids progresses quite rapidly, as may be proved by finding the middle-products and end-products of gastric digestion present, so that the presence of free lactic acid does not prohibit digestion.

As soon as food enters the healthy stomach the secretion of hydrochloric acid is excited and it increases in amount until the production of lactic acid is checked. The exact origin of lactic acid in the healthy stomach is still a matter of debate. It may arise wholly from fermentation, or from the combination of some food-product with a secretion from the gastric glandules, or from the gastric

[1] Read before the Buffalo Academy of Medicine, November 14, 1893.

mucosa as a distinct secretion, although electric stimulation of the gastric glandules excites the secretion of hydrochloric acid and not of lactic acid. I think it arises largely from fermentation of the food, as its amount is usually proportionate to the amount of starchy, saccharine, and milk foods taken.

I have, however, many times found lactic acid present in the stomach-contents two, three, or more hours after the ingestion of lean meat alone, in some cases the patient having been on a meat-diet for several days; under such circumstances I have followed the usual custom of calling it sarcolactic acid.

If after a test-meal consisting of albuminoids and starches, lactic acid is found in the stomach-contents at the expiration of one hour or longer, it may be called abnormal. I have found during the past few years that lactic acid very frequently exists in large quantities in the stomach during the late hours of digestion, and that it is persistently present in some cases, without regard to the character of the food or to the period of digestion. Indeed, I have cases on record in which lactic acid was present in excess during the whole period of gastric digestion, and as many of these cases had diminished peristalsis, their stomachs were free from lactic acid only a few hours during the twenty-four.

When hydrochloric acid exists in the stomach in proportions over from 0.2 to 0.4 of 1 per cent., we dignify the defect in gastric chemistry by the name hyperchlorhydria, or an excess of hydrochloric acid. But such a state is not more definite, nor is it more susceptible of detection, study, and treatment, than lactic-acid excess; nor are the etiologic factors more definite in the former than in the latter. I therefore think it reasonable to recognize the condition as an entity, and so consider it.

Lactic acid in abnormal quantity is found in the stomach in many cases having a deficiency of hydrochloric acid. It is difficult to determine in these cases whether the lactic-acid excess is the cause or the consequence of the diminished amount of hydrochloric acid. If, however, upon the withdrawal of all starches and milk-foods from the diet free hydrochloric acid appears in normal amount, it is probable that the excess of lactic acid depends upon improper diet rather than upon primarily diminished secretion of hydrochloric acid. If, on the other hand, free hydrochloric acid does not appear in the gastric contents after stopping starchy and milk foods, it is probable that its secretion is really deficient and therefore lactic-acid fermentation is rendered easy.

A very common cause of lactic-acid excess is found in impaired motility of the stomach, which allows too long retention of its contents, with the over-production of lactic acid by fermentation. With insufficient peristalsis poor absorption often exists, and it is in such conditions that I have frequently been able to demonstrate an excessive total acidity of the gastric contents, owing to the presence of both hydrochloric and lactic acids. Thus in gastrectasia of the Germain-Sée type, the stomach contains not only an excess of hydrochloric acid, but usually also an excess of lactic acid, and the gastric mucous membrane is incessantly subjected to the action of highly irritating contents. When dilatation is associated with stenosis of the pylorus from a malignant growth, hydrochloric acid is present in small amounts only, or is entirely absent. In some of these cases I have found very large quantities of lactic acid, usually with other organic acids, making a total acidity far in excess, while other cases were characterized by a very small amount of lactic acid and a faint total acidity.

Chronic catarrhal gastritis, resulting from whatever cause or causes, renders lactic-acid excess liable. In cases of atrophy of the gastric glandules and a consequent absence of gastric juice we would expect to find lactic-acid fermentation at its height, but such is not the case. In four cases of this nature that I reported[1] the gastric contents were almost invariably neutral in reaction unless acid foods had been taken. In other cases, as yet unreported, lactic acid was found in moderate amounts, and the total acidity was always subnormal.

Of all the factors entering into the production of lactic-acid excess, none is so potent as improper diet. The ingestion of mixed starchy milk puddings at the end of a hearty meal results in the formation of so much lactic acid that its fermentation is perpetuated throughout the entire period of digestion, to the hindrance of proper change of the albuminoids and starches. The common custom of eating pastries, sweetmeats, ice-cream, cakes, and cheese after having eaten thick soups, meats, fish with various sauces, entreés made with cream, salads and salad dressings, is to blame for many digestive disorders.

Drinking milk at meals and between meals, or living on milk alone, not uncommonly lights up the lactic-acid habit in the stomach, and cases of this habit illustrate the baneful effects of persistence in a diet that is not regulated by the condition of the gastric chemistry.

I cannot emphasize sufficiently the importance of lowered general health in the establishment of a gastric state in which the over-production of lactic acid is made easy. When the blood is reduced and the nervous and muscular systems are very much enfeebled, the functions of the stomach are imper-

[1] New York Medical Journal, May 27. 1893.

fectly performed, because the organ is supplied by impoverished blood, its innervation is disturbed, and its musculature is weak. Therefore under the many indiscretions in diet that are inevitable as the average individual lives and as the average cooking prevails, with all its death-dealing virulence, gastric chemistry is necessarily disturbed.

ANTIQUITY OF SYPHILIS AND OF THE USE OF MERCURY IN SYPHILIS IN JAPAN AND CHINA.

BY ALBERT S. ASHMEAD, M.D.,
OF NEW YORK.

THERE is a Japanese book published in Kioto in 1801, by T. Wake, a descendant of the famous Wake Ihinari, who brought the Chinese medicine into Japan. The title—*Bai-so yaku-gen*—signifies brief account of syphilis. Tamba, who wrote its preface, is also a descendant of a very famous Japanese-Chinese physician, Tamba Yorimochi,[1] who introduced the acupuncture treatment into Japan. These two distinguished physicians are often mentioned together—Wake and Tamba—as representing the whole of what Japan owes to China in the way of medicine.

The original Tamba, who lived in the seventh century, wrote the oldest medical book known in Japan, *the Ishinho* or *po*—Japanese encyclopedia of Chinese medicine, in the period 689–807 A.D. It comprised thirty volumes, but is now lost. All that is known of it is taught by word of mouth by the descendants of the author, whose name goes from father to son—that is, to adopted son. One of these Tambas is the author of the preface mentioned. The author (Wake) states that his own work is a copy of the most noted Chinese book on the subject of syphilis—*Bai-so-hiroku*—(secret manuscript on syphilis, written during the Ming dynasty, 1368–1644 A.D.), with his own experiences added to it. In the time of the Chu dynasty—that is, before Confucius—there were, says the writer, two kinds of doctors in China: one to treat skin-diseases (which the author says included syphilis), the other to treat all other diseases. He found that statement in the *Chu-Kwan*, the book of ancient Chinese officers.

The following passage is extracted from the second volume of this very interesting treatise: "Keifun[2] (calomel) is very difficult to handle, and requires in the physician great skill; an imprudence would necessitate a special cure. When this medicine has been unskilfully used a long time its bad effects are difficult to cure at all." The author possesses secret remedies, which he declines to make public, but promises to use them on his own premises. He quotes a certain Jichen, author of an *Encyclopedia of Natural History*, written over a thousand years ago: "Suigin" (literally water-silver—quicksilver), says that ancient writer, "is a negative poisonous matter. It is manufacturned by boiling and burning [some substance, which is probably cinnabar]. When sulfur is added to it, it becomes vermilion. It cures dropsy, mucous-membranous troubles, wet-heat diseases (that is, catarrhs and colds), and especially poisonous syphilis (by which are meant the secondary forms). After its use saliva flows from the gums; in this way the poison is driven out. But if the remedy is used in excessive quantity the poison is driven into muscles, nerves, and bones, which makes it incurable. As an effect of its use, the nourishing power of the blood becomes insufficient; convulsions and pains in the bones may occur; sores and diseases of the penis; also cracks of the feet and hands. Skin-diseases also are a consequence of the abuse of the remedy; these conditions are apt to become incurable."

The author (Wake) says that "in difficult cases the use of keifun is imperative. But if there is a mistake made in the application (probably when the remedy is applied to the wrong stage of the disease) the consequences are fearful. The results cannot be cured." But the use of chicken-diet is recommended, and the remedies are applied as he advises in his cure of tertiary syphilis.

I quote the following passage from the second volume of the *Daido Ruishuho*, a work of eight volumes, composed 806–809 A.D. It is a collection of prescriptions and treatments from all parts of Japan. It is a book in which the authors—a commission appointed by the government—endeavored to antagonize the Chinese methods of Wake and Tamba, and vindicate the independence of Japanese medicine. The principal object of the work was to bring into favor the use of Japanese remedies, as the treatments of Wake and Tamba's school in skin-diseases, and especially syphilis, had proved to be so successful. Of course this shows that mercury was used, otherwise success would have been out of the question.

"*The Wake Medicine or Kasa* (*syphilis*) *Medicine.* The manner of making this is inherited in the house of Wake (that is, the original Wake). As used by Wake, this medicine had been invented and was taught by *Sukunahiko*" (the Æsculapius of Japan), who went about teaching medicine throughout the country in the time before Jinmu Tenno—that is, more than 600 years B.C.

Dr. Hide Miyake, Dean of the Medical College, University of Tokio, in answer to my inquiry as to the use of mercury in the treatment of syphilis in

[1] Said to be descended from a Chinese emperor.

[2] First manufactured in Japan in 714 A.D. (Geert's Minerals and Metallurgy of Japan). Before that time it was imported from China.

Japan, writes me that "the use of this medicine in syphilis was not imported from Europe, but undoubtedly from China."

CHRONIC RETRO-BULBAR NEURITIS.[1]

BY WILLIAM CHEATHAM, A.B., M.D.,
OF LOUISVILLE, KY.

THE true pathology of chronic retro-bulbar neuritis was not well understood until the first demonstration in an autopsy by Samelsohn, in 1882. Leber, Michel, and others had referred to it before, but had never demonstrated the fact by autopsy. It has been demonstrated that "the marginal fibers of the disc end in its immediate vicinity, and in general the central fibers go to the periphery of the retina, while the peripheral fibers of the disc supply the central part of the retina; the papillo-macular fibers entering the eye as a wedge-shaped cluster on the temporal side of the disc, occupying nearly its inner and lower quadrant." As the title of the paper implies, it is generally only the fibers of the optic nerve in front of the chiasm that are involved.

The principal cause is alcohol, or tobacco, alone or combined. Some authors say that it is tobacco alone, the alcohol acting only as a depressant. Of 138 reported cases, 64 were from alcohol, 23 from tobacco, 45 from tobacco and alcohol combined, diabetes 3, lead 1, and sulphuret of carbon 2. Other causes, as cold, and especially cold blasts on the face, chloral, stramonium, and syphilis, are given by Swanzy.

The failure of vision is usually so slow that the patient does not discover it until it is well advanced. Only this week a man came to me with tobacco-alcohol amblyopia, whose vision was but half of normal. The patient complains of seeing as if he was looking through smoke or a veil. The vision of the two eyes is usually about the same, which is a point in differentiating it from disease of central origin. In the beginning there is no trouble with the field of vision; later on, however, there will be discovered a central negative scotoma for colors, especially for green and red. This scotoma is usually oval in shape, with the long axis horizontal, the retina involved being that portion extending from the temporal edge of the disc to the outer edge of the macula. Later on the perception of white will diminish in this area, and, if the disease progresses, may be entirely lost. Vision is often reduced to almost nothing in this affection, but total blindness is exceedingly rare.

It is not the periodic drunkard who is liable to suffer from this trouble, but the sipper, or steady drinker, who never gets drunk. The disease is more common in the male than in the female, in the old than in the young, for reasons easily understood. Some author has stated that it does not occur in persons under twenty years of age, yet I have a patient now only sixteen years old, in whom the condition may be ascribed to the abuse of tobacco and beer.

A peculiarity of the disease is that a person may be nearly blind from tobacco-alcohol amblyopia, who under treatment may recover vision, then return to his old habits, and exceed even the abuse formerly practised, and yet have no relapse. The ophthalmoscopic symptoms, especially in the early stage of this disease, are usually negative. The optic disc may be a little hyperemic, or present what I used to call a granular, brick-dust appearance. Later on the temporal half of the disc becomes quite pale. A point in differential diagnosis that has been made somewhere—just where, I cannot now recall—is that by the inhalation of a little amyl nitrite, vision is much improved for a while. I tried this experiment last week on a gentleman about sixty years of age, whose vision was only half of normal, the result of alcohol and tobacco abuse, especially of the latter. I told him to look at the test-card, and passed under his nose a glass stopper, with a drop or so of the amyl nitrite on it, and he immediately exclaimed with much joy that he could see as well as ever. He demonstrated the fact by reading 20/15, or more than required in a test for perfect vision. How long this lasted I do not know, as I have not seen him since. Strychnin hypodermatically in a large dose may have the same effect.

As given by Samelsohn and others, the pathologic changes in the optic nerve consist in an interstitial neuritis at its axis, commencing outside of the chiasm (preferably this portion of the nerve), and leading to proliferation of connective tissue, and to secondary atrophy of a certain bundle of nerve-fibers; the changes are analogous to those that take place in the liver and brain as the result of chronic alcoholism.

As to treatment, the first indication is, of course, to correct the cause. Promises to do so are easily gotten and as easily broken. A majority of the cases, if not too far progressed, will recover with no other treatment than the correction of the cause. Again, others will need the leech, Turkish bath, and strychnin, the latter preferably hypodermatically. I usually order strychnin nitrate, gr. iv; aqua ℥j, each drop containing gr. $\frac{1}{120}$ of the strychnin. I commence with gtt. ij, and increase one drop per day until the physiologic effect is reached, which may be anywhere from gtt. xv to gtt. xl. Potassium iodid is also indicated; I often give zinc phosfid and strychnin in pill, with good result.

[1] Abstract of essay read before the Louisville Clinical Society, November, 1893.

CLINICAL MEMORANDA.

CELIOTOMY FOR ABSCESS OF THE PANCREAS; WITH THE REPORT OF A CASE.

BY JOHN E. WALSH, M.D.,
GYNECOLOGIST TO ST. ANTHONY'S HOSPITAL, DENVER, COL.

MRS. G., aged forty-seven, of good personal history, had also no hereditary taint. For four months before admission to the hospital she was practically bed-ridden. For six months she suffered from sharp burning pains in the epigastric region and complained of tenderness on pressure. Prior to this, with the exception of an occasional mild attack of pelvic peritonitis, her general health was good.

On admission to the hospital she presented a deplorable condition. Her abdomen was distended and very sensitive to touch. There was an area of dulness, extending from the ensiform cartilage half-way to the umbilicus and reaching to the left costal arch. Examination revealed an enlarged uterus, a slight bilateral cervical laceration, and a chronic endometritis. The woman was extremely emaciated; and during the few days she was in the hospital before operation, she suffered from diarrhea, going to stool at least every half-hour. Her stomach would retain little or no nourishment, and her great pain demanded frequent doses of opium. Her pulse was small, rapid, and wiry. The temperature at no time exceeded 98°; it was always subnormal in the morning. There was no history of rigors or chills; but the woman stated that previous to the onset of the diarrhea, which began about a month before coming under observation, she had fever every evening.

Nothing of clinical importance was elicited from an examination of the urine. The stools were watery, of a yellowish-gray color, and had a very strong odor. The vomited material had a greenish tinge and smelled sour. The tongue was dry and had a thick, brown coating. The examination of the lungs and heart was negative. There was no edema of the lower limbs. The pain in the epigastrium was aggravated during the acts of vomiting or coughing; but the woman experienced relief when her stomach was empty.

An effort was made to improve her general health, by carefully prepared liquid food and the administration of alcoholic stimulants, but without result.

At the earnest request of the patient, it was decided to make an exploratory incision both for the purpose of elucidating the diagnosis and with the hope that something might be done to relieve her sufferings and improve her condition. On July 16th, with the assistance of Drs. Cuneo, Hally, and Edward Walsh, an incision was made in the abdomen, beginning at the tip of the ensiform cartilage, running obliquely downward and ending about one inch above and two inches to the left of the umbilicus.

The abdominal wall was unusually vascular. On passing the hand into the abdominal cavity, a fluctuating mass could be felt beneath the greater curvature of the stomach. The great omentum was now incised, and the stomach pushed upward and the abscess-wall freely exposed. The margins of the wound were then pressed inward by an assistant and the abscess-wall stitched to them. On account of the deep seat of the swelling, I was unable to approximate the peritoneal surface with the margins of the wound. The sutures, however, answered a very good purpose, in preventing a recession of the abscess-wall after tapping, and in supporting the gauze packing, which I resorted to for the protection of the peritoneal cavity. The abscess-cavity contained over a pint of pus, in which could be seen portions of the pancreatic gland and a curdy-like substance. At the bottom of the abscess-cavity a small portion of the body and tail of the pancreas was found attached. These attached portions were soft and easily removed by cureting with the finger. The cureting was followed by a brisk hemorrhage, which necessitated a firm packing of the cavity with iodoform-gauze. The wound was now dressed in the usual manner, the bandage being pinned as tightly as possible to keep the margins of the wound pressed inward, and to prevent any undue tension on the stitches.

At the completion of the operation, which lasted about forty minutes, the patient was very weak and had to be freely stimulated. No rise of temperature followed until the third morning, when the thermometer registered 100°. After a thorough purge it dropped to normal. On the fifth day the gauze packing was removed; by this time adhesions had formed between the abscess-wall and the margins of the wound, completely shutting off the peritoneal cavity. After a copious irrigation with a hot boric-acid solution, the cavity was dusted with iodoform, and a drainage-tube inserted surrounded by iodoform-gauze.

The most prominent symptoms before operation, such as pain, diarrhea, and vomiting, disappeared within forty-eight hours after the operation, and there was a rapid and marked change for the better. During the first four days rectal feeding was resorted to, after which the patient was able to partake of large quantities of liquid nourishment without experiencing any feeling of nausea or distress. On the eighth day the stitches were removed. The fistulous tract was now well established and the abscess-cavity had contracted to about one-fourth its former size. On the eleventh day, much against my wishes, the woman got up, dressed and left the hospital, walking to her carriage without assistance.

In reviewing the literature at my command on abscess of the pancreas, I find no case reported in which surgical interference has been successfully resorted to for the relief of this condition. Cases have been reported from time to time in which the pancreas was found to be the seat of suppuration, but in the majority of these the actual conditions were discovered on post-mortem examination. "The two principal reasons for this may be found in the facts that abscess of the pancreas is of rare occurrence, and that the recognition of the lesion when it does exist is surrounded by many difficulties." (Senn.)

The recorded symptoms of this disease are very indefinite, and would scarcely lead one to a diagnosis. The emaciation, vomiting, constipation or diarrhea, localized tenderness, etc., are symptoms frequently associated with diseases of adjacent organs.

In the case here reported even the usual symptoms of pus-formation were wanting, so far as I could learn. According to Fitz, the symptoms are essentially those of peritonitis, beginning in the epigastrium; and he mentions pain, tenderness, localized tympany, and the

gradual development of a deep-seated inflammation in the region of the pancreas, as diagnostic points.

Age, says Senn, is an important element to be considered in the diagnosis, as most of the cases of abscess of the pancreas were found in patients over forty years of age. He also states that nausea, vomiting of a clear, greenish or viscid fluid, thirst, loss of appetite, constipation, progressive emaciation, and distention of the epigastrium have been observed as prominent and somewhat constant symptoms. Taken singly or as a whole, none of these symptoms can be said to be pathognomonic; in fact, they are symptoms common to many other diseases that have their origin in the epigastric region.

We are forced, then, to the conclusion that with our present knowledge of the clinical history of abscess of the pancreas we cannot make an accurate diagnosis without resorting to exploratory incision; and in all cases of doubtful diagnosis, when several of these symptoms are associated and when the health or life of the patient seems seriously threatened, I believe we are justified in giving the patient the benefit of operative procedures.

The operation will vary according to the size of the swelling. The cases must be rare wherein the swelling is so prominent as to permit the stitching of its peritoneal surface to the peritoneal surface of the anterior abdominal wall, but when this can be done it simplifies the operation.

It is to those cases in which the distance between the anterior abscess-wall and the margins of the wound is so great as to preclude the possibility of bringing them in contact that I wish more particularly to call attention. The management of this part of the operation will tax the ingenuity of the surgeon. In my own case I found this to be the most difficult step in the operation; and while the method employed as described gave good results and is an ideal way of dealing with such cases, providing the gauze packing would in all cases afford ample protection against infection of the peritoneal cavity, nevertheless if it is ever my fortune to have to deal with a similar case I am inclined to think that I would perform the operation in the following manner: After passing several sutures through the abdominal wall and the abscess-wall for the purpose of lessening the distance between their peritoneal surfaces, the wound should be packed from the bottom with iodoform gauze, which should be allowed to remain for several days, until firm adhesions had formed between the anterior abscess-wall and the margins of the incision. The abscess could then be freely incised and drained without the slightest danger of infecting the peritoneal cavity.

CIRCULAR-SAW INJURY.

BY B. MERRILL RICKETTS, M.D.,
OF CINCINNATI, OHIO.

THE patient, a white male, twenty-one years of age, fell, on July 20th, a distance of twelve feet upon a slowly-moving circular saw eighteen inches in diameter. Although the saw was not in rapid motion, it was started by the man striking the band-lever in his falling; the saw was perhaps not revolving faster than 500 revolutions per minute. He struck the saw in a sitting position, rebounding about two or three feet, falling to one side. It was found that the left buttock was more seriously injured than the right, and that there was numbness in the left toes, indicating that the great sciatic nerve had been injured. It was also found that the entire body of the penis was divided, thus allowing the urine to escape through the wound at time of micturition. The patient was treated by Drs. Titus and Halderman, and made a good recovery, with a small perineal fistulous opening. He had good use of his limb and urinated without trouble, though there was occasional dribbling from the fistula. There was complete loss of erectile power, also of sexual desire. There was congenital phimosis.

Upon being consulted I advised that the extensive cicatricial tissue be divided and that the fistula, if possible, be obliterated. To this the man consented. It was also my opinion that the man would never have the power of erection; whether or not he would have sexual desire I was not able to determine. This presents a question that must often be fully considered. Is it best to have sexual desire without the ability to gratify it? If not, would it not be best to resort to castration?

Under the influence of chloroform, a perineal section was made, and after the operation there was an uninterrupted recovery. An illustration from a photograph, showing the wound made by the saw, is appended.

I held that it was my duty to remove the entire cicatricial tissue in the line of the corpus spongiosum, bringing the two ends of that body together. Although I did not do this at the time, I suggested that it could have been done, and with the patient's consent that I would do it. However, I am not convinced in my own mind that even the removal of the cicatricial tissue and the bringing together of the two parts of the corpus spongiosum would be of any material benefit. It is, therefore, a question in my mind as to the propriety of subjecting the man to an operation that promises so little. If there were any possibility of reëstablishing the nerve-connections, it might be well to take the chances. As it is, he will never be able to propagate his kind.

Landouzy has been made professor of clinical Medicine and Therapeutics at Paris in succession to Hayem.

MEDICAL PROGRESS.

The Morbid Anatomy of Akromegaly.—SQUANCE (*British Medical Journal*, No. 1714, p. 993) has reported a case of akromegaly in a woman, thirty-five years old, who presented intense neuralgic pains through the temples and the top of the head, and also shooting pains at the back of the neck, accompanied by general languor and inability to apply herself to any prolonged occupation. Her memory was defective and her articulation slow and deliberate. There was no complaint of impairment of vision. The hands, the feet, the malar bones, and the maxillæ were enlarged. Diabetes developed, and, later on, pulmonary tuberculosis, to which the woman ultimately succumbed. Only a partial post-mortem examination was permitted. The head was increased in size, the face elongated; the malar bones were enlarged and prominent; the superior and inferior maxillæ were considerably hypertrophied, though the lower jaw did not project in advance of the upper. The eyelids were thickened and the supra-orbital ridges enlarged. The nostrils were considerably increased in size and very broad, and the ears were greatly hypertrophied. The hair was scanty and coarse, and the skin harsh and rough in appearance. The hands and feet were symmetrically enlarged; the nails were broad and the big toes large in proportion. The shafts of the long bones were not only considerably thickened, but they were also roughened, approximating the male type. The thorax was considerably enlarged, especially in the upper part; the ribs were uniformly hypertrophied, as were also the clavicles. In the lower cervical and in the upper dorsal region there was a certain amount of prominence of the spine. On opening the skull, the frontal, parietal, and occipital bones were found to be thickened, the hypertrophy principally involving the diploë. The brain weighed forty-six ounces and its membranes were normal. The pituitary body was considerably enlarged, and the canal between it and the third ventricle was patent. The optic nerves immediately in front of the commissure were much flattened, especially the right, which was exceedingly soft and tearing easily. The thyroid gland was enlarged and weighed nearly two ounces. The thymus gland was persistent, the left lobe being hypertrophied and passing behind and to the left of the manubrium sterni. The gland measured nearly two inches in length and weighed one ounce. Its surface was lobulated, its consistence pulpy, almost diffluent, and its color a brightish-pink.

A Peculiar Occupation-Neurosis—Trombone-player's Cramp.—FRANCIS (*Lancet*, No. 3663, p. 1184) has reported the case of a trombone-player, twenty-nine years old, who presented a form of spasmodic wry-neck that had been present for eight months. At first the spasm was slight in character, and only noticed when the man was very tired, after a long evening's work. It gradually increased in frequency and severity until he was obliged to discontinue his employment. For two months the spasm had been almost continuously present, not only by day, but also by night, and interfering with sleep. Varied treatment had failed to give relief. The patient was highly nervous and excitable, and for some weeks had suffered from delusions that he was ill-used, laughed at, and followed on the streets by persons who mockingly called the attention of others to his wry-neck. There was no facial spasm or spasm of any other muscles than the right sterno-mastoid and right trapezius. These muscles were in a state of tonic spasm, which prevented the head from being held straight, its usual position being inclined to the right side. Every few minutes these muscles were affected by clonic spasm, by which the head was drawn strongly toward the right shoulder. There was severe cramp-like pain in the muscles during the clonic spasm, which occurred throughout the whole day and night, and even during sleep. They were most frequent and severe when the patient was tired or excited, and were found to occur during the slighter stages of chloroform-narcosis. There was almost complete anorexia and insomnia. Division of the spinal accessory nerve was proposed, and performed at the point where the nerve is about to enter the sterno-mastoid muscle. During the first six days after the operation the patient was comfortable, and completely free from the slightest spasm. At this time; however; a slight twitching of the sterno-mastoid was noticed for a few hours, but unattended with pain. The patient, however, became wild and irritable, and his previous delusions returned. From this maniacal outbreak he soon recovered. Thereafter slight twitching of the sterno-mastoid could be induced by having the patient look steadily at an object held above the level of the eyes. On resuming his occupation it was found that the twitching returned. In view of this evident relation the patient was advised to learn to play upon some other instrument than the trombone, and upon acting on this advice the spasm never reappeared.

Partial Symphysiotomy.—MÜLLER and VAN NOORDEN (*Berliner klinische Wochenschrift*, 1893, No. 48, p. 1163) have reported the case of a woman, thirty-seven years old, pregnant for the fifth time and presenting the appearance of a dwarf, with evidences of previous rhachitis. The first and second pregnancies had been terminated by craniotomy; the third was terminated artificially, at the end of the seventh or beginning of the eighth month; and the fourth in the thirty-second week, but in both instances the children succumbed. The distance between the iliac crests was 8.6 inches; that between the anterior superior iliac spines 9.8 inches; and the conjugate measured 2.75 inches. The woman was desirous of having a living child and, accordingly, labor was induced in the thirty-second week of the fifth pregnancy. The head, however, would not descend below the pelvic inlet, and the condition of the woman becoming alarming, symphysiotomy was decided upon and undertaken with great care. After the symphysis had been but partially divided the head began to descend, and in a short time, with the aid of the forceps, the child was delivered, the wound being meanwhile packed with iodoform-gauze. The child was asphyxiated and could not be resuscitated. After expulsion of the placenta, which followed almost immediately after the birth of the child, sutures were introduced and a wide band tied about the hips.. The latter was retained for but three days. At the end of three weeks the woman was up and about. For a few days after labor there was considerable meteorism and sensitiveness of

the uterus to pressure, with transient slight elevation of temperature. The lochia were offensive, and it was found that a vesico-vaginal fistula had been formed. This was in due time operated upon, with success.

Argyria from the External Application of Silver Nitrate.—Olshausen (*Deutsche medicinische Wochenschrift*, 1893, No. 47, p. 1206) has reported the case of a woman, forty-three years old, who came under observation on account of extensive burns of the first and second degrees. For a month dressings of bismuth were applied; then applications of a one-tenth per cent. solution of argentic nitrate were made to limited areas upon the arms and back. Shortly afterward an intense stomatitis developed, in the lesions of which streptococci were found. After the lapse of a further seven weeks, transplantation of skin was practised upon the right forearm, and as the wounds upon the back had healed, only the left arm and the right upper arm were wrapped in the solution of argentic nitrate. Some days later the stomatitis recurred and the silver applications were permanently discontinued. Upon inspection areas of bluish-black discoloration were seen upon the mucous membrane of the cheeks and upon the gums; the lower lip presented an irregular zone of similar discoloration and some of the lacunæ of the tonsils displayed bluish-black points. Similar spots were also observed on the inferior surface of the tongue, to either side of the frenum. The condition of the patient grew progressively worse; the bluish discoloration extended; ulceration of the inner aspect of the cheeks took place; diarrhea set in; convulsions occurred, and death ensued. Upon post-mortem examination, in addition to those already noted, pigmentary deposits were also found in Douglas' cul-de-sac and upon the posterior wall of the pharynx, while the colon was the seat of a chronic pigmentary ulcerative inflammation. Chemic examination of tissue from the colon and microscopic examination of a portion of the lower lip in each instance disclosed the presence of silver.

THERAPEUTIC NOTES.

Thyroid Feeding in Exophthalmic Goiter.—Owen (*British Medical Journal*, No. 1718, p. 1211) has reported the case of a laborer, forty-six years old, who came under observation on account of an attack of diarrhea, and who for twenty years had had swelling of the neck and a protrusion of the eyes, together with palpitation and breathlessness. The expression of the face was anxious, a white band of sclerotic was visible, the upper lips did not follow the globe in looking downward, and passing the hand before the face did not induce winking. There was visible throbbing in the neck, and the pulse was 126. The apex-beat of the heart was displaced to the left, but no adventitious sound could be heard. The diarrhea was controlled by opium. Then quinin, iron, digitalis, and arsenic were given for two weeks without benefit. Then a quarter of a lobe of sheep's thyroid gland, to be taken daily, minced and flavored with little salt and vinegar, was prescribed. Through a misunderstanding one-quarter of a pound was administered for two days, giving rise to dyspeptic symptoms—nausea, eructations, vertigo, and insomnia—and the face and legs swelled. The thyroids were withheld for a week, and these symptoms passed off, when the administration of the dose intended was begun. Steady improvement ensued, so that the man became able to take up laborious work that he had not undertaken in many years. The exophthalmos became scarcely perceptible, and the swelling of the thyroid diminished, while the pulse declined to 76 and the arterial throbbing disappeared.

Salts of Aluminum in the Treatment of Diseases of the Nose and Throat.—Heymann (*Monatschr. f. Ohrenheilk., etc.; Wiener med. Presse*, 1893, No. 48, p. 1894) has reported the results obtained from the employment of salts of aluminum in the treatment of diseases of the nose and throat. Aluminum salicylate, or salumin, is said to be insoluble in water and in alcohol, but soluble in alkalies. With ammonium it forms a neutral double salt, which is soluble in glycerin and in water. This preparation has been found to be an excellent astringent. It is irritating to the mucous membranes of the nares, and is thus indicated in the dry inflammations of the naso-pharynx. Either of the preparations may with advantage be employed in powder by insufflation, in cases of ozena. Applications to the pharynx of a solution in glycerin may be made by means of a brush. Aluminum tannate is also insoluble, while the tannotartrate is soluble. The latter is indicated whenever an active non-irritant astringent is desired. It may be employed by insufflation, as a gargle, by inhalation, or it may be applied in solution by means of a brush.

Quinin for Pertussis.—Baron (*Berliner klinische Wochenschrift*, 1893, No. 48, p. 1165) praises warmly the employment of quinin in the treatment of pertussis, particularly when pneumonia occurs as a complication. He prescribes thrice daily one-seventh of a grain for every month of life, and a grain and a half for every year. Six o'clock in the morning, two in the afternoon, and ten at night are preferred as the hours for administration. More than six grains three times a day have not been found necessary even for children older than four years. After decided improvement has manifested itself, the dose may be administered but twice a day; then the dose may be gradually diminished and finally but one dose given daily. To very young children the drug was given dissolved in a teaspoonful of water; to older children in the form of wafers.

For Acute Gout.—

℞.—Ext. colchici. acetic. . . . gr. x.
Pulv. ipecac. comp.
Pulv. digitalis . . āā gr. xij.—M.
Ext. colocynth. comp.
Ft. pil. no. xij.
S.—Take one twice or thrice a day.

Practitioner, No. 306.

For Morphinism Kochs (*Ther. Monatsh.*, Nov., 1893, p. 539) recommends the subcutaneous injection twice daily of atropin, gr. $\frac{1}{300}$, with which in his own practice he conjoined morphin, gr. $\frac{1}{3}$.

For Epithelioma Morau (*Journ. de Méd. de Paris*, No. 43, p. 506) recommends the topical application of a saturated solution of picric acid in water.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

FOREIGN DEPOSITS IN THE LUNGS.

As to particles of dust, and the like, being found in the lungs there is now no doubt; yet the point was formerly contested. For example, VIRCHOW wrote "that the black deposits in melanotic lungs (deposits, be it noted, distributed freely, and not imbedded in cells) were not, as some supposed, collections of carbon, but substances totally distinct from the vegetable character."[1] And again: "It might easily be seen from the fact that coal-dust colors the sputum gray or black, that it has by the same token been expectorated in the bronchial mucus."[2] TROUSSEAU,[3] another effective witness on this side, wrote: "The cause of melanosis is nothing more than 'une aberration du pigment,'" that is, of course, of the blood.

It is hardly necessary, and surely not very profitable, to go any deeper into a controversy that was fought out with the usual prolixity. Those who wish to do so should consult an account of it by an excellent author.[4] The question of chief consequence is whether or not deposits of foreign bodies have really been found in the lungs, and, if so, how were they composed and situated. LEWIN[1] and RUPERT,[2] and not a few others, have shown by experiment that under some conditions dust may be plentifully deposited in the lungs. For instance, the animals of RUPERT's experiments breathed an atmosphere of coal-dust through T-shaped tubes fixed in their open windpipes. These tentative efforts were followed by a very handsome result, and an enormous quantity of the dust was found in the bronchi, bronchioles, and alveoli. LEWIN adopted a simpler and less redoubtable method. He kept some animals confined in a cage densely filled with dust, where they were allowed to breathe naturally. The post-mortem examinations gave a similar, though not so striking a result as RUPERT's. And these results have been confirmed by the most respectable authority.[3]

But, turning from this view of the matter, let us examine the clinical records for human cases. We shall find many examples, deeply and critically studied, of the fortuitous inhalation of dust, such examples, we mean, as occur in workingmen in the habitual pursuit of their trades. We shall attend only to those cases in which an autopsy has furnished us with the data for an exact judgment. For this we conceive to be a more accurate, not to say a more soundly critical, method than one in which a diagnosis is made from the history and symptoms merely, and no proof afforded of the presence of dust in the lungs. Nor is it always safe to assume that pulmonary disease has been caused by a man's pursuing a confined occupation.[4] An acute and patient observer,[5] indeed, has made this assumption, and compiled extremely valuable statistics of many thousand cases to show the influence of occupation and environment in the causation of pulmonary tuberculosis—who, by arranging, rearranging, and comparing his data enables us to see the object from every point of view, yet, because he assumes that the same cause is at work in every case, comes to some conclusions that neither he nor anyone else can accept. Thus, his statistics show, to his utter surprise and disbelief, that a cold damp atmosphere is less injurious than a warm dry one. Secondly, some of his best tables are vitiated by the prevailing error, as in the following:

[1] Archiv für path. Anat., 1847, p. 466.
[2] Ibid., p. 466.

Proportion of pulmonary tuberculosis among workingmen surrounded by an atmosphere charged with detritus:

Proportion of Cases per 1000.

Hospitals:	Geneva.	Paris.
From soft bodies . . .	127	280
From hard bodies . . .	120	210
From very hard bodies . .	290	525

"This table shows," he says, "that the detritus of hard bodies is more injurious than that of soft ones." To us it does not show this directly; and the conclusion is only partially true. For, if we inquire what the results of post-mortem examinations show (which is the test or criterion that we shall use throughout this article), we shall find that deposits of hard substances in the lungs, such as flint and emery, are very fatal, and deposits of cotton and woollen filaments not less so. LEWIN[1] notes the extraordinary frequency of pulmonary tuberculosis among upholsterers. Among these workpeople 100 per cent. of the deaths were from this disease. It is not less curious to find that stonemasons and makers of wadding alike suffer seriously from pulmonary complaints. On the other hand, workers in coal, stokers and chimney-sweeps are a remarkably healthy set of men. It is even believed that deposits of carbon in a fine state are beneficial; and the pathologic studies of GUILLOT and LEWIN render this supposition extremely probable. And we might add that another authority[2] has come to a similar conviction.

It might assuredly be expected that bits of lead or steel, for instance, should do more harm than a fine substance like soot, which, moreover, does not appear to be irritating, as lead and steel unquestionably are on account of their chemic properties. Nor does it seem to us at all fanciful to suppose that sharp surfaces are more destructive than smooth, angular than round, heavy particles than light. And such indeed we find on examining the abundant records to be the truth. A particle of charcoal, with its sharp, prismatic needles, or a bit of stone, with its "horns," may lodge in an alveolus and split it open. TRAUBE'S case is a beautiful instance of this kind. We extract from the history of it a passage bearing on the matter in hand: "These black particles (*of charcoal*) were so completely imbedded in cells that the cell-walls were bored through."

It is impossible to explain in a more striking manner the kind of injury, and the curious manner in which it is done. What follows such an injury has been described in the best experimental study of this subject known to us. VON IUS,[1] the author of the paper in question, investigated the action of quartz dust, the particles of which are acute-angled polygons of four and five sides. "This dust would enter the alveoli, be taken up by the cells thereof, and migrate thence into the lung-tissue."

In this manner an "inflammation," best described as "catarrhal," would arise; and the "exudate coming chiefly from the cells would flow into the lung-tissue, and remaining there would cause an interstitial pneumonia." A single example, occurring among the animals of his experiments, furnishes a good picture of an affection that has often been observed in workingmen. It is really this affection, and not tuberculosis (except secondarily), that is caused by inorganic deposits. "In one case a dog died after inhaling the dust for twenty-eight days, and without showing any particular disturbance except some cough and languor during the last two days." A section of the lungs showed an "extensive pneumonic infiltration, from which only the apices were free." In man, a very striking example of this affection is described by DUPONT.[2] The patient, a worker in emery, suffered from bronchitis and from pains resembling those of tuberculosis. DUPONT, not detecting dulness at the apices, or any signs which he judged distinctly characteristic of tuberculosis, hesitated to pronounce a diagnosis, save that the lungs were apparently affected in some manner by the emery dust.

According to KUSSMAUL this form of pneumonia is caused by "mechanical irritation."[3] Particles of sandstone, he observed, were very commonly the cause; and it is worthy of remark that these particles compose in large part the dust of streets. A cavity may form, either from a chronic circumscribed pneumonia, or secondly, from a partial gangrene of the lung.[4] In the latter case, the cause is usually a deposit of charcoal, and hence the name "*anthracosis.*" As to cases of the first kind, cases that are variously and somewhat pedantically termed "*pneumonokoniosis*," "*siderosis pulmonum*," "*phthisis siderotica*," etc., we proceed to adduce more

[4] Seltmann: Ibid.

evidence to show that it is the sharp crystalline particles that act so disastrously. ZENKER[1] reports three cases with elaborate post-mortem examinations and plates, and MERKEL[2] two. Under the microscope, ZENKER discovered crystalline plates of oxid of iron, which he describes as "Hörnchenkugeln," that is, "little horned particles," 10–26 μ in size. These were deposited for the most part in the lobular and infundibular septa. MERKEL'S cases are reported in an equally elaborate manner, but we cannot particularize them further than to mention that he saw in the alveoli the crystalline plates of oxid of iron of 0.075–0.125 mm. in size.

These were cases in workingmen. But to what extent do people of ordinary experiences and casual occupations suffer? To what extent is the dust of streets and rooms received into the lungs? An exact observer[3] has remarked that we always find traces of sand, the common element of dust, in the lungs of adults. And since, says he, we do not find any in the newly born, we may infer that it is always inhaled. Another observer[4] asserts that we may reckon on finding some sand in the lungs from three and four years upward.

It is, therefore, extremely curious that more mischief is not done. And when we consider the amount of dust in the air, to say nothing of the enormous numbers of microbes, and when we reflect that it is inevitable that no mean quantity must be taken in with the breath, the matter appears even more wonderful. It is probable either that we must ascribe a large number of cases of pneumonia to such causes or reduce our notions of the danger. It may be, too, that the lungs have some way of getting rid of foreign bodies. To conclude: the chief danger appears to us to arise from the weight, shape, physical and chemic properties of the particles breathed. We believe that we have not dwelt too fancifully on this point, and we are satisfied that the recorded cases and post-mortem examinations on which we have exclusively depended tend to support, rather than oppose, our opinion.

THE COST OF SANITARY NEGLIGENCE.

THE following table, according to Secretary CARTER, of the Maryland Board of Health (as reported by *The Scientific American*) shows the mortality of the cities of this country and Europe having a population of more than 100,000:

	Population.	Deaths.	Death-rate per 1000.
London	5,849,104	55,895	19.11
Paris	2,424.705	28.675	23.61
New York	1,801,739	23,856	26.47
Berlin	1,669,124	17,181	20.58
Chicago	1,458,000	13,590	18.95
Vienna	1,435,931	18,005	25.07
Philadelphia	1,115,562	12,249	21.95
Brooklyn	978,394	10,682	21.84
St. Louis	520,000	4,802	18.47
Brussels	488,188	4,359	17.86
Boston	487,397	5,816	23.88
Baltimore	455,427	4,806	21.10
Dublin	349,594	4,735	27.05
San Francisco	330,000	3,006	18.21
Cincinnati	305,000	3,000	19.67
Cleveland	290,000	2,538	18.19
Buffalo	290,000	2,361	16.28
Pittsburg	255,000	2,923	22.92
New Orleans	254,000	3,598	28.72
Edinburgh	267,000	2,572	19.22
Milwaukee	250,000	2,000	16.00
Louisville	227,000	1,630	14.80
Minneapolis	209,000	1,004	9.60
St. Paul	155,000	745	9.61
Christiania, Norway	156.500	1,385	17.75
Denver, Colorado	150,000	871	11.61
Rochester, N. Y.	144,834	1,291	17.87
Rheims, France	105,408	1.503	28.62

There is no more accurate gauge of the state of civilization actually attained by cities than their comparative mortality tables. It is the object not only of medicine to save and lengthen human life, but it is also the supreme object of the entire governmental and social mechanism. Hence every man interested in social progress, be he physician, hygienist, Christian citizen, or simply good citizen, watches the death-rate as constantly and as carefully as the engineer watches his steam-gauge, or as the clinician watches the thermometric reading. It is the precise indication of the success of science and of civilization. In a general way, subject to inconsiderable exceptions and modifications, the higher the death-rate the greater the social and governmental sins of selfishness and recklessness, the greater the indifference to the hygienic conditions of life.

The most striking fact that appears in the table is the healthfulness of London as compared with other great cities, Chicago excepted. With a population twice as great as that of Paris, and three times as great as that of New York, her death-rate is wonderfully less than that of either. There is no reason except a disgraceful reason why New York allows a death-rate of 7.36 higher than that of London. What does this mean except that New York permits the unnecessary deaths of 6630 of her citizens every year?

[1] Ibid. [2] Ibid. Bd. vi, p. 206.

[3] "Aschenbestandtheile der Lungen u. Bronchialdrüsen." Deutsches Archiv, Bd. ii, p. 91.

[4] Arlidge: Brit. and For. Medico-Chir. Rev., 1875, p. 438.

If it is thought that it may be unjust to statistically compare cities as far apart as London and New York, it is certainly proper to compare New York and Brooklyn. With a difference in death-rate of 4.63 this leaves New York criminally chargeable with 4171 additional and unnecessary deaths each year. As compared with Philadelphia there are 4071 more deaths to her debit; and as compared with Chicago, the figures reach the appalling number of 6774. There is certainly no good reason why the mortality of Philadelphia and of Boston should be higher than that of Chicago, but the table shows that Philadelphia kills proportionally 1673, and Boston 1200 more of her citizens each year than the city that is credited with drinking her own diluted sewage. It is plain that there is something radically wrong about all this. Death-rate figures are surely among those that do not lie. It may not be quite just to compare the awful death-rate of New Orleans with the splendid showing of Minneapolis and St. Paul, but no such extenuating circumstances as are to be considered in reference to the Southern city can be adduced to excuse the glaring differences between the principal Northern and Northeastern cities of our country. These differences are a profound reproach to City Boards of Health, to the city governments, and to all public-spirited citizens. New York is in every way better situated than Chicago as regards easy sanitation, and in many ways possesses such excellent natural advantages over the Western city that her present death rate is a disgrace that cries out against her.

It is absolutely undeniable that these deaths are avoidable. If the city governments of American cities would spend money *as freely and as wisely* as London has done, the brutal death-rates and slaughter of her citizens would lessen just as they have lessened in London. If London cared as little for the lives of her citizens as New York seems to care for hers, there would die in that great city every year 21,524 people more than at present die. Let us take the useless deaths of the five largest Eastern cities of the United States as compared with Chicago:

AVOIDABLE DEATHS.

Boston as compared with Chicago	1200
Philadelphia " " "	1673
New York " " "	6774
Brooklyn " " "	1413
Baltimore " " "	490
Total	11,550

This is the cost of criminal negligence of the known laws of health in only five of our cities.

Let us estimate the financial value of this loss. The average rate of American wage-earners at the lowest estimate is about one dollar a day. That is, one can buy the labor of the average American citizen for not less than $300 a year. According to insurance life-tables, the average length of our life is about forty years. Our working or productive period is about half that time, and the average market value of one of us is, therefore, twenty times $300, or about $6000. Put up for sale, one of us is approximately worth $6000 in the labor market. Now, let us allow of the 11,550 killed in five cities by carelessness and neglect, one-third of the number as having passed the laboring age, and therefore to be thrown out of this accounting. The remaining 7700 sacrificed to short-sightedness are thus seen to be worth in the labor market over forty-six millions of dollars.

But this is by no means all the loss; as for every death DR. FARR estimates that two persons are on an average continuously ill, *i. e.* there are two years of sickness for every annual death. With the 11,550 needless deaths, therefore, there are also each year the equivalent of 23,100 years of needless illness. Again estimated in money values, this means in lost time alone, $6,930,000, besides the bills of the doctor, the druggist, the nurse, and all the rest.

And yet when the city fathers are asked for a few thousand dollars for meat-inspectors and milk-inspectors, for new and necessary sewers, for an unpolluted water-supply, or for other measures of preventive medicine, the request is refused, or acceded to with such crippling stinginess as to be ludicrously inadequate.

Were it not for the possible charge of exaggeration, one might add that if our present knowledge of sanitation and prevention were only applied, our death-rate might be reduced by one-half.

But leaving out such a possible hoped-for reduction from future applications of sanitary science, we may consider as a national crime our failure to lower the death-rate in some and in most cities to the point reached by other cities. In only five cities, and estimated in crude financial losses, we have seen there is a squandering of some $53,000,000. Extend the calculation, easily made, to the whole country, and it is recognized that we are wasting several hundred millions of dollars' worth of human lives each year by our recklessness and stupidity.

Thousands or millions of people become morbidly absorbed in a single murder or a murder trial, ignorant, or, if not so, indifferent to these thousand social and governmental murders. Statesmen and political parties are engrossed in questions relating to a few million dollars' worth of silver ore, a few Pacific Islanders, or a bit of tariff legislation, all together of immeasurably less importance financially, or humanly, than the needless waste of human lives about which they do not care a blue bean. The medical profession heroically works to save a few thousand sick while the community goes on blunderingly and savagely killing, and making sick, by the millions.

EDITORIAL COMMENTS.

The First Collegiate Protest against Foot ball.—It is with profound gratitude and satisfaction that we chronicle the first signs of courage and dignity that have been shown by any American College as regards the foot ball craze. In future years it will be to the undying honor of THE UNIVERSITY OF VIRGINIA that she has been the first to raise her corporate voice in clear and manly warning, and in determined opposition to the plain downward tendency. The faculty has issued a circular clearly pointing out the wrong, and advising students, parents, and guardians against the evils of the game, and especially of the intercollegiate contests. It is, in fact, the intercollegiate game that is the root of the whole mischief. Abolish this and the psychologic professors and eminent D.D.'s will at once be able to know what all the world knows, and to do what all the world is ashamed they are not doing. Brutality will then disappear from local college games, and the vaunted utilities and splendors of the game as it has been will be at once recognized as an excuse for a long step toward barbarism, as advertising dodges, and as downright bosh. Mr. William A. Bancroft, Mayor of Cambridge, Mass., in his day the most prominent oarsman in Harvard College, says: "I am opposed to all intercollegiate games. They detract from the purpose for which young men are sent to college. If two business men spend four hours per day playing chess or some kindred game, it is certain their business will suffer. That is exactly the condition of intercollegiate athletics." From the circular of the Faculty of Virginia we quote a few paragraphs concerning the intercollegiate game:

"They are compelled to regard this practice as one which has consequences almost wholly evil. The aggregate loss of time is considerable and the mind of the student is distracted from his collegiate duties, and returns to regular habits of application only after still greater loss. The outlay in money is not unworthy of account. Temptations to evil living arise, which are not met in the wholesome and regular routine of college life; and while careful inquiry has convinced us that our students conduct themselves as a rule with praiseworthy decorum, both at the University and abroad, instances are not wanting where individuals have so acted as to bring discredit upon themselves and reproach upon the school. We have been repeatedly informed by the managers that this escort is not desired, and that their presence and gate-fees poorly compensate the team for disorders, of which they have sometimes been the occasion.

"As a plan more consonant with the spirit of this University and, we trust, of better ultimate effect, it has been determined to appeal to the good sense of the students and to the affecionate solicitude of their parents and with respectful insistence to urge that this evil be eradicated or at least largely abated. Students who have come to years of discretion are requested to abstain from this relaxation in the interest of collegiate order, as well as for their personal good. The parents of others are advised rigorously to withhold consent to such excursions. The Faculty earnestly trust that this expression of their serious opinion will receive serious heed.

"All boyish and manly sports have in them an element of danger; it is the price which mankind sees fit to pay with cheerfulness for virile indifference to physical peril. But careful guard is to be had at this point, and we shall not hesitate to demand the correction of features which lead either to moral or to physical excesses."

This noble and dignified position should at once double the number of students in the University of Virginia, and there are numerous indications that sensible parents are preparing to give a stinging rebuke to colleges that have sought to advertise for students by means of semi-professional gamesters. To thus advertise for students to educate in intellectual things, because of success in winning so-called athletic games, is an illogicality most glaringly absurd.

As we go to press we hear also that the Faculty of the Kansas State Normal School has forbidden the game in future.

Mr. Stead's Remarkable Doings.—Our wonder is ever called forth afresh at the unlimited impertinence and successfulness of the mephistophelean quack. However crushed by exposure, however deep the disgrace, he rises phenix-like from the ashes of one diabolic scheme to start anew with another still more preposterous and brazen. The stupidity and gullibility of human nature is always equal to the challenges of its inordinate masters. The career of Stead is in evidence. He should have realized a satisfying fortune from the Mattei cancer-cure swindlers. Simple, plain, unadulterated water was sold at about a dollar a bottle under the name of white, green, and red electricity, until the Medical Investigating Committee cornered him up, and he was forced to confess that his partners were unmitigated scamps. *Food and Sanitation*, a brave English journal, says the thieves derive a profit from the Mattei "cures" of $500,000 a year. How sincere was his "shame" and his "denunciations" is shown by the fact that the English agent of the Mattei swindle is a certain A. J. L. Gliddon. Stead is now pushing a scheme to get 100,000 persons to subscribe $5 each to found a new paper. The first number of the new paper is largely devoted to editorial interviews and puffs of the Mattei agent, Gliddon, and his quack cures, but especially to a "drunk-cure," also worked by Gliddon. The Pooh-Bah Gliddon as drunk-curer demands $100 from his dupes, boards and treats them for a month at a net profit from the one hundred patients he says he already has, of something like $6000 a month. The crowning touch of marvel is not wanting in the fact that Stead announces that his new journal and his personal rôle in life is "the rooting out

of mean fraud, and the punishment of the scoundrels who would steal under the cover of business." Amazing products of nineteenth century civilization are these Steads and Steadisms! But it is still more amazing that poor, stupid, deluded human nature never tires of welcoming and loving them.

Exemption of Charges for Medical Services and Nursing.—The matter of exemptions is one which is more or less different in different States, depending altogether upon the wording of local statutes. In Texas, where the statute, among other things, exempts from attachment or execution, and every other species of forced sale for the payment of debts, "current wages for personal services," it has been held that the fee of an attorney is not exempt from garnishment when he has not been hired for his services by the day, week, month, or year, to be paid at the expiration of the time for which he was hired, and not in proportion to the business done. But the same court held that the fees of a physician, when he was employed, and his compensation fixed per diem, were exempt. And now the Court of Civil Appeals of that State, in the case of Dempsey *vs.* McKennell, holds that when a nurse is employed during an attack of sickness under promise to be paid well for his services, though there is no agreement fixing the compensation to be paid, either for the entire service, or by the hour, day, week, or month, the amount due him is to be classed as current wages for personal services, and is exempt under such a statute as the foregoing. The mere circumstance that the rate of compensation was not agreed on in advance ought not, the court says, to take the case out of the exemption. In nursing, the person employed was actually occupied by the day, and his right of compensation accrued as he served, being measured by customary or reasonable rates rather than by express contract. Such wages being exempt, it was also held that the employer could not afterward buy up a debt due from the nurse to a third person and set it off against his promised remuneration.

Unauthorized Use of Physicians' Portraits by Advertisers.—We hope all good physicians will follow the example of Dr. Joseph D. Bryant, of New York, in putting in force the full power and penalties of the law against the unauthorized use of physicians' portraits by unscrupulous advertisers. Dr. Bryant's indignation is more than justifiable in the case of a calendar-issuing advertiser, who also inserted portraits of a number of other prominent physicians, and especially because puffs of the proprietary preparation, cunningly placed below the portraits, make it seem as if the men whose portraits appeared above had thus actually praised and recommended the preparation. This is an old dodge, a sneaking way of deceiving and yet of escaping the law. Some time ago a similar method was pursued by an advertiser, who headed his circular "*From Medical News*," leaving it possibly doubtful whether the things quoted were simply medical news gossip, or were genuinely from the columns of the journal, MEDICAL NEWS.

The Foot-ball Injuries in the United States, during the season just closed, have been in part collected by a New York newspaper. We have epitomized them as lows:

Deaths	8
Fracture of the leg	6
Double fracture of the leg	1
Fracture of the thigh	1
Fracture of the arm	1
Fracture of the collar-bone	1
Dislocation of the shoulder	1
Dislocation of the patella	1
Especially serious injuries	5
Sundry disabling injuries	119
Total	144

What would be the proportions of this list when swollen by the "accidents" not reported, or by the mischiefs to develop by and by?

Credit to which Expert Testimony is Entitled.—It is a well-established rule of law, according to a recent decision of a New York court, that the testimony of experts is entitled to the same credit, and is to be tested by the same rules, as are to be applied to the testimony of other witnesses, and should have weight according to their qualifications and opportunities. While their opinions are not conclusive, they are to receive so much weight as a jury may deem them entitled to, when viewed in connection with all the other circumstances, and they must also be predicated upon the facts established by the proofs in the case.

To Escape Vaccination.—The unpopularity of vaccination in England, amongst parents, is said to have led to a new form of offence, consisting in falsely declaring the place of birth on registering the child. By this means the vigilance of the vaccination officers has been to some extent defeated. To counteract this the Registrar-General recently had three matrons prosecuted and fined at Marleybone.

SELECTIONS.

THE USES OF THE CODE.

THE vast majority of the medical profession is, I would maintain, notwithstanding discreditable cases that are sometimes brought to light, and even the medicated-wine scandal, well able to withstand the seductions of charlatanry, and—sound in conscience—to pursue the path of rectitude without monitions or fear of penalties. But for the weaker brethren—and there are weaker brethren in all professions—a code of honor supplemental to the general ethical code is an admirable tonic. And, indeed, for the profession as a whole, such a code has its value, raises the standard of work and exalts the sense of duty. The sustaining influence of a code of professional honor, in moments of supreme trial, was brilliantly illustrated in the Charge of Balaklava, and in the wreck of the "Victoria" only three months ago, when bands of men were dauntless, steadfast and heroic, standing face to face with sudden death; and the same influence is, less conspicuously but not less truly, manifested in the self-denying devotion with which medical men carry on daily their incessant guerilla warfare with disease. The moral qualities

displayed by the profession should, I think, be its charter to public esteem, and protect it from the humiliation which the present widespread patronage of quackery really amounts to. For quackery is patronized in high places, and is supported not only by the dull and ignorant, but by the presumably educated and intelligent. It flourishes, no doubt, in our great manufacturing towns like Sheffield, but the very hot-beds of it are our fashionable watering-places and health-resorts, and I am assured that, while our skilled artisans are least of all given to quackery, our learned clerics are most addicted to it. Well, I think our learned clerics should seriously reflect that in giving countenance to the nostrums of the empiric, they exhibit a credulity and superstition that must seriously impair their usefulness in their sacred calling with all thoughtful men. Great may be the faith but small must be the wisdom of the man who believes he derives benefit from a non-electric belt! What exegetical insight is possible in him who swallows patent pills? They should remember—these learned clerics—the commendation of the Bereans, and search the Scriptures—the Scriptures of Science and common-sense—to see whether these things be so.

Above and beyond, however, any special code of honor appertaining to the medical profession, there is the general code of ethics to which that and all professions are amenable, and as regards that general code, I would say that medical practice is daily demonstrating to those engaged in it its reasonableness and wisdom. To those who faithfully pursue it, medical practice affords an ethical training and discipline of the best kind; it opens a refuge from pessimism in the opportunities it gives for the relief of sorrow and suffering; it unveils, in the tender ministrations of the sick-room, some token of the angel as plainly as competition discloses vestiges of the tiger and the ape, and it fosters that wide sympathy that yields hope for the future of our race. "The man shall die," said David, not because he did this wrong, but "because he had no pity." Surely one of the most moving of texts is this: "He had compassion on the multitude," which, translated into my native language as it has been by Scott Riddell, becomes even more expressive in the words, "He was wae for the folk." To bread-winning industry, to an honorable ambition, the medical man must add compassion for the multitude, if he would make his work fruitful to his patients, to the public, and to himself.—Sir James Crichton-Browne in address at opening of the Sheffield (London) Medical School.

PHYSICIANS AS PRESCRIBERS OF NOSTRUMS.

There is a disease that has eaten like a cancer into our profession, and has weakened its constitution in many points. It is a contagious disease, and when once contracted it is hard to cure. It seems to enter the very life of the physician and finally causes his death. He carries the disease to his patients, and when they become infected they leave him and give it to others. The physician may keep this affection a secret for a time, but sooner or later it will come to light. This disease has various names given it, but it is best known as the patent-medicine humbug. There is nothing so detrimental to the honor and dignity of the medical profession as the fact that many of our physicians will prescribe a medicine of which they know literally nothing, except that it was said to have been discovered and used by the Indians of the West or the negro slaves of the South, and that it is dispensed under a high-sounding name, is protected by a trade-mark, and is recommended for every disease under heaven. All good and effective medicines have a very limited scope of usefulness, and whenever a physician becomes too negligent to study his cases and prescribe well-known and tried remedies for definite pathological conditions he is no addition to his profession. As long as pure drugs are manufactured, as long as scientific works on materia medica and therapeutics are written, as long as ample facilities for acquiring a knowledge of medicine exist, there is no excuse for the physician acquiring the habit of prescribing patent medicines. The physician who does form such a habit becomes a self-constituted and unremunerated agent to advertise the nostrums of the unscrupulous manufacturer, and assist in deceiving the public.—*Address to the Profession and the Public by* Dr. J. T. Graham, *of Wytheville, Va.*

REVIEWS.

The Principles and Practice of Surgery. By John Ashhurst, Jr., M.D., Barton Professor of Surgery and Professor of Clinical Surgery in the University of Pennsylvania, etc. Sixth edition, enlarged and thoroughly revised. With a colored plate and 656 illustrations in the text. 8vo, pp. 1166. Philadelphia: Lea Brothers & Co., 1893.

When a scientific work passes through six editions in a little over twenty years, this fact may by itself be accepted as evidence that it has been found to possess substantial merit. In the present instance there can be no question of the soundness of the verdict of approval. The author is widely known as perhaps the most scholarly of American surgeons. Like his other contributions to the literature of his profession, this book is written in a clear, accurate, and forcible style, and contains well-weighed and positive views, based upon extensive reading and practice. Its terse and pregnant sentences will not attract and fascinate, but their careful study will amply repay the true seeker after knowledge.

Dr. Ashhurst is far more conservative in his opinions than most of the surgical writers of the present day. With this attitude of his we are not disposed to find fault. So many enthusiasts are eager to adopt every new idea, to regard change as in itself desirable, that it is well indeed that there should be some to insist upon the proving of all things, in order that we may hold fast that which is good, old though it may be. We think, however, that in the work before us there is too scant stress laid upon the importance of the so-called antiseptic system as an element of daily practice. Our own opinion is that its adoption has worked such a change that statistics derived from the earlier time have no longer more than a historic interest or value; that it has vastly enlarged the field of surgery, and increased the safety of every procedure previously known. Yet Dr. Ashhurst has devoted but a page and a half to the subject, and does not, we believe, give it the briefest mention elsewhere. He speaks of it only as used in

operations; of its employment in such dressings as may be called for in the after-treatment, or in dealing with wounds, compound fractures, etc., he says nothing at all. We regret very much to have to note this serious defect in an otherwise altogether admirable book.

One other point we would touch upon. Primarily intended for the use of students, this work must be often consulted by those engaged in the practice of surgery, or in research upon special subjects; to such it would be a great aid if at the end of each chapter there were a list of the authors named, with the exact references to the passages containing the views or records quoted from each.

A noteworthy feature of this, as of the former editions, is the extreme accuracy of the typography.

A COMPEND OF HUMAN PHYSIOLOGY. ESPECIALLY ADAPTED FOR THE USE OF MEDICAL STUDENTS. By ALBERT P. BRUBAKER, A.M. M.D., Demonstrator of Physiology in Jefferson Medical College; Professor of Physiology, Pennsylvania College of Surgery; Lecturer on Anatomy and Physiology, Drexel Institute of Art, Science, and Industry; Fellow of the College of Physicians of Philadelphia. Seventh edition, revised and enlarged. With new illustrations and a table of physiological constants. Philadelphia: P. Blakiston, Son & Co., 1893.

IN his preface the author of this most popular and excellent of compends says:

"In the preparation of a seventh edition of the *Compend of Physiology* the attempt has again been made to still further adapt it to the necessities of medical students during their attendance upon the lectures and in reviewing the subject prior to examinations.

"With these objects in view, not only has the book been revised, but special chapters on the physiological anatomy of the skeleton and the joints, the physiology of muscular tissue and of special muscular groups have been inserted."

THE PHYSICIAN'S CHART-BOOK is a convenient little arrangement devised by Dr. John A. Hawkins, of Pittsburg, and published by Bailey & Fairchild, of New York, which makes it possible for the physician always to have with him, in bound form, a sufficient number of temperature charts, each provided with space for making various notes of one kind or another in connection with the individual case.

CORRESPONDENCE.

WHITE'S OPERATION FOR PROSTATOMA; REMOVAL OF SECTIONS OF THE VASA DEFERENTIA FOR THE SAME DISEASE.

To the Editor of THE MEDICAL NEWS,

SIR: On December 12, 1893, I removed the testicles for hypertrophy of the prostate. Is not this the first White's operation recorded in this country?

On December 15, 1893, I removed one and one-half inches of each vas deferens for the same affection. I got the suggestion from Mr. Harrison's case of subcutaneous division of the vasa deferentia mentioned in a recent issue of your journal. The results will be duly published. Very sincerely yours,

FRANCIS L. HAYNES, M.D.

LOS ANGELES, CAL.

NEWS ITEMS.

Eleventh International Medical Congress.—Dr. A. Jacobi, of New York, Chairman of the American National Committee of the Eleventh International Medical Congress, announces:

1. Papers to be read in any of the Sections of the Congress should be announced on or before January 31, 1894, to the Secretary-General, Prof. E. Maragliano, Ospedale Pammatone, Genoa, Italy.

2. The title of the paper ought to be accompanied with a brief abstract of its contents and conclusions.

3. The program to be distributed will contain the titles of all papers announced before August 31, 1893, and since.

4. The reductions granted by the railway companies months ago will be available from March 1 to April 30, 1894.

"Travelling documents" will be sent to the address of every subscriber on or before February 15, 1894; and after that date congressists will have to apply to Dr. Jacobi.

Members' dues are five dollars (money order to Prof. L. Pagliani, Rome); guests' (wives and adult relations) two dollars; medical students no fees. All are entitled to travelling documents.

In the interest of such medical men as will sail for Europe before official cards will have been received from the General Committee, Dr. Jacobi proposes to supply, in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. It is suggested, besides, that a passport may increase the traveller's facilities.

Football Casualties.—On the 18th ult., during a match between the Western Mail Rovers and Guildford Star A, at Cardiff, a player aged fifteen years sustained a fracture of the arm and was taken to the infirmary.—A well-known Chesterfield player aged twenty-four years, died on the 23d ult. from injuries received to the abdomen while playing full-back with Chesterfield against the Derby Junction, on the Chesterfield ground, in the English Cup competition.—On Saturday last a youth seventeen years of age, in a match at Knostrop, had his femur fractured, and was admitted to the Leeds General Infirmary.—On the 28th ult. a student at the Downton Agricultural College, Salisbury, died from injuries sustained in a Rugby match on Saturday last. One of his arms was badly fractured, lockjaw supervening with a fatal result.—*Lancet, December 2, 1893.*

The British Medical Association will hold its next annual meeting at Bristol on July 31, August 1, 2 and 3, 1894, under the presidency of E. Long Fox, F. R. C. P. An Address in Medicine will be delivered by Dr. T. Grainger Stewart, of Edinburgh; an Address in Surgery by Mr. J. Greig Smith, of Clifton; and an Address in Public Medicine by Sir Charles Cameron of Dublin.
